The support frames were rubber-diaphragm formed from 0.032-in.-thick AM-350 stainless steel sheet, to a web width of 1½ in. and a flange width of ¾ in.; they had an outside diameter 0.050 in. less than the inside diameter of the outer-skin cylinder. After forming, the frames were rolled to produce a convex radius at the circumference, with the outermost diameter exactly matching the inside diameter of the outer-skin cylinder. A cross section of the frame before and after rolling is shown at lower left in Fig. 20.

Before welding, the cylinders and frames were cleaned and prepared as follows:

1. Clean in a hot (180 to 200 F) aqueous solution of heavy-duty alkaline cleaner (8 to 12 oz per gal) for 15 to 20 min.
2. Rinse in clean water at room temperature.
3. Descale in an aqueous solution of nitric acid (15 to 20%) and hydrofluoric acid (3 to 5%) at 120 to 140 F for not more than 30 min.
4. Rinse in clean water at room temperature.
5. Drawfile and deburr faying surfaces.
6. Wipe all surfaces with acetone, and remove residues with a lint-free cloth.

The upper right view in Fig. 20 shows the setup used for welding the longitudinal seam of each outer-skin cylinder. Conventional hold-down bars (not shown in Fig. 20) with 1-in.-wide fingers were used to clamp the cylinder at a pressure of 80 psi. The inner surface of the cylinder was supported by a deoxidized copper backing bar, which also served as a chill. Except for occasional repair welds, the longitudinal joints were welded without filler metal, because filler metal increased shrinkage and was not required to ensure x-ray soundness. Helium was used as backup and shielding gas. Starting and runoff tabs were used at the beginning and ends of the weld. Welding details for the longitudinal weld are given in the table with Fig. 20.

After fabrication of the outer skin, the supporting frames were fitted inside the cylinders (supported on a wooden block to prevent "belling" of the cylinder walls) at a distance of 8 in. from the ends as shown in Fig. 20 (upper left). The frames were joined to the outer skin of the cylinders by a single-pass circumferential melt-through weld. The frames provided backup for welding, and two copper rings (⅛ in. thick by 1½ in. wide) slipped over the cylinder served as hold-downs (see Fig. 20, detail B). This arrangement prevented any drawstring effect at the circumferential joint. Welding conditions for the circumferential joint are given in the table with Fig. 20. For joining the ends of two cylinders to a supporting frame providing internal linkage at the joint, an ER308 filler metal was used; other welding conditions were the same as those listed under "Circumferential weld" in the table.

Restricting the Heat of Welding. Small electrical assemblies are often protected by enclosure in sheet-metal housings which may be sealed mechanically or by soldering, brazing or welding, depending on the specific application and on cost considerations. The metal selected for the housing, as well as the method for sealing, usually depends on service requirements. When a small, delicate electrical switch assembly is enclosed in a stainless steel housing sealed by welding, extreme care must be taken to keep the assembled components clean, dry and relatively cool. Heat from welding must be minimized. Ordinarily, only automatic welding can provide the degree of control required to minimize the heat input and produce a smooth, leakproof joint, as illustrated in the following example.

Example 262. Automatic Precision Welding of Microswitch Housing Assembly With Minimum Heat Transfer to Internal Components (Fig. 21)

Enclosures for protection of microswitch assemblies, as shown in Fig. 21, consisted of 0.010-in.-thick (type 347) rectangular housings (with rounded corners) welded on one side to a 0.030-in.-thick (type 305) cover and hermetically sealed on the other (after backfilling with nitrogen) with a 0.1-in.-thick layer of dielectric material.

Welding of the recessed corner joint between the cover and housing (Fig. 21, detail A, Before welding) was accomplished in a single pass by the automatic gas tungsten-arc process with argon shielding (and backing) and without addition of filler metal. The welded joint was required to be leakproof with the leakage rate for each switch (after sealing) not exceeding 0.3 cu cm per year. Extreme care was required to minimize heat input during welding, in order to prevent damage to the brazed flexible diaphragm (Fig. 21) and other delicate components of the microswitch.

Several modifications in the process were adopted to minimize heat input. Thus, the tungsten electrode was taper ground to a point to obtain a fine, high-current-density arc at low amperage. Straight polarity was selected over reverse polarity to produce a finer arc and to avoid overheating the electrode tip. The combined effect of these modifications was to increase welding speed while limiting heat input to a narrow weld and heat-affected zone. Argon was selected over helium for shielding to obtain smoother arc action at lower voltage. Other advan-

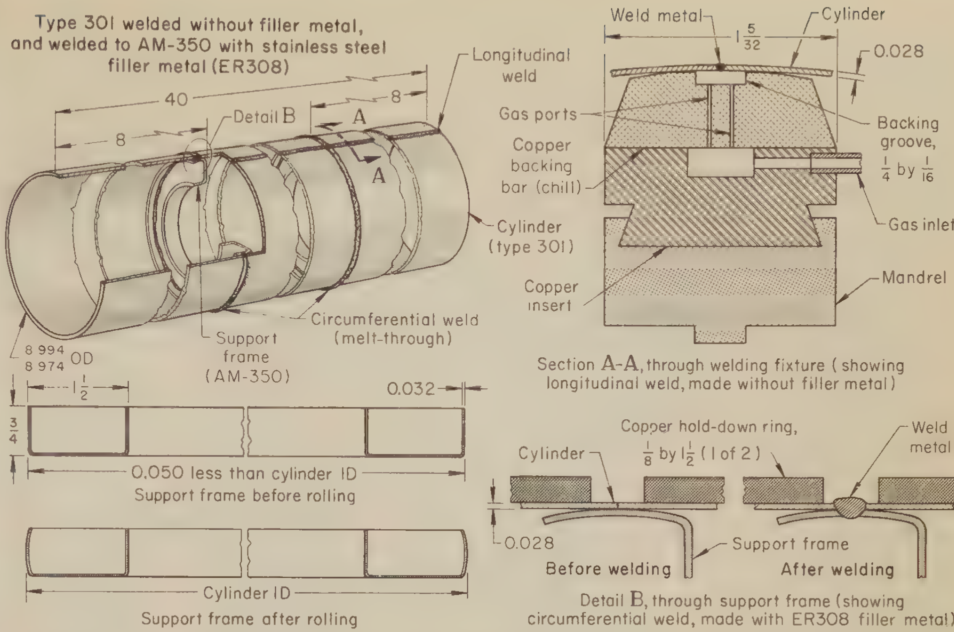
tages of argon were that arc starting was easier, and heat input was more stable because small changes in arc length resulted in less change in arc voltage.

To facilitate rapid withdrawal of heat from the weld zone, the housing and cover were clamped in a water-cooled copper alloy chill-block fixture that exposed only the corner to be welded (Fig. 21, detail A, Before welding). The fixture was attached to a sliding mechanism designed for easy loading and unloading of the workpiece and for positioning the joint directly under the electrode. Motion of the electrode holder was controlled by a magnetic tracing unit, which was driven by rotating a knurled magnetic pin around the edge of a steel template. An ultraviolet lamp aimed at the electrode tip provided an ionized path for easy arc starting.

Welding current was supplied by a 200-amp transformer-rectifier and the entire welding cycle was regulated by a sequence timer equipped with controls for argon preflow and postflow, arc starting and stopping, torch travel, and current downslope. Welding was done in two steps. First, one half of the joint was welded from end to end by melting the corner edge of the cover to form a smooth radius as shown in detail A, Fig. 21. The assembly was then unclamped, rotated 180°, and reclamped, and the other half was welded in the same manner. Production was 59 switches per hour.

After welding, the switch body was tested for leaks, using a leak tester of the mass-spectrometer type. If acceptable, the switch was backfilled with dry nitrogen and sealed off. If a leak was detected, a bubble test was made to locate the leak. If the leak was in the weld, the switch was rewelded and again backfilled with dry nitrogen and resealed. Rejections for defects in welding were generally below 5%.

Melt-through welding refers to the welding of a joint from one side only in a manner that provides complete joint penetration of weld metal, with visible root reinforcement. The melt-through technique is limited to the joining of relatively thin sections, and gas tungsten-arc welding is a preferred process for such applications, especially when the elements to be joined are made of stainless steel or of a nickel-base alloy. Obtaining a satisfactory weld from one side only is most advantageous when accessibility is largely limited to one side; in such applications, melt-through welding may also be more economical than conventional techniques because the amount of welding required is less. Both factors — accessibility and economy — were involved in the application described in the following example.



Item	Longitudinal weld	Circumferential weld
Process	Automatic gas tungsten-arc welding	
Joint type	Butt	Edge
Joint location	Cylinder joint	Frame to cylinder
Weld type	Square groove	Square groove
Fixtures	Backing bar(a), hold-down bars	Copper hold-down rings
Power supply	200-amp transformer-rectifier	
Electrode	1/16-in.-diam EWTh-2	3/32-in.-diam EWTh-2
Electrode taper	1/4 in. long to point	1/8 in. long to point
Nozzle diameter	3/8 in.	5/8 in.
Filler metal	None(b)	0.030-in.-diam ER308(c)
Filler-wire angle	...	30° from horizontal(c)
Filler-wire tip to electrode	...	3/8 in.(c)

Filler-wire feed rate	...	28 ipm
Electrode extension	13/32 in.	7/16 in.
Travel speed	10 ipm	10 ipm

(a) Made of deoxidized copper. (b) Except for weld repair. (c) Applies only to circumferential welding of joint between two cylinders and supporting joint providing internal link.

Fig. 20. Precision welding of thin-skin missile-body segments that were fabricated to close dimensional tolerances and carefully cleaned before assembly and joining (Example 261)

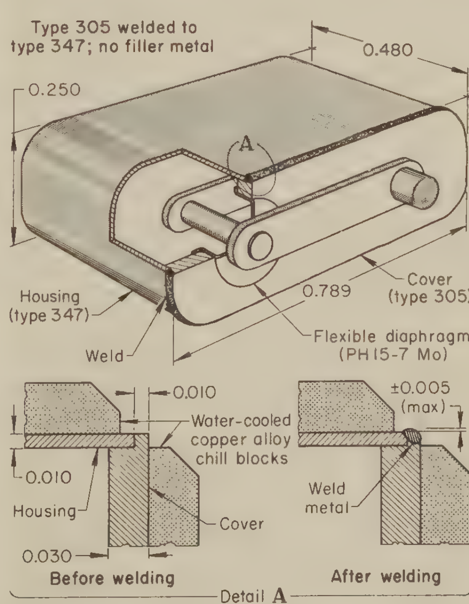

Fig. 21. Microswitch housing assembly that required close control over heat input during welding to obtain hermetic sealing between the cover and housing without damage to internal components (Example 262)

Example 263. Single-Pass Melt-Through Welding of T-Joints on a Strut-Cover Sheet Assembly (Fig. 22)

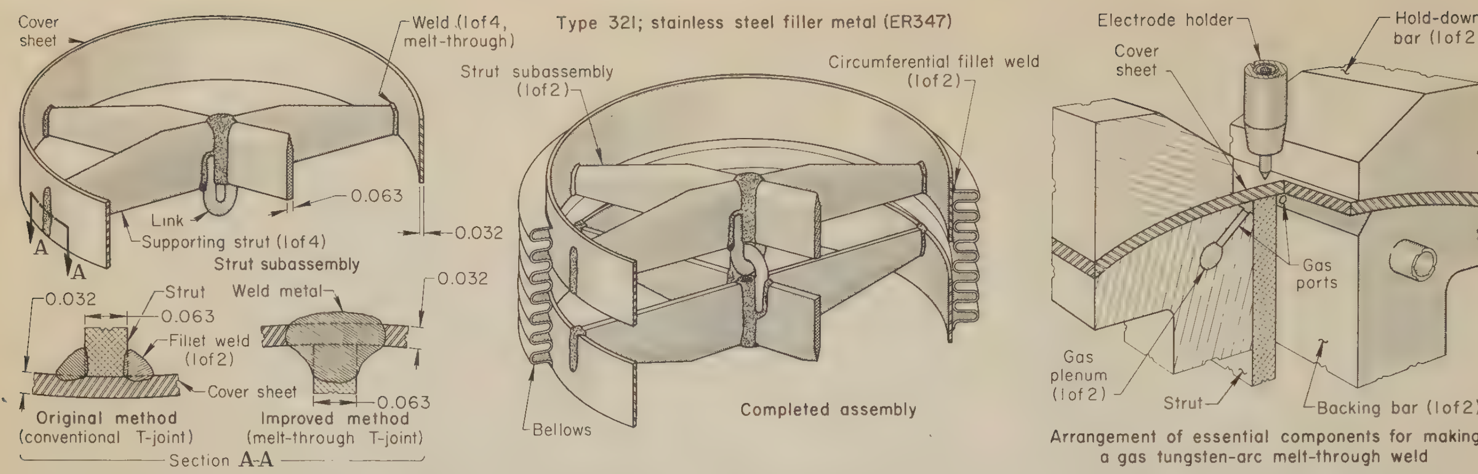
The left view of Fig. 22 shows a welded assembly consisting of a cylindrical cover sheet enclosing a central link and four supporting struts. The cover sheets of two of these assemblies were joined by circumferential fillet welds to the opposite ends of a bellows (Fig. 22, center). The completed weldment was used in an aerospace application to provide a strong, flexible connection to rigid segments of a ducting system. This example deals only with the welding of the supporting struts to the cover sheet of the assembly.

Originally, the T-joint between the ends of the struts and the inside surface of the cover sheet was made by two fillet welds deposited by the gas tungsten-arc process. Success of the welding procedure depended largely on the inside diameter of the cover sheet, which (depending on the size of the assembly) ranged from 1¼ to 8 in. As the diameter decreased, joint accessibility (for manipulation of the torch and filler metal) also decreased; as a result, weld quality was adversely affected, and meeting radiographic standards became difficult.

The difficulty was overcome by joining the cover sheets to the struts from the outside by melt-through welding. Complete joint penetration was obtained in a single pass; filler metal was added to supply the volume needed to form a double-fillet-welded T-joint (see section A-A in Fig. 22). A minimum fillet-weld size of 0.040 in. was adequate for strength.

To establish welding conditions for various combinations of work-metal thickness (ranging from 0.032 to 0.250 in.) and alloys, about 250 strut-cover sheet assemblies were joined by melt-through welding and inspected. Welding conditions for three such combinations are summarized in the table accompanying Fig. 22. A typical arrangement of components for welding is shown at the extreme right in Fig. 22.

The completed melt-through welds were found to be of excellent quality. All welds met the minimum requirements for fillet size and surface appearance. Radiographic examination, which was simplified because of the absence of discontinuities at the root of the weld, showed complete fusion and adequate joint penetration. Porosity was encountered only when preweld cleaning had been inadequate. No significant indications were noted under dye-penetrant inspection. Macrographs of weld sections showed no significant defects. Failures in



Welding condition	0.063-in. type 321 struts welded to 0.032-in. type 321 cover sheet, as shown	0.093-in. alloy A-286 struts welded to 0.063-in. type 321 cover sheet	0.188-in. Inconel 718 struts welded to 0.060-in. type 321 cover sheet

Table 9. Nominal Conditions for Gas Metal-Arc Welding of Austenitic Stainless Steel With a Spray Arc (Source: Same as Table 4)

Plate thickness, in.	Joint and edge preparation	Electrode wire diameter, in.	Current (dcrp), amp	Wire-feed speed, ipm	Welding speed, ipm	Number of passes
0.125	Square butt with backing	1/16	200-250	110-150	20	1
0.250	Single-V butt, 60° incl angle, no root face	1/16	250-300	150-200	15	2
0.375	Single-V butt, 60° incl angle, 1/16-in. root face	1/16	275-325	225-250	20	2
0.500	Single-V butt, 60° incl angle, 1/16-in. root face	3/32	300-350	75-85	5	3-4
0.750	Single-V butt, 90° incl angle, 1/16-in. root face	3/32	350-375	85-95	4	5-6
1.000	Single-V butt, 90° incl angle, 1/16-in. root face	3/32	350-375	85-95	2	7-8

peel tests occurred wholly in the base metal. Mechanical tests indicated significant improvement in fatigue life. Thus, melt-through welding not only solved the problem of how to obtain accessibility but also produced superior welds and reduced the number of welds for the assembly.

Plasma-Arc Welding

Plasma-arc welding is frequently used for joining stainless steel. The use of the process for welding stainless steel and other metals is described in the article on Plasma-Arc Welding, which begins on page 138 in this volume. Examples 143, 146 and 147 in that article deal with austenitic stainless steel; Tables 6 through 9 present welding data on stainless steel.

Gas Metal-Arc Welding

Most of the advantages of the gas metal-arc process for welding stainless steel are the same as for welding carbon steel of low carbon content. Major advantages are: (*a*) the continuously fed electrode wire permits long, uninterrupted periods of welding; (*b*) the process can be readily automated; (*c*) the use of shielding gas instead of a flux eliminates the need for slag removal and enables the operator to watch the welding operation; and (*d*) low-hydrogen deposits are obtained without the need for baking the electrodes (as may be required in shielded metal-arc welding). Also, the gas metal-arc process offers a variety of means by which transfer of weld metal can be effected: spray arc, short-circuiting arc, and pulsed arc.

Limitations of the process are also essentially the same for welding stainless steel as for welding low-carbon steel. Compared with shielded metal-arc welding, the equipment costs more and is less portable, and gas metal-arc operations must be shielded from drafts. For details of the process, see the article on Gas Metal-Arc Welding, page 78 in this volume.

Welding Current. The polarity of the welding current used in gas metal-arc welding depends primarily on the penetration desired. The greatest penetration is obtained with reverse polarity (electrode positive). Regardless of whether the electrons impinge on the electrode wire (as in reverse polarity) or on the work (as in straight polarity), heat builds up in the base metal through the metal drops. Reverse polarity results in the metal drops being subjected to considerable force by the positive ions of gas, resulting in deep penetration. Conversely, when straight polarity is used, the force exerted on the metal drops by the gas ions tends to support them, resulting in shallow penetration. It is estimated that more than 95% of all gas metal-arc welding of stainless steel is done using reverse-polarity direct current, straight polarity being restricted to applications requiring shallow penetration.

Because the electrical resistivity of stainless steels is greater than that of carbon steels, the electrode melting rate is higher for a given electrode stickout. Allowing for some variation among different grades, the same deposition rate can be achieved for stainless steels at about 80% of the current required for plain carbon steels, other conditions being the same. Some typical current values for specific conditions are given in Tables 9 and 10.

Table 10. Nominal Conditions for Gas Metal-Arc Welding of Austenitic Stainless Steel With a Short-Circuiting Arc (Source: Same as Table 4) (a)

Plate thickness, in.	Joint and edge preparation	Electrode wire diameter, in.	Current (dcrp), amp	Voltage, v	Wire-feed speed, ipm	Welding speed, ipm	Number of passes

(a) With a shielding gas containing 90% helium, 7.5% argon and 2.5% carbon dioxide

Spray Transfer. High current density is the principal requirement for spray transfer of metal from the electrode to the base metal. At a certain minimum current density, which varies with electrode size and material, metal transfer through the arc changes from very large globular drops, which fall off the end of the electrode, to a stream of extremely fine droplets axially projected from the end of the electrode. The metal transfer changes from a fluttering, erratic discharge with a wandering cathode spot to a steady, quiet arc column. This arc column is a well-defined, narrow, incandescent, cone-shape core within which metal transfer takes place. Because the method utilizes high current and voltage, the weld puddle is quite fluid (limiting welding to the flat or horizontal position). Deposition rates are high, penetration is deep when reverse polarity is used, and the arc is exceptionally stable. The minimum thickness of stainless steel that can be satisfactorily welded using spray transfer is about ⅛ in. Generally, it is used on materials ranging from ¼ to 1 in. in thickness. The diameter of electrode wire for spray transfer is usually 0.045 to 3/32 in. (Table 9).

On square-butt welds, a backing strip should be used to prevent weld drop-through. When fit-up is poor or copper backing cannot be used, a short-circuiting transfer for the root pass will minimize drop-through.

Short-Circuiting Transfer. Welding with a short-circuiting arc employs lower current, generally ranging from 50 to 225 amp, low voltages of 17 to 24 volts, and small-diameter wires — 0.030, 0.035 and 0.045-in. diameters being the popular sizes. The distinctive feature of the short-circuiting arc is the frequent shorting of the electrode wire to the work. All metal transfer takes place at arc outages, which occur at a steady rate and can vary from 20 to more than 200 per second. The net result is a stable arc of low energy and heat input, ideally suited to the welding of thin sections in all positions. The low heat input minimizes work-metal distortion. The short-circuiting arc is better than the spray arc for welding joints that have poor fit-up.

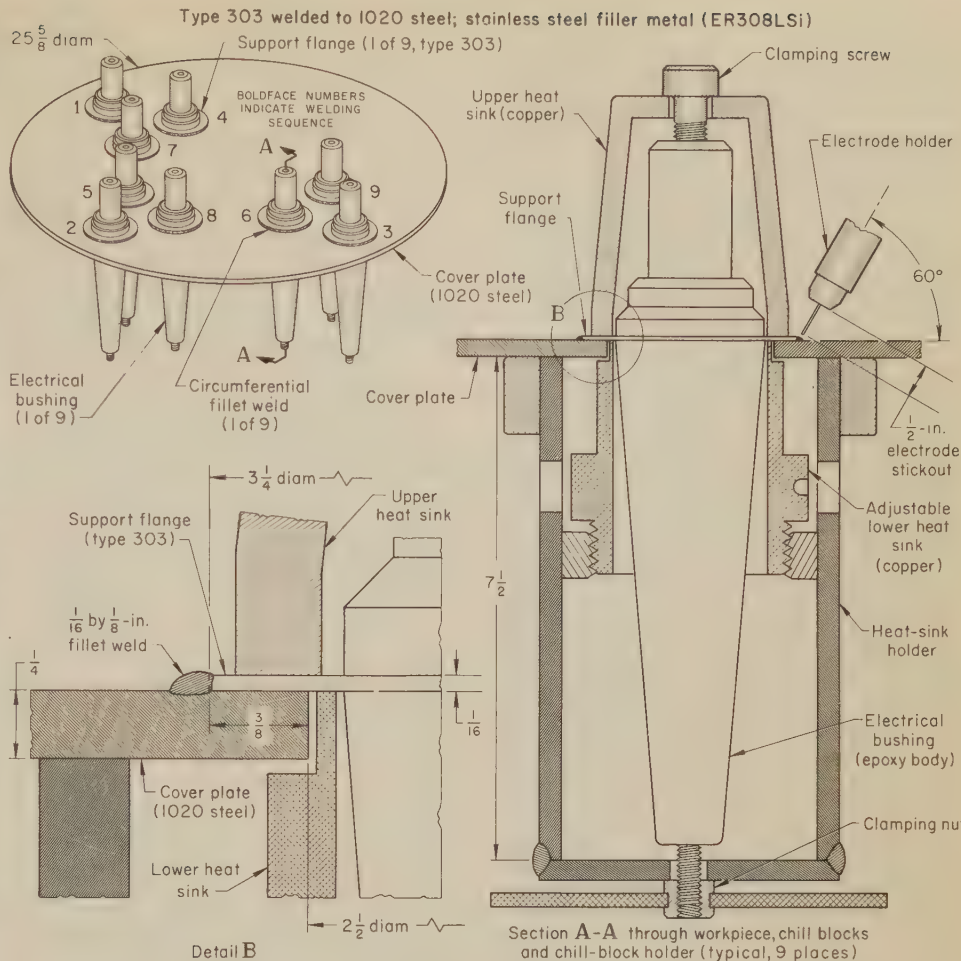
The short-circuiting characteristic cannot be obtained for the full range of operation with ordinary or conventional power-supply units. Machines are available that contain slope, voltage, and inductance adjustments suitable for producing the controlled current surges needed to implement short-circuit transfer on stainless steel. Inductance, in particular, plays an important part in obtaining proper puddle fluidity when short-circuiting transfer is used on stainless steel.

Electrode-wire extension (stickout) should be kept as short as possible. Backhand welding is normally easier on fillet welds and results in cleaner welds. Forehand welding is used for butt welds; outside corner welds are made with a straight motion. Table 10 gives typical welding conditions.

Pulsed-arc transfer is a spray-type transfer occurring in pulses at regularly spaced intervals rather than at random intervals. In the time interval between pulses, the welding current is reduced and no metal transfer occurs.

Pulsing is obtained by combining two current levels provided by two separate power supplies. One power supply provides a background current to preheat and precondition the advancing (continuously fed) electrode wire; the other supplies a peak current for forcing the drop of molten filler metal from the electrode to the workpiece. Drops are transferred 60 times (or multiples of 60 times) per second, because the peak current is tied in with the line frequency.

Electrode wire diameters of 0.045 to 1/16 in. are most commonly used for pulsed-arc transfer welding of stainless steels. Because of the lower heat input, the process is capable of welding sections thinner than are practical to weld by conventional spray transfer; work-metal distortion is also lower, as in the example that follows.



Item	Spray-arc transfer	Pulsed-arc transfer
Process	Automatic gas metal-arc welding	
Joint type	Lap	Lap
Weld type	Fillet	Fillet
Fixtures	Copper chills(a)	Copper chills(a)
Power supply	500-amp transformer-rectifier(b)	250-amp dual transformer-rectifier

Welding speed or time	22 ipm	30 sec per pass

(a) Rotatable three-jaw chuck; manipulator boom. (b) With slope control. (c) Low-carbon, high-silicon ER308L(Si) electrode was selected to minimize base-metal dilution and for ease of deposition. (d) Maximum setting of pulse voltage is 38 volts; peak near 50 volts.

Fig. 23. Sequence and arrangement of fixtures for welding joints between electrical bushings and a cover plate, which required careful control of heat input and weld-bead size to minimize distortion and leakage (Example 264)

Example 264. Change From Spray Transfer to Pulsed-Arc Transfer and the Use of Heat Sinks To Minimize Distortion and Leakage (Fig. 23)

Excessive distortion and leakage were encountered in welding the supporting flanges of electrical bushings to the cover plate of a switching device (see Fig. 23, upper left). The supporting flanges, consisting of 1/16-

in.-thick type 303 stainless steel disks molded to the epoxy body of the electrical bushings, were joined to the 1020 carbon steel cover plates (¼ in. thick) by a single-pass circumferential fillet weld. The principal requirements were that the welds be leaktight under an air pressure of 5 psi and that the cover remain flat, as any distortion of the subassembly would cause misalignment and malfunctioning of parts to be installed later. The problem of distortion was further complicated by the number and arrangement of bushings in the cover and by differences in thermal conductivity and expansion of the two metals being welded.

Originally, ⅛-in. fillet welds were deposited at the joint between the flange and cover plate by automatic gas metal-arc welding with spray transfer, under conditions listed in the table accompanying Fig. 23. The procedure had to be abandoned because even the smallest welds deposited by this procedure were oversize in relation to the nominal 1/16-in. size of the joint and resulted in excessive heat buildup and distortion of the welded components.

To reduce heat buildup in the subassembly, copper heat sinks were placed on either side of the flange, as shown in Fig. 23. The upper heat sink, consisting of a heavy thimble-shape cap, was held firmly against the flange by a clamping screw; the lower heat sink was placed inside a 4-in.-diam schedule 80 pipe and held in place by an adjustable clamping nut. The copper heat sinks were used in pairs and alternated with other pairs, the working pair being removed and cooled in water after two successive runs.

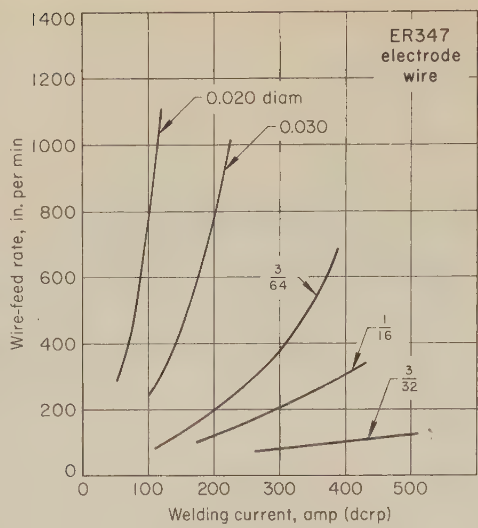
Before welding, the pipe was clamped vertically in a rotatable three-jaw chuck (not shown in Fig. 23); the cover plate was positioned over the pipe; and the bushing hole centered. The bushing was then inserted in the cover and the assembly was drawn up tight by the clamping nut at the bottom. The upper heat sink was fastened in place, and the bottom (adjustable) heat sink was run up with a special wrench, through circumferential slots in the pipe. The electrode holder and wire drive, which were mounted on a manipulator boom, were adjusted so that the electrode holder maintained a 60° angle with the horizontal during welding (see Fig. 23, section A-A).

Heat dissipation was assisted by welding the nine joints in the numerical sequence shown in Fig. 23 (upper left).

Although the use of heat sinks and sequential welding reduced distortion to an acceptable level, about 80% of the weldments still showed small leaks during air testing. Inadequate joint penetration at the overlap of the start and finish of the weld and fast cooling of the oversize bead were suspected to be responsible for the leaks.

The difficulties were overcome by changing to pulsed-arc transfer using a 250-amp dual rectifier and the same setup of equipment for heat dissipation from the weld zone as described earlier. Welding conditions are shown in the table with Fig. 23. With pulsed transfer, penetration was satisfactory and a smaller bead with a lower heat input was obtained. Distortion was further reduced and rejections for leaks were decreased to about 20%.

Electrode Wires. The electrode wire diameters for gas metal-arc welding are generally between 0.030 and 3/32 in. For each wire diameter, a certain minimum welding current must be exceeded to achieve spray transfer. For example, when welding stainless steel in an argon-oxygen atmosphere with a 3/64-in.-diam stainless steel electrode wire, spray transfer will be obtained at a welding current of about 225 amp, dcrp. Figure 24 illustrates typical deposition rates and welding current values for various sizes of ER347 electrode wires, using a mixture of argon with 1% oxygen as the shielding gas. With the minimum current, a minimum arc voltage must also be used. This is generally between 25 and 30 volts.



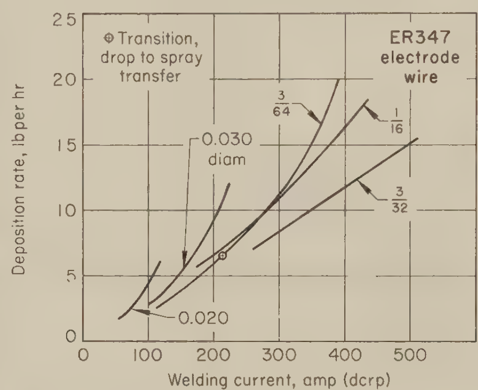


Fig. 24. Relations of welding current to deposition rate for various sizes of ER347 electrode wires. Shielding gas, argon plus 1% oxygen.

Table 11 lists 17 austenitic and precipitation-hardening stainless steel base metals and the electrode wires recommended for welding them. Electrode wires made of high-silicon austenitic stainless steel and wires for welding straight-chromium stainless steel are also available. The austenitic wires with higher silicon content have particularly good wetting characteristics when they are used with short-circuiting transfer.

Shielding Gases. Although the range of choice of shielding gas for welding stainless steels is considerably narrower than for carbon and low-alloy steels, several gas mixtures have proved satisfactory. The mode of metal transfer influences the choice of shielding gas. For instance, with spray-arc or pulsed-arc transfer, a shielding-gas mixture containing 99% argon and 1% oxygen has been widely used and generally recommended. In some plants, 98% argon and 2% oxygen is used with success (see Example 264).

Table 11. Recommended Electrode Wires for Gas Metal-Arc and Submerged-Arc Welding of Austenitic and PH Stainless Steels

Base metal	Filler metal	Base metal	Filler metal

316L	ER316L	AM-355	AM-355

SOURCE: Same as Table 4

For short-circuiting transfer, a mixture of 90% helium, 7.5% argon, and 2.5% carbon dioxide has been extensively used for shielding (see Example 265); but helium is gradually losing favor because of its high cost. However, a mixture in which the above proportions of helium and argon have been reversed — that is, 90% argon, 7.5% helium, 2.5% carbon dioxide — has proved successful for short-circuiting transfer (see Example 266).

Regardless of other variations, the shielding gas for gas metal-arc welding of stainless steel should contain at least 97.5% inert gas (argon or helium, or a mixture of the two). When carbon dioxide is used, the maximum is usually 2.5%, to retain weld quality and corrosion resistance.

Automatic Gas Metal-Arc Welding. A principal advantage of the gas metal-arc process over shielded metal-arc welding is that it is automatic or semiautomatic. Although this advantage prevails in the welding of carbon steel as well as stainless steel, the degree of control that can be achieved with automatic welding makes it especially appropriate for the welding of stainless steel. Specific applications are described in the two examples that follow.

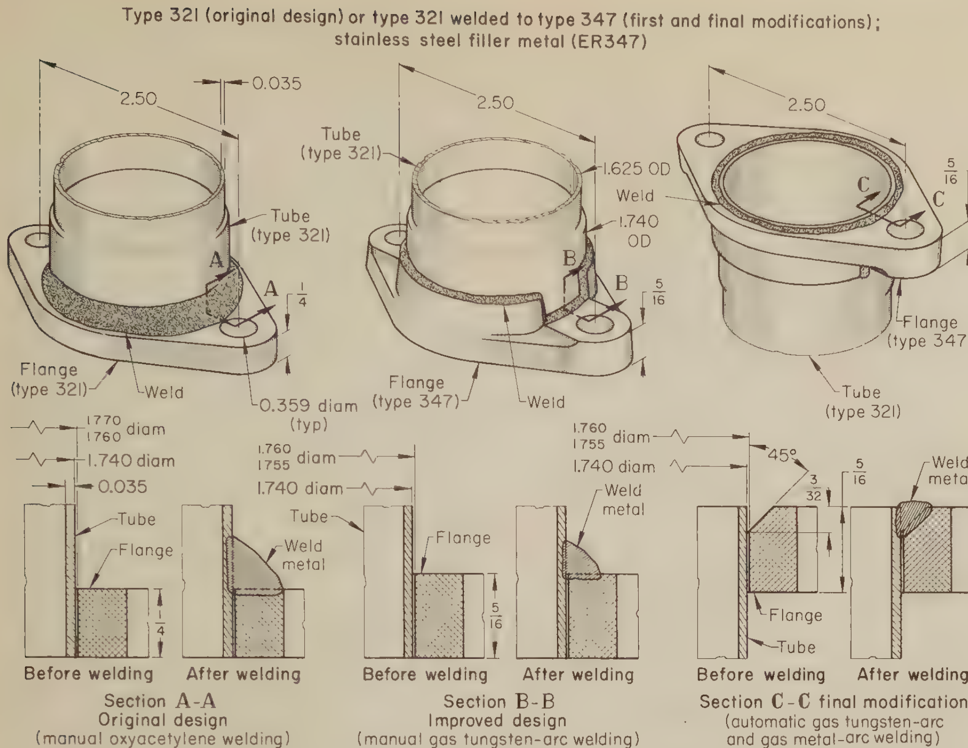
Example 265. Change From Oxyacetylene to Gas Tungsten-Arc to Automatic Gas Metal-Arc Welding for Increased Quality and Production Rate (Fig. 25)

The tube-and-flange assemblies shown in Fig. 25 served as part of the exhaust system for a small reciprocating-type aircraft engine. Specifications required that the joint between the thin-wall stainless steel tube and the mounting flange be of adequate strength, free from leaks, and with alignment accurate enough to permit minimal machining of the flange face and the bolt-head seat.

The original flange design shown in Fig. 25 (left) consisted of a ¼-in. flat flange of type 321 stainless joined to a 0.035-in.-wall tube of the same material. The tube was expanded from 1.625-in. OD (0.035-in. wall) to 1.740-in. OD for a distance of 1 in. at the joint. A single-pass circumferential fillet weld was made by oxyacetylene welding with a 1/16-in.-diam rod of type 347 stainless steel and a proprietary flux. Inspection of the weld resulted in some rejections because of distortion and crack indications in fluorescent-particle testing. Moreover, welding speed (average welding time was 7 min per weld) was necessarily low, to prevent burn-through of the thin-wall tube and to avoid overwelding at the points requiring bolt-head clearance.

Improved results were obtained by welding the same flange and tube joint by the manual gas tungsten-arc process. Using a 250-amp dc power supply having a foot-operated current control, a light-duty electrode holder, low welding current, and ER347 filler metal, a single-pass weld was made in an average time of about 5 min. Argon shielding was used at the torch and argon purging inside the tube assembly. This process produced less distortion and fewer weld defects than did oxyacetylene welding. However, results were still not acceptable.

To eliminate distortion, flange design was changed. The hub-type flange, slotted for bolt-head clearance as shown in Fig. 25 (center), was made of type 347 stainless steel, and was provided with a thicker cross section to resist distortion. The hub



Conditions for Automatic Gas Metal-Arc Welding

Fixtures	Adjustable torch holder, turntable, assembly fixture
Power supply	300-amp, constant-potential transformer-rectifier(a)
Electrode holder	Fixed machine type
Electrode	0.030-in.-diam ER347
Shielding gas	90% helium, 7.5% argon, 2.5% CO_2; at 15 cfh
Welding position	Flat
Number of passes	One
Voltage	25 v
Electrode-feed rate	216 ipm
Mode of transfer	Short circuiting
Electrode stickout	⅜ in.
Preheat	None
Welding speeds for all processes (different designs):	
Gas welding (section A-A)	¾ ipm
Gas tungsten-arc (section B-B)	1.1 ipm
Gas metal-arc (section C-C)	30 ipm

(a) With variable slope control

Fig. 25. Original, improved, and final modified designs and welding procedures for flange-to-tube joint (Example 265)

(including the sides and bottom of the slotted portions) was welded all around by the gas tungsten-arc process. Although there was no distortion, welding time was increased and difficulty was encountered in leaving bolt-head clearance when making the weld in the small slotted area.

To overcome this difficulty, the circumferential part of the weld was transferred from the hub to the face of the flange, as shown in Fig. 25 (right), the welds on the vertical sides of the slots being retained. The weld was deposited in a groove formed by a 3⁄32-in., 45° bevel. Part alignment and bolt clearance were satisfactory; there were no difficulties in machining the face of the flange, and dye-penetrant inspection indicated very few flaws.

Because the weld was circular and easily accessible, the gas tungsten-arc process was readily automated, using an adjustable torch mount, wire-feed drive and a rotatable turntable. To obtain a consistently small weld bead without burn-through or overlapping in the thin tube wall, voltage was automatically controlled, but despite the automation of equipment, the bead contour was insufficiently uniform.

Finally, automatic gas metal-arc welding with short-circuiting transfer was tried. The low heat input of the process allowed a small weld bead of the desired contour to be consistently deposited at a rate of 30 ipm. Argon purging of the inside of the tube was no longer needed. Once the machine settings were established, parts were welded with repetitive accuracy, meeting all specification requirements. A simple welding fixture was constructed to align the flange with the tube and to hold the assembly in position during welding. Supplementary tests showed that the welds on the vertical sides of the hub slots could be eliminated, reducing production time further. Welding conditions for the process are given in the table accompanying Fig. 25. Fluctuations in line voltage had no serious effect, because at the low voltages used, only minor adjustments in the power supply were required.

Example 266. Full-Penetration Weld in 0.045-In.-Wall Tubing by Automatic Gas Metal-Arc Welding (Fig. 26)

Obround tubing for use in low-pressure heat exchangers was formed from 0.045-in.-thick type 304 stainless steel sheet, and welded along the longitudinal seam as shown in Fig. 26. The principal objective was to obtain a sound weld with full penetration, at low cost and a high production rate. By automatic gas metal-arc welding with short-circuiting transfer, full-penetration welds were obtained (at a welding speed of 30 ipm) with relatively simple equipment and tooling.

The tubing was formed from a stainless steel sheet 8 ft long and 0.045 in. thick. The as-sheared square-butt joints were brushed with a stainless steel wire brush and wiped with a solvent cleaner. The 8-ft length of tubing was placed between the jaws of a hydraulically operated clamping fixture, which forced the joint edges together along the full length of the seam. Starting and runoff tabs, about ½ in. square, of the same material and thickness as the base metal, were tack welded in place to ensure sound weld metal at the tube ends (see Fig. 26).

The electrode holder, wire-feed drive and filler-metal coil (ER308) were mounted on a motor-driven carriage that traveled on a horizontal track above the joint. Welding was done in a single continuous pass (see the welding conditions in the table that accompanies Fig. 26).

The significant variables in the process were joint fit-up, wire feed and travel speed. Some burn-through occurred, which required repair welding, but rejections resulting from this cause amounted to less than 2%, a figure considered acceptable.

After welding, completed tubes were inspected visually for continuity and soundness, and were leak tested at an air pressure of 5 psi under water. Qualification tests for the welding procedure and for operators were conducted according to Section IX of the ASME code.

Shielded Metal-Arc Welding

The shielded metal-arc process ("stick electrode" manual welding) is widely used for welding stainless steel. Its principal advantage is flexibility. For a description of the process, see the article on Shielded Metal-Arc Welding, which begins on page 1 of this volume.

The disadvantages of shielded metal-arc welding are: (*a*) the slag blanket constitutes a potential source of inclusions; (*b*) control of weld-metal deposition requires more skill than is needed in gas-shielded arc welding; (*c*) visibility during welding is impaired by slag; (*d*) slag removal between passes is necessary; (*e*) the process is not adaptable to very thin

SOURCE: Same as Table 4

sections; and (*f*) electrodes are sensitive to moisture pickup. Because of the requirements for corrosion resistance that normally apply, these disadvantages must be taken into account in the welding of stainless steel.

Constant-current (drooping-voltage) power sources, conventionally used for shielded metal-arc welding, are applicable for welding stainless steel. Either alternating current or reverse-polarity direct current is suitable in most applications. Direct-current power supply can be of the motor-generator or transformer-rectifier type.

Electrodes. Table 12 lists austenitic stainless steel electrodes used for shielded metal-arc welding. The suffix number is related to the polarity to be used. The suffix -15 indicates that the coating is primarily of the lime type, containing a fair amount of calcium or other alkaline elements, and that the electrodes are suitable for use with reverse-polarity direct current. For welding with alternating current, an electrode with the suffix -16 should be selected. Such electrodes can be used with reverse-polarity direct current as well and can have either a lime-type or titania-type covering. For welding with alternating current, the coating, besides having alkaline elements, also contains readily ionized elements to stabilize the arc. The designation E16-8-2 refers to the chromium, nickel and molybdenum contents of electrodes not otherwise identifiable by the AISI system of designations.

Electrodes of the -15 and -16 types up to 5⁄32 in. in diameter can be used in all welding positions; electrodes 3⁄16 in. in diameter and larger, in the flat and horizontal fillet positions only.

The electrodes listed in Table 12 cover most requirements for welding the standard austenitic grades and, to a large extent, the straight chromium grades (martensitic and ferritic), depending mainly on whether the weldments will be subjected to postweld heat treatment or not. Suggested electrodes for welding the austenitic, martensitic and ferritic grades are given in Table 1. In applications where the mechanical properties of welded joints are not critical, the precipitation-hardening steels can be welded with standard austenitic electrodes.

For welding special grades of stainless steel, it may be necessary to use composite electrodes of special composition. For shielded metal-arc welding, a composite electrode consists of a flux-covered carbon steel tube containing the alloying elements, in powder form, in the core. These electrodes are available for depositing the standard compositions of stainless steel.

The example that follows describes an application that required the use of a composite electrode.

Example 267. Use of a Composite Electrode To Weld Two Stainless Steel Castings (Fig. 27)

Air separators for self-priming pumps to be used in a corrosive medium were cast from high-strength CD-4MCu stainless steel in the form of hemispheres and were joined at the equator by shielded metal-arc welding, as shown in Fig. 27. The composition of the austenitic-ferritic (CD-4MCu) stainless steel castings was: 0.04 C max, 1.0 Mn max, 1.0 Si max, 24.5 to 26.5 Cr, 4.75 to 6.0 Ni, and 1.75 to 2.25 Cu. Minimum mechanical properties were: tensile strength, 100,000 psi; yield strength, 70,000 psi; and elongation in 2 in., 20%.

Because no standard filler metal was available to match the base-metal composition, a composite electrode was formulated. Low-carbon steel tubes were filled with alloy powder in proportions that would produce a deposit equivalent in composition to the base metal. The electrodes were manufactured as follows: carbon steel strip was partially roll formed and filled with the alloy powder. Roll forming was continued until the tube was tightly closed and crimped, after which it was pulled through dies to reduce the outside diameter of the tube to 5⁄32 in., and it was cut to length. The tubes were then processed through a press that extruded a flux covering concentric with the tube.

The hemispheres (of 3⁄8-in. wall thickness, 11-in. diameter and 7-in. height) were cast with 45° bevels at the joint edges (see Fig. 27 for joint details). Casting skin at the joint edges was removed by grinding, and the parts were assembled in a lathe-type positioner for flat welding. Welding was accomplished in three passes under the conditions listed in the table with Fig. 27. Welds were carefully cleaned between passes, using a stainless steel wire brush. The width of weave was not permitted to exceed four times the electrode diameter — that is, 5⁄8 in. max.

After welding, the assembly was solution heat treated to obtain maximum corrosion resistance. Following heat treatment, the weldments were sand blasted, machined, and pressure tested with air at 100 psi.

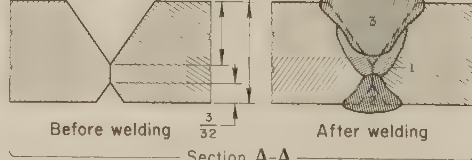
General Welding Procedure. In general, the procedure used for welding plain carbon steel of low carbon content is followed for welding stainless steels, although the differences in physical and chemical properties may necessitate modifications. Because most stainless steels have a higher coefficient of thermal expansion than carbon steels, distortion in welding is likely to be greater. On the other hand, the lower thermal conductivity of stainless steels and their higher electrical resistivity permit greater deposition rates at the same current.

When welding stainless steels, it is especially important that the weld area be clean and free of foreign matter. Organic material on the surface can break down in the heat of the arc and cause porosity and carburization of the weld metal.

The workpieces should be carefully prepared and fitted. Thin-gage stainless steel, especially, should be properly clamped and held in alignment to reduce the probability of buckling.

Large electrodes (more than ¼ in. in diameter) and excessive arc length will contribute to loss of chromium in the weld deposit. Excessive weaving of electrodes of any size should be avoided;



Pass number	Current (dcrp), amp	Voltage, v	Welding speed, ipm
1	400	26	20
2	420	28	20
3	450	32	18

Electrode: 3⁄32-in.-diam ER308; neutral flux, 12 × 150.

maximum width of weave should be limited to four times the core-wire diameter. In general, the stringer-bead technique is recommended.

Special care is required between weld passes to remove all slag from the deposited bead. Only stainless steel wire brushes and tools should be used for this purpose. If grinding wheels are used, the wheels should not have been contaminated by use on metals other than stainless steel.

Discoloration on either side of the weld metal by a thin oxide layer is a harmless surface condition. It can be removed by pickling, sand blasting, or power brushing, or by electrolytic cleaning if a bright surface is required.

Care in the storage of electrodes is important. Electrode coatings pick up moisture, which may lead to weld porosity. Electrode manufacturers generally supply stainless steel electrodes in moistureproof packages to prevent moisture pickup. Electrodes exposed to air and humidity can sometimes be restored to their initial condition by baking, as explained in the section on Effect of Moisture on Electrode Coverings in the article "Shielded Metal-Arc Welding" in this volume. It is best not to use such restored electrodes for critical welding applications. No attempt should be made to restore electrodes that are wet; they should be discarded.

Typical welding conditions for several metal thicknesses and types of joints are given in Table 13. The illustrations in Table 13 for butt welding of austenitic stainless steel sheet and plate show copper chill bars for all base-metal thicknesses, with chill bars on both top and bottom for base-metal thicknesses less than 3/16 in.

Welding the Austenitic Steels. Austenitic stainless steels should be welded in the annealed condition. Because the austenitic steels are not hardenable by heat treatment, preheating is rarely used. Their mechanical properties are not substantially changed by welding, although stainless steel that has been purposely work hardened to increase its strength will be softened in the heat-affected zone.

For welding in the flat position, the stringer-bead technique should be used for the first pass; when the fit-up is poor, a slight weave may be required. For succeeding passes, stringer beads or a slight weave should be used. The arc should be no longer than 1/8 in. For vertical-down welding, the same technique is used, but with the electrode tilted so that the force of the arc pushes the molten metal back up the joint. Vertical-up welding calls for a triangular weave with 5/32-in.-diam or smaller electrodes. A shelf is made at the bottom of the joint (lower end) and succeeding passes are made using a slight weaving motion with the electrode pointed slightly upward. Overhead welding requires a whipping technique and a slightly circular motion. Weaving should be avoided. The arc should be as short as possible and the movement should be rapid.

Welding the Straight-Chromium Grades. Straight-chromium (ferritic or martensitic) stainless steels differ somewhat in welding characteristics from the austenitic steels because they

have a lower coefficient of thermal expansion — about the same as ferritic carbon steel. Therefore, warpage and distortion are less likely to occur. The ferritic stainless steels may become embrittled during welding and require control over preheat and postheat. (See the sections on ferritic and martensitic stainless steels, page 248 in this article.)

Submerged-Arc Welding

Among the advantages of submerged-arc welding are high deposition rate and high welding speed, which result in good economy. The principal disadvantage of the process is its inflexibility. Most installations are mechanized, although semiautomatic welding is possible. The use of flux to shield the weld requires flux handling and slag removal operations. Moreover, submerged-arc welding is restricted to the flat and horizontal positions.

For a detailed description of the process, see the article on Submerged-Arc Welding, page 46 in this volume.

Weld Quality. The quality of welds made by the submerged-arc process is generally high, but some conditions restrict use of the process. Generally, the composition of the weld metal is more difficult to control with submerged-arc welding than it is with gas tungsten-arc, plasma-arc, or electron beam welding. The heat input can be much greater than in other arc welding processes, and solidification of the weld metal is generally slower. These conditions can raise problems in welding stainless steel that are not encountered when welding carbon steel. For instance, the silicon content of the weld metal may be much higher in submerged-arc welding than in other processes, and increased silicon content may cause hot shortness or fissuring. Basic-type flux minimizes this effect.

When the weld deposit must be fully austenitic, or when the ferrite content of the deposit must be controlled to less than 4%, the risk of microfissuring is considerable, particularly in welding heavy sections, which are generally well suited for welding by the sub-

merged-arc process. The welding of relatively thick sections of type 347 stainless steel also presents a problem; service failures have occurred because of strain-induced precipitation of columbium carbides in the heat-affected zone during postweld heat treatment or service at elevated temperature.

Welding Current. Direct current is normally used for welding thin sections. For welding thicker sections, either alternating or direct current can be used. Current for welding stainless steel is usually about 80% of that used for welding carbon steel, section thickness and other conditions being the same. Some typical values of current for specific welding conditions are given in the table with Fig. 28. There are, however, conditions where alternating and direct currents cannot be interchanged in welding stainless steel. One such application is described in the example that follows.

Example 268. Change From Alternating to Direct Current for Welding Turbine Wheels When Material Was Changed From Alloy to Stainless Steel (Fig. 29)

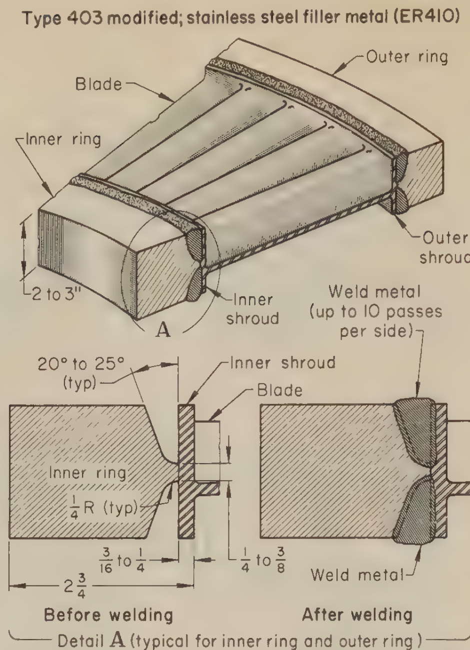
Turbine wheels of several sizes were fabricated by joining two rings to the inner and outer shrouds of the blade assembly by means of two double-J-groove welds, as shown in Fig. 29.

When low-alloy steel shrouds were joined to carbon steel rings, a neutral flux was used with a carbon steel electrode wire and alternating current. Distortion was minimized by control of the sequence of passes and the volume of weld metal deposited, and acceptable results were obtained.

Similar assemblies designed for higher-temperature service were made from a modified type 403 stainless steel and welded with ER410 electrode wire. This modified grade had a somewhat higher chromium content than standard 403 stainless steel. The welding conditions used for the low-alloy steel wheels were not satisfactory for welding the stainless steel wheels. The alternating-current arc was unstable and caused bridging to the sides of the groove without penetrating to the bottom, entrapping slag. Increasing the travel speed resulted in an irregular, ropey type of bead.

Two means of stabilizing the arc and thereby correcting the difficulty were considered: (*a*) widening the J-grooves by 25%, and (*b*) using direct current with reverse polarity. Because widening the J-grooves would require more filler metal, this change would increase distortion and add to the welding cost. Therefore, the change to reverse-polarity direct current was made.

Welding was done under the conditions listed with Fig. 29. Up to 20 passes were required for each joint. The first side was welded until a measurable amount of distortion was observed (usually after 3 to 5 passes); then the weldment was turned over and passes were made on the reverse side until distortion was observed; welding was alternated from side to side until the weldment was completed.



Process	Submerged-arc welding

Electrode Wires (Filler Metals). Table 11 lists designations of electrode wires applicable to submerged-arc welding. Selection of filler metal for a particular grade of stainless steel is complicated by the differences in service requirements. If experience with a similar application is not available, use of a filler metal similar in composition to the base metal should be considered (see Examples 268 and 269). Adjustments (based on experience) may be required in the composition of the filler metal or the flux, or both, to arrive at a suitable composition of weld deposit. In some applications, a filler metal that is higher in alloy content than the base metal is used. For instance, the data with Fig. 28 show the use of ER308 filler metal for welding type 304 stainless steel.

Table 14. Relation of Wire Diameter to Current for Submerged-Arc Welding of Stainless Steel

Wire diameter, in.	Current range, amp	Wire diameter, in.	Current range, amp

SOURCE: Same as Table 4

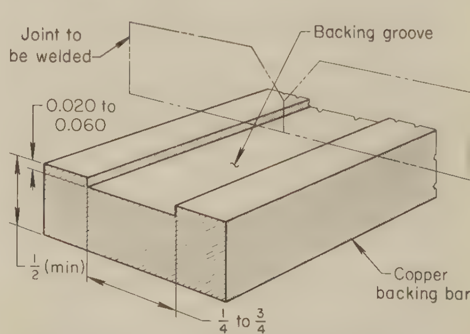

Fig. 30. Recommended groove dimensions for copper backing bars used in submerged-arc welding of stainless steel

Typical electrode wire size and current combinations are given in Table 14. Sizes larger than 3/16-in. diameter are seldom used, and may result in heavy deposits with undesirable metallurgical and mechanical properties.

Flux. Submerged-arc fluxes (either prefused or bonded) are available as proprietary materials for welding stainless steel. Alloying elements such as chromium, nickel, molybdenum and columbium are frequently added to the weld deposit through the flux. If the flux contains no alloying additions, it is said to be "neutral".

Weld Backing. Submerged-arc welding deposits relatively large volumes of metal that remain fluid for longer periods than are possible with the other arc methods discussed in this article. Thus, for many types of joints, backing is required.

The two common types of weld backing are nonfusible and fusible. Copper is the nonfusible backing material most frequently used in the welding of stainless steel. In effect, the copper bar serves more as a chill than as a backing, helping to distribute heat from the weld metal to adjacent areas. Recommended dimensions for grooves in copper backing bars are given in Fig. 30; many designs other than that shown in Fig. 30 are also used. With a fusible backing, made of stainless steel, the weld penetrates and fuses with the backing, which becomes, temporarily or permanently, an integral part of the welded joint (see Example 269).

Joint Design. Sound single-pass welds can be made in square-groove butt joints up to 5/16 in. thick, without root opening and with suitable nonfusible backing. Two-pass welds (one pass on each side) are made without root opening on metal up to 5/8 in. thick, but it is essential that the edges of the joint be closely butted to avoid burn-through, since weld backing is not used. A square-groove butt joint requires a minimum of edge preparation and produces sound welds that have adequate penetration.

Single-V-groove welds with a root face are used with nonfusible backing for single-pass butt joints of 5/16-in. thickness or more. For most applications, the maximum thickness of single-V-groove welds is 1¼ to 1½ in., with root-face dimensions 1/8 to 3/16 in. This joint design can be used for multiple-pass welds, without backing, where plate thickness exceeds 5/8 in. The first pass is made in the shallower V; the work is then turned over and welded on the reverse side. The root face is about 3/8 in. for multiple-pass welds.

The double-V-groove butt joint is the basic design for submerged-arc welding of material having a thickness of ½ in. or greater. A large root face is generally used. Figure 28 shows a typical double-V-groove weld in ½-in. type 304 plate. Welding conditions are included in the table with Fig. 28. A single-U-groove butt joint is also commonly used. Shielded metal-arc welding is often used to make a root pass, or backing pass, on the reverse side of the joint.

Welding Position. Submerged-arc welding is done in the flat or horizontal position. Operation difficulties in-

crease and preferred shape of beads is sacrificed when the work is inclined. Typical effects of inclination of the joint on formation of bead shape are compared in Fig. 31.

Welding Technique. The most common method of starting the arc when welding stainless steel is the fuse-ball start. A tightly rolled ball of stainless steel wool, about ⅜ in. in diameter, is placed between the end of the electrode and the work. The electrode wire is inched forward to compress the ball. Flux is added and the arc is initiated and flashes through the stainless steel wool. For details on other methods of starting the arc, see the article on Submerged-Arc Welding, which begins on page 46 in this volume.

Once the arc is started, welding conditions must be carefully monitored. The most important are current, voltage and travel speed. If current is too high, likely results are burn-through, pear-shape fusion zones, excessive penetration, and overlap or excessively high reinforcement. If current is too low, inadequate penetration and low reinforcement will result. When voltage is too high, the most common results are shallow penetration and wide reinforcement. Low voltage results in pear-shape fusion zones and narrow and steep-side reinforcement, or overlapped reinforcement. When welding speed is too high, undercutting and low reinforcement are likely results; too low a speed leads to overlap.

Circumferential Welding. Submerged-arc welding is used extensively for making girth welds for joining pipe or other cylindrical sections. Equipment required is generally the same as for welding cylindrical workpieces of carbon steel and is described in the article on Submerged-Arc Welding, which begins on page 46 in this volume.

In the application of submerged-arc welding to stainless steel pipe joints, some difficulty may be encountered in cleaning the root of the joint and in obtaining a sound weld root inside the pipe. These problems can be overcome by: (*a*) using a backing ring and making the root pass by shielded metal-arc welding, followed by submerged-arc welding for the filler passes; or (*b*) making the root pass by gas tungsten-arc welding, without backing, and completing the joint by submerged-arc welding. The example that follows describes the first of these alternatives.

Example 269. Use of a Stainless Steel Backing Ring in Welding Type 347 Stainless Steel Pipe Joints (Fig. 32)

Service conditions required the joint between type 347 stainless steel pipe sections, shown in Fig. 32, to be made with full penetration but without weld metal on the inside of the pipe. The groove was prepared by gas tungsten-arc cutting, with the pipe sections in position on turning rolls. Oxide on the surface was removed mechanically, and the pipe sections were assembled, with a stainless steel backing ring, to form the joint. The root pass was made by shielded metal-arc welding, and the weld was cleaned with a stainless steel brush and inspected visually. Visible flaws were removed by grinding.

Welding was completed in five additional passes by the submerged-arc process, under the conditions shown with Fig. 32, which were selected so as to avoid undercutting on the sidewalls of the weld groove. After each bead had been deposited, slag was removed by wire brushing, and any cracks and porosity were removed by chipping and grinding. Because of the susceptibility of the bead to cracking, the arc could not be struck on the weld bead already deposited and so it was struck on the side of the weld groove, and the stops and starts were subsequently ground out.

After completion of the joint, the fused flux was removed by brushing and the joint was prepared for radiographic inspection. Rejection rate was less than 5%.

Welding of Dissimilar Alloys

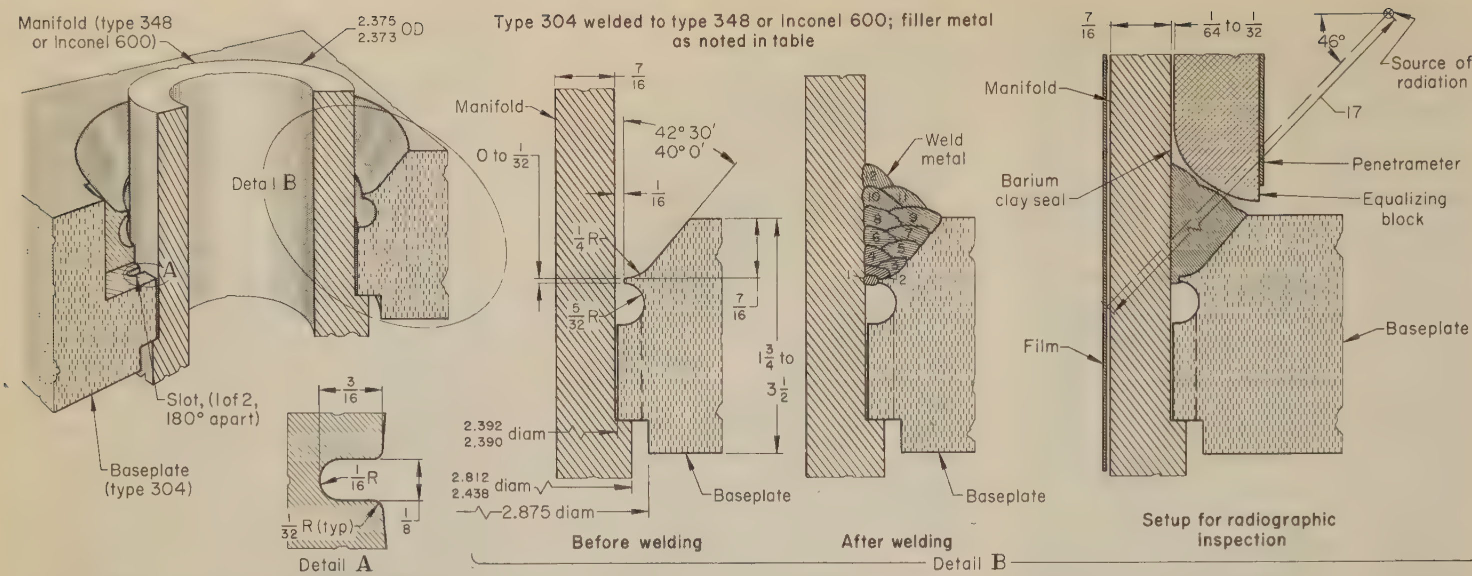
The welding of dissimilar austenitic stainless steels to each other is fairly common practice. When suitable welding procedures and filler metals are employed, most austenitic stainless steels can also be welded satisfactorily to several different classes of weldable steel, including ferritic and precipitation-hardening stainless steels, carbon steels, and low-alloy steels. The following examples in this article describe the welding of dissimilar austenitic or precipitation-hardening stainless steels, or of austenitic stainless steels to weldable carbon steels: Example 259 (316L to 17-7 PH); Example 260 (321 to low-carbon steel); Example 261 (AM-350 to 301); Example 262 (305 to 347); Example 264 (303 to 1020 low-carbon steel); Example 265 (321 to 347); and Example 270 (304 to 348 or Inconel 600). Example 251 in this article illustrates the use of spot welding to tack a ferritic stainless steel sheath to a carbon steel stiffener.

Dissimilar Austenitic Alloys. To accommodate varying requirements in service, it is not uncommon to weld different austenitic stainless steels, such as types 304 and 347, to each other or to a nickel-base alloy, using a filler metal that differs in chemical composition from both base metals. Recommended filler metals for welding dissimilar austenitic stainless steels are given in Table 8. In some applications, such as that described in Example 261, a precipitation-hardening stainless steel is welded to a conventional austenitic stainless steel. In the example that follows, welded components were made either of two different austenitic stainless steels or of an austenitic stainless steel and a nickel-base alloy.

Example 270. Welding Dissimilar Austenitic Alloy Components for a Nuclear Application (Fig. 33)

A sectional view of the manifold and baseplate assembly of a heat exchanger used in a nuclear application is shown at the extreme left in Fig. 33. Specifications required the use of manual gas tungsten-arc welding for the root pass and second pass of the joint between the baseplate (made of type 304 stainless steel) and the manifold (made of either type 348 stainless steel or Inconel 600). The remaining passes could be made by either gas tungsten-arc or shielded metal-arc welding. In this example, all weld metal was deposited by gas tungsten-arc welding.

Before welding, the joint edges of the baseplate and manifold were machined to the dimensions shown in Fig. 33 (detail B, Before welding). The joint and adjacent base metal (for a distance of 2 in.) were cleaned free of oil, scale, oxide, and other contaminants. Welding-grade argon was used for shielding and purging during welding, and purging-gas flow was continued until all metal surfaces had cooled to 300 F. The root pass and second pass were made by depositing small (as small as possible) stringer beads that merged uniformly with the base metal. After deposition, each weld was cleaned thoroughly and inspected visually at a magnification of not less than 5×. Cracked welds were removed completely and rewelded. After each subsequent pass, the weld beads were cleaned with a stainless steel brush or an aluminum oxide grinding disk not previously used on other kinds of metals.



Process	Manual gas tungsten-arc welding
Joint type	Circumferential T
Weld type	Single-J groove(a)
Power supply	600 amp
Shielding gas	Argon, at 10 to 15 cfh
Arc starting	Manual
Electrode:	
Root pass and 2nd pass	1/16-in.-diam
Subsequent passes	3/32-in.-diam
Filler metal:	
Root pass and 2nd pass	1/16-in.-diam, ER308(b) or FM82(c)
Subsequent passes	3/32-in.-diam, ER308(b) or FM82(c)
Current (dcsp):	
Root pass and 2nd pass	110 to 120 amp
Subsequent passes	110 to 130 amp
Voltage	12 to 14 v
Preheat and postheat	None(d)
Interpass temperature	300 F (max)
Welding speed	12 to 18 ipm

(a) Fillet reinforced. (b) For joining type 304 to type 348 steel. (c) For joining type 304 to Inconel 600 (0.10 C, 67 Ni, 20 Cr, 2.5 Cb). (d) Work metal heated to 60 F if temperature before welding was below 60 F.

Fig. 33. Joint design, weld pass sequence and setup for radiographic inspection of finished weld of manifold and baseplate assembly for a nuclear application (Example 270)

The minimum allowable base-metal temperature at the start of welding was 60 F, and the maximum interpass temperature was 300 F. No postweld heat treatment was required. Other welding conditions are given in the table that accompanies Fig. 33.

A pedal for controlling amperage at starts and stops of the weld passes was used to control heat buildup and to minimize crater cracks. Procedures and welders were qualified in accordance with nuclear standards. In addition to visual inspection, the root and final passes were inspected by the liquid-penetrant method and the completed weld was inspected radiographically. To equalize the intensity of the x-rays across the entire width of the weld, a contoured, 3/8-in.-thick equalizing block (corresponding to the alloy used in the vertical member of the weldment) was placed, as shown at the extreme right in Fig. 33, at a distance of 1/64 to 1/32 in. from the vertical member and separated from the vertical member and weld by a layer of barium clay. Verification radiographs of the weld were made with a penetrameter in place.

Welding Austenitic Stainless Steel to Carbon or Low-Alloy Steel. In joining austenitic stainless steel to carbon or low-alloy steel for service applications involving exposure to temperatures not exceeding about 700 F, it is good practice to use a stainless steel filler metal of total alloy content high enough to prevent martensite formation in the weld after dilution by the opposing base metal and to preserve residual amounts of ferrite to minimize the possibility of hot cracking resulting from welding under severe restraint. Type 309 (25Cr-12Ni) filler metal is most widely used for joining carbon or low-alloy steel to austenitic stainless steel; it normally contains about 5 to 10% ferrite. Type 312 (29Cr-9Ni), also used for this purpose, is more strongly ferritic. Satisfactory welds are also obtained with ERNiCrFe-6 filler metal.

In joining austenitic stainless steel to carbon steel, it is good practice first to surface (butter) the carbon steel with a layer of type 309 or other suitable stainless steel weld metal, so that the portion of the weld (on the carbon steel member) where difficulties are most likely to occur is deposited while there is little restraint on the weld metal. Thus, following deposition and inspection of the surfacing layer (or layers), the joint between the stainless steel member and the surfaced layer becomes a stainless-steel-to-stainless-steel joint, which can be welded by using a conventional stainless steel filler metal.

The deposition of carbon steel or low-alloy steel filler metal on austenitic stainless steel should be avoided whenever possible because it can result in hard, brittle weld deposits.

A procedure for joining stainless steel to carbon steel or to stainless-clad carbon steel is shown in Fig. 34. This procedure is widely used in the welding of stainless steel pipe to stainless-clad carbon steel, low-alloy steel, and carbon steel.

In depositing the surface layer, dilution of the stainless steel weld metal by carbon steel, which can cause cracking of the weld, can be minimized with the following practices. If the cladding on stainless-clad steel is type 304 stainless steel, type 309 should be used for the surfacing layer. After depositing the surfacing layer, the component is stress relieved, if necessary. The final weld between the solid stainless steel and the surfaced stainless-clad steel or carbon steel can be made either with the filler metal normally employed for welding the solid stainless steel member or with the one that was used for the overlay.

In another method, a short stainless steel transition member is welded to the carbon steel or stainless-clad carbon steel member prior to stress relieving and final welding. This method ensures protection of the carbon steel base metal from the effect of final welding, and stress relieving can be done while there is little restraint on the joint. This method, however, is more costly than the procedure for producing a surfacing layer.

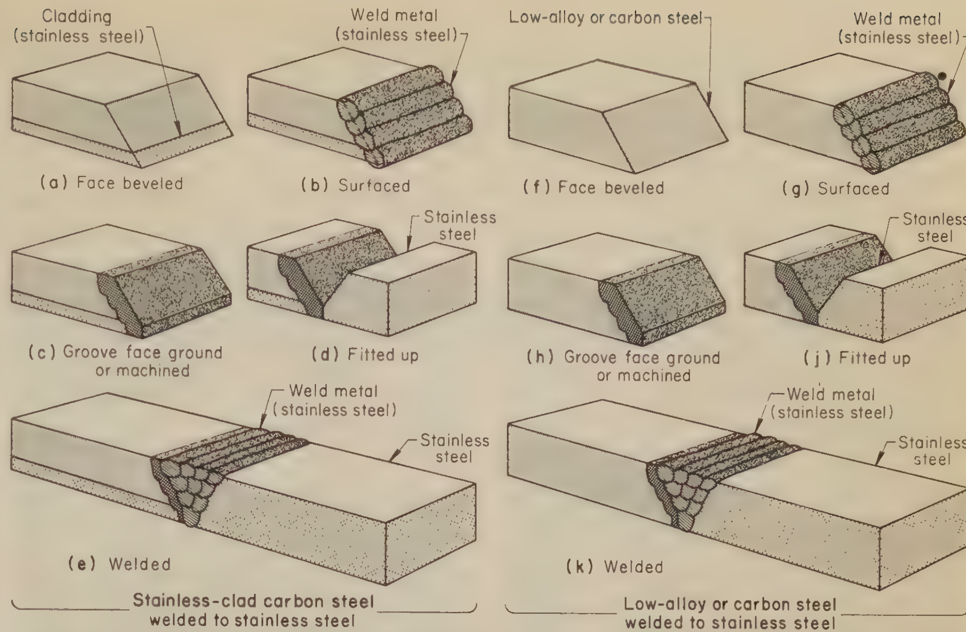
In a third method, the workpieces (stainless steel and carbon steel or stainless-clad carbon steel) are beveled and fitted, leaving a root opening at the joint that is then welded with a filler metal of sufficiently high alloy content to prevent cracking of the weld after dilution by carbon steel. The welding procedure should be controlled to hold penetration into the surface of the carbon steel to a minimum. A disadvantage of this method is that the joint is under restraint both during welding and local stress relieving. This method, although often used, is the least desirable of the three.

Welding Ferritic and Martensitic Stainless to Carbon and Low-Alloy Steel. When welding ferritic or martensitic stainless steel to carbon or low-alloy steel for general service (not high-temperature service), the use of austenitic stainless steel or modified ERNiCrFe-6 filler metal can produce welds of suitable quality if correct welding procedures are followed.

Two methods are commonly employed. The first method involves surfacing both members of the joint, using suitable preheat and postheat treatments as required, and then making a weld between the buttered surfaces without preheat or postheat. Filler metals, such as type 309, that are sufficiently high in alloy content to minimize dilution by carbon steel or straight-chromium stainless steel are widely used with this method. Penetra-

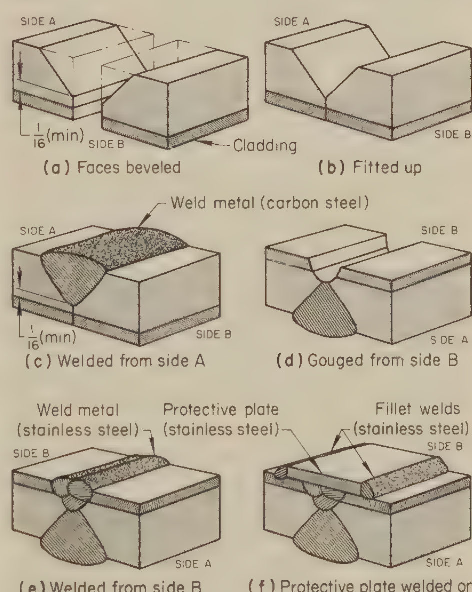
tion into the base metal should be kept to a minimum.

The second method involves depositing the filler metal directly on the surfaces of the two members of the joint without using a separate surfacing layer. Dilution of the weld metal by both base metals must be kept under close control while the restrained joint is being welded.



Stainless-clad, low-alloy or carbon steel edges are beveled for welding (a and f); an overlay (or "buttering" layer) of stainless steel filler metal is applied to the beveled edge (b and g); the layer is machined or ground to required dimensions and stress relieved, if required (c and h); the components are fitted up for welding (d and j); the weld is completed, using the filler metal normally used for welding the stainless steel member or that used for the surfacing pass on stainless-clad, low-alloy or carbon steel (e and k).

Fig. 34. Procedures for joining austenitic stainless steel to stainless-clad carbon steel, solid carbon steel, and low-alloy steel



(a and b) The clad plates are machined for a tight fit-up, with the bottom of the weld groove not less than $\frac{1}{16}$ in. above the stainless steel cladding; (c) carbon steel filler metal is deposited from side A (a low-hydrogen filler metal is used for the first pass), taking care not to penetrate closer than $\frac{1}{16}$ in. to the cladding; (d) stainless steel cladding on side B is back gouged until sound carbon steel weld metal is reached; (e) the back-gouged groove is filled with stainless steel weld metal in a minimum of two layers. (f) When required for severely corrosive service, a protective strip of stainless steel plate may be fillet welded to the cladding to cover the weld zone.

Fig. 35. Procedure for welding stainless-clad carbon and low-alloy steel, using stainless steel filler metal only in portion of joint from which cladding was removed

Welding Austenitic-Stainless-Clad Carbon or Low-Alloy Steel Plate

To preserve its desirable properties, stainless-clad plate can be welded by either of the two following methods, depending on plate thickness and service conditions:

1 The unclad sides of the plate sections are beveled and welded with carbon or low-alloy steel filler metal. A portion of the stainless steel cladding is removed from the back of the joint and stainless steel filler metal is deposited.
2 The entire thickness of the stainless-clad plate is welded with stainless steel filler metal.

When the nonstainless portion of the plate is comparatively thick, as in most pressure-vessel applications, it is more economical to use the first method. When the nonstainless portion of the plate is thin, the second method is often preferred. When welding components for applications involving elevated or cyclic temperatures, the differences in the coefficients of expansion of the base plate and the weld should be taken into consideration.

All stainless steel deposits on carbon steel should be made with filler metal of sufficiently high alloy content to ensure that normal amounts of dilution by carbon steel will not result in a brittle weld. In general, filler metal of type 308, 316 or 347 should not be deposited directly on carbon or low-alloy steel. Deposits of type 309, 310 or 312 are usually acceptable, although type 310 is fully austenitic and is susceptible to hot cracking when there is high restraint in a welded joint. Thus, welds made with type 310 filler metal should be carefully inspected. Welds made with types 309 and 312 filler metals are partially ferritic and therefore are highly resistant to hot cracking.

The procedure most commonly used for making welded joints in stainless-clad carbon or low-alloy steel plate is shown in Fig. 35. Stainless steel filler metal is deposited only in that portion of the weld where the stainless steel cladding has been removed, and carbon or low-alloy steel filler metal is used for the remainder.

The back-gouged portion of the stainless steel cladding should be filled with a minimum of two layers of stainless steel filler metal (Fig. 35e); an additional layer is recommended if a high weld reinforcement at the cladding surface can be tolerated.

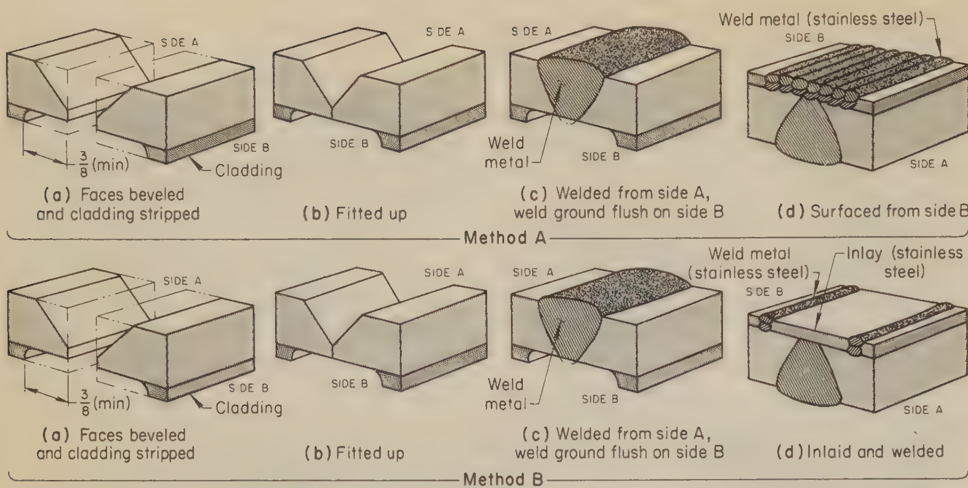
If the cladding is of type 304 stainless steel, the first layer of stainless steel weld metal should be of type 309 or 312. Subsequent layers of weld metal can be of type 308.

If the cladding is of type 316, the first layer is deposited with type 309(Mo) filler metal and the subsequent layers with type 316. Alloy 20 (20 Cr, 29 Ni, 2 Mo, 3 Cu, 0.07 C) filler metal is also frequently used on plate clad with type 316. When the cladding is of type 304L or type 347, the welding procedure must be carefully controlled to obtain the desired weld-metal composition in the outer layers of the weld. Chemical analysis of sample welds should be made before joining of clad plates intended for use under severely corrosive conditions.

In some applications, a narrow protective plate of wrought stainless steel of the same composition as the cladding is welded over the completed weld (Fig. 35f) to ensure uniformity of corrosion resistance. The fillet welds joining the protective plate to the cladding should be carefully inspected after deposition. These welds, of course, are made with stainless steel filler metal.

Figure 36 illustrates an alternative method (method A) of welding clad plate in which a carbon or low-alloy steel weld joins the carbon steel portion of the plate and the use of stainless steel filler metal is limited to replacement of the cladding that was removed prior to making the carbon or low-alloy steel weld. This method is more expensive than the previous one (Fig. 35), because of the cost of removing a larger portion of the cladding and depositing more stainless steel filler metal. Because there is no danger of alloy contamination from the cladding layer, method A in Fig. 36 permits the use of faster welding processes, such as submerged-arc, in depositing the carbon steel weld.

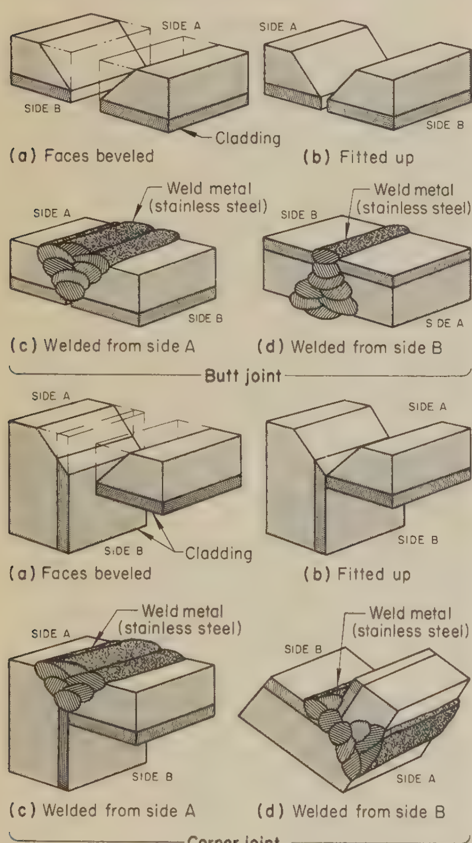
In depositing the stainless steel weld metal, the first layer must be sufficiently high in alloy content to avoid cracking as a result of normal dilution by the carbon steel base metal. A stringer-bead technique should be employed, taking care to hold penetration to a minimum. If the proper weld-metal composition is not achieved after the second layer has been deposited, a



The joint is prepared by beveling side A and removing a portion of the stainless steel cladding from side B to a minimum width of ⅜ in. from each side of the joint, and the joint is fitted up in position for welding; use of a root gap (not shown) is permissible (a and b, methods A and B); carbon steel filler metal is deposited and the root of the weld is ground flush with the underside of the carbon steel plate (c, methods A and B); the area from which cladding was removed is surfaced with at least two layers of stainless steel weld metal (d, method A), or an inlay of wrought stainless steel can be welded in place (d, method B).

Fig. 36. Alternative procedures for joining stainless-clad carbon and low-alloy steel plate involving different techniques for replacing portions of the stainless steel cladding removed before welding the carbon or low-alloy steel side

portion of the second layer should be ground off and additional filler metal should be deposited to obtain the desired composition. Method B, Fig. 36(d), shows an alternative procedure in which the exposed carbon steel weld on side B is covered by welding an inlay of wrought stainless steel to the edges of the cladding.



The clad plates are beveled and fitted up (a and b, butt and corner joints); stainless steel filler metal is deposited from the carbon steel side (c, butt and corner joints); the root of the weld is cleaned and gouged, if necessary, before depositing stainless weld metal from the stainless steel side (d, butt and corner joints).

Fig. 37. Procedures for welding V-groove butt and corner joints in stainless-clad carbon or low-alloy steel plate, using stainless steel filler metal exclusively

The most common method of joining stainless-steel-clad carbon or low-alloy steel plate with a weld that consists entirely of stainless steel is shown in Fig. 37. This method is most frequently used for joining thin sections of stainless-clad plate.

The same basic welding procedure is followed for both the butt and corner joints shown in Fig. 37. After the plate has been beveled and fitted up for welding, a stainless steel weld is deposited from the carbon steel side, using a filler metal sufficiently high in alloy content to minimize difficulties (such as cracking) resulting from weld dilution and joint restraint. Types 309 and 312 filler metals are suitable for this application.

After the stainless steel weld has been deposited from the carbon steel side (Fig. 37c), the root of the weld is cleaned by brushing, chipping or grinding, as required, and one or more layers of stainless steel filler metal are deposited (Fig. 37d). The filler-metal composition should correspond to that normally employed to weld the type of stainless steel used for the cladding. If the cladding is type 304, the final layer of weld metal should be type 308. If the cladding is type 316, it may be necessary to back-gouge before deposition of the final weld-metal layers to ensure that the proper weld-metal composition is obtained at the surface of the weld.

Welding of Castings

Table 15 lists designations for 12 corrosion-resistant steel casting alloys covered by ASTM A296, and relates these alloys to the AISI types of wrought stainless steels that are approximately equivalent to the respective casting alloys in composition. From Table 15 it is evident that corrosion-resistant steel castings are produced in conventional austenitic, ferritic and martensitic grades, as well as in some special grades such as extra-low-carbon (CF-3) and columbium-stabilized (CF-8C).

Commercial uses for the casting alloys are closely related to the applications for their wrought counterparts; principally for service in corrosive environments at temperatures no higher than 1200 F. Valves, piping and vessels in chemical-processing plants are typical applications for welded corrosion-resistant steel castings, welded either to other castings (to produce composite castings) or to wrought components. A major field of application is welding for repair of defective castings in the foundry.

Welding Processes. All of the arc welding processes and electroslag welding are used for welding of corrosion-resistant steel castings. For information on the individual processes, see the articles on Shielded Metal-Arc Welding, Gas Metal-Arc Welding, and so on, in this volume.

For the repair of casting defects in the foundry, shielded metal-arc welding is most often used, largely because of its versatility. For welding to produce composite castings or to join sections of cast pipe, one of the arc processes capable of higher deposition rates, such as gas metal-arc or submerged-arc welding, is more often used. For joining large castings with relatively thick walls (generally, thicker than 1 in.), electroslag welding is often used because it costs less than arc welding for thick sections.

Welding Procedures. With other conditions being equal, whether a given part is wrought or cast has little or no effect on procedures and filler metals used for welding. (For instance, if a part of specific size and shape was made from type 410 stainless steel for which a welding procedure was established, changing to a CA-15 casting would not require a change of filler metal or procedure.) However, as-cast surfaces require more elaborate preparation for welding; foreign materials such as oxides and sand inclusions must be removed before as-cast surfaces can be satisfactorily welded.

Filler metals, joint design and operating conditions for welding wrought stainless steels, but also applicable to their cast counterparts, are given in Tables 1, 4, 5, 6, 7, 8, 9, 10, 12, 13 and 14 in this article.

The discussion in this article on causes and prevention of undesirable conditions, such as carbide precipitation in the welded joints of certain austenitic grades of wrought stainless steels, is generally applicable also to the corrosion-resistant steel castings.

Table 15. Some Corrosion-Resistant Steel Casting Alloys, and Wrought Stainless Steels of Approximately Equivalent Compositions

Casting alloy (ASTM A296)	Wrought alloy (AISI type)	Casting alloy (ASTM A296)	Wrought alloy (AISI type)

CF-8	304	CK-20	310

Arc Welding of Heat-Resisting Alloys

*By the ASM Committee on Welding of Heat-Resisting Alloys**

HEAT-RESISTING ALLOYS considered in this article include nickel-base alloys, iron-nickel-chromium and iron-chromium-nickel alloys, cobalt-base alloys, and refractory metals. The procedures used in welding heat-resisting alloys depend to some extent on the mechanism by which they are strengthened for high-temperature service — primarily solid-solution strengthening or precipitation hardening.

Many of the heat-resisting alloys are susceptible to cracking during welding or during subsequent heat treatment. The severe service conditions to which heat-resisting alloys are exposed make changes in microstructure and properties, as produced by arc welding, of special importance, and make avoidance of cracking imperative.

Nominal compositions of commonly arc welded heat-resisting alloys are given in Table 1.

Welding Processes. Heat-resisting alloys can be welded by all the arc welding processes. Gas tungsten-arc welding is widely used, especially for joining thin sections. In general, shielded metal-arc and gas metal-arc welding are used in joining sections more than 1 in. thick, where the heat input will not adversely affect the weld metal or the base metal. Submerged-arc welding is used to a lesser extent. Example 285 describes the use of submerged-arc welding in joining an Fe-Ni-Cr heat-resisting alloy to an alloy steel.

Argon is generally preferred as the shielding gas for arc welding of heat-resisting alloys because of its low cost and high density, and because of the arc stability and weld uniformity obtainable with it. Argon was used in most of the examples of gas-shielded arc welding described in this article. Helium, because of the higher heat input obtainable with it, is used in mixtures with argon, and alone, in welding thick sections. Small amounts of hydrogen, and less frequently of carbon dioxide, are sometimes added, as in Example 275.

Welding current is typically straight-polarity direct current (dcsp) for gas tungsten-arc welding and reverse-polarity direct current (dcrp) for gas metal-arc welding.

The data in Table 2 are intended to serve as starting points for the establishment of machine settings for gas tungsten-arc welding. These conditions are, in general, suitable for welding nickel-base, Fe-Ni-Cr, Fe-Cr-Ni and cobalt-base alloys, when making butt, corner or T-joints, using an appropriate groove design based on stock thickness and application. An increase in welding current of 10 to 20 amp may be needed for melt-through T-joints. Generally, the interpass temperature should be below 200 F. Oscillation of the welding torch may help to prevent cracking by changing the solidification pattern and may also improve the appearance of the weld.

Edge Preparation. Edges should be squared, aligned properly, and, if necessary, tack welded before welding. Misalignment and misfit cause variation in bead contour and root opening, and stresses in the weld area, which can cause cracking in the welded joint.

Machining is the best way to obtain a good-fitting bevel edge. When sheet or plate more than 0.090 in. thick is sheared, the sheared edge should be ground or machined back an additional 1/32 to 1/16 in., to remove stressed metal, before welding.

Cleaning of Workpieces

The weldability of heat-resisting alloys is markedly affected by the cleanness of the base metal and of the filler metal. Shop dirt (such as paint, grease, and oil), oxide film, and scale are the main surface contaminants. Sulfur and lead in foreign material on the workpiece surface can diffuse into the base metal when it is heated and can result in severe cracking.

Processes for the removal of surface dirt are described in Volume 2 of this Handbook. Grease and oil are removed by commercial solvents and by vapor degreasing. Soaps can be removed by rinsing in hot water. Soluble oils, tallow, fats and fatty acids require a more complex cleaning procedure.

Techniques for removal of tarnish, oxide films, and heavy scale are described in the articles on Cleaning and Finishing of Heat-Resisting Alloys and Cleaning and Finishing of Nickel and Nickel Alloys, beginning on pages 607 and 661, respectively, in Volume 2 of this Handbook.

Dust that has settled on the workpieces after cleaning can be removed by carefully wiping the joint area with clean, lint-free cloths dampened with a solvent such as methyl ethyl ketone. In order to avoid surface contamination of cleaned workpieces, white gloves are used during handling. In some of the examples in this article, carbon tetrachloride was used to wipe the joint area after machining. This should be done only in a well-ventilated shop, because the fumes are highly toxic. In some states, the use of carbon tetrachloride is prohibited.

After welding, all slag must be removed. If slag left on a weldment should become molten during service, severe attack on the metal may occur. With multiple-pass welding, slag must be removed between passes; sometimes, grinding of the weld bead is needed.

Welding Fixtures

Fixtures used in arc welding heat-resisting alloys are generally similar to those used in a similar applications on other metals. Chill bars are often used to cool the weld area rapidly. Backing bars, inserts and facing plates that are in contact with the workpieces on either the root or the face side of the welds should be located so as not to contaminate the weld metal or base metal. These accessories are usually made of copper.

Hold-down bars and backing bars extend the full length of the weld. The backing bars usually contain passages to facilitate inert gas shielding. When grooved backing bars are used, the grooves should be shallow to minimize melt-through and to limit the height of the root reinforcement. Grooves in backing bars should have rounded corners or be elliptical in shape to prevent entrapment of slag.

In the following example, a fixture was used to locate and clamp each piece during tack welding and to provide firm support during the final welding pass.

Example 271. Use of a Shaped Backing Fixture and Clamps To Provide Alignment in Gas Tungsten-Arc Welding of Two Formed Rings (Fig. 1)

Two formed rings were circumferentially butt welded to form an air seal for a compressor stage, as shown in Fig. 1. The thickness of each ring varied, but it was 0.040 in. on each ring at the weld joint.

SPICER (retired), formerly Senior Technical Representative, Huntington Alloy Products Div., International Nickel Co., Inc.; E. G. THOMPSON, Atomics International Div., North American Rockwell Corp.

Some of the examples presented in this article were contributed by members of other Metals Handbook welding committees.

The welding procedure described below was that used for completing Waspaloy rings; rings made of Inconel alloys were also assembled by welding.

The fixture and method of clamping the rings for welding are shown in Fig. 1, detail A. The groove in the backing fixture provided a passageway for the backing gas, which was fed into the groove through a series of small holes, to ensure its being distributed evenly.

The rings were in the solution-treated condition when welded. Surface oxides were removed for a minimum of ½ in. from the joint edges by a 240-grit aluminum oxide wheel mounted on an air grinder, followed by wiping with carbon tetrachloride. The cleaned rings were assembled in the fixture, as shown in Fig. 1, detail A, making certain that the joint line was centered over the backing groove and that joint alignment was within 0.005 in. as determined by dial-indicator measurement. The backing groove was purged with shielding gas before welding began.

The rings were tack welded by the manual gas tungsten-arc process, using 24 welds ⅜ in. long, equally spaced along the joint. A penetration of 0.010 to 0.015 in. was required. After tack welding, the rings were welded in one pass by the automatic gas tungsten-arc process, using high-frequency arc starting, Waspaloy filler metal, and gas shielding from the torch and a trailing shield, and through the backing fixture. After the weld was made, wire feed was stopped and the current was decreased slowly. Shielding-gas flow was maintained until after the weld metal solidified.

The welded assembly was heat treated at 1600 F for 1 hr and at 1400 F for 10 hr. Before and after heat treatment, welds were inspected for surface cracks by fluorescent-penetrant techniques, and for internal cracks by x-ray radiography.

Details of the welding operation are given in the table that accompanies Fig. 1.

In the example that follows, a welding positioner with a table that could be rotated 360° and tilted from a horizontal to a vertical position permitted welding in the flat, or nearly flat, position and rotation of the workpiece.

Example 272. Use of a Tilting, Rotating Welding Positioner for Making Circumferential Welds (Fig. 2)

A 1/16-in.-thick inner band was welded to a ¼-in.-thick section of the outer case of a Waspaloy turbine-shroud ring, as shown in Fig. 2. Two corner-joint welds were made automatically in two passes each, using a fixture that was mounted on the table of a welding positioner. The outer case was clamped to a backing ring and the inner band was held against the outer case by expanding jaws while the first weld was being made (detail B in Fig. 2). The expanding jaws were removed to provide access for the second weld. The workpiece and torch were positioned for each weld as shown in Fig. 2. The welding positioner continuously rotated the workpiece under the torch, which was stationary.

Gas tungsten-arc welding was used. The initial pass for each weld was made without filler metal, and the second pass was made with a 0.032-in.-diam Waspaloy filler-metal wire. The assembly was purged with argon for 5 min before beginning each weld, and argon shielding gas was used at the torch for all passes. Details for making the two welds are summarized in the table that accompanies Fig. 2.

The parts were welded in the solution-treated condition. Welded assemblies were heat treated at 1600 F for 1 hr and at 1400 F for 10 hr.

The J-grooves were machined, and then the grooves and the surfaces adjacent to the weld area on both components were wiped with methyl ethyl ketone. White gloves were used for handling the workpieces after cleaning.

In order to obtain reproducible results, electronic governor controls were used to maintain the proper welding speed and wire-feed rate.

Welding chambers can be used for welding complex assemblies that would be difficult to fixture and protect properly in air. However, unless the chamber is properly designed and constructed, the inert gas in it is likely to be of much poorer quality, and less effective in shielding the work metal, than the inert gas contained in the conventional flowing shields, because of leakage of air and water vapor.

Table 1. Nominal Composition of Heat-Resisting Alloys

Alloy	Composition
Solid-Solution Nickel-Base Alloys	
Hastelloy B	0.05 C, 28 Mo, 5 Fe, 0.4 V, rem Ni
Hastelloy C	0.08 C, 15 Cr, 16 Mo, 6 Fe, 5 W, rem Ni

Nickel-Base Heat-Resisting Alloys

Some nickel-base heat-resisting alloys (see Table 1) are solid-solution strengthened, and others are strengthened by the precipitation of a second phase from a supersaturated solid solution. Many of the solid-solution nickel-base alloys, including Inconel 600, Hastelloy B and Hastelloy C, are widely used in applications requiring resistance to corrosion at temperatures ranging from cryogenic to 800 F or higher; these alloys, therefore, are classified as being *both* heat-resisting and corrosion-resisting. Welding of other corrosion-resisting nickel-base alloys, including nickel-copper alloys, is discussed in the article on Arc Welding of Nickel Alloys, which begins on page 366 in this volume.

The nickel-base alloys are commonly welded by the gas tungsten-arc and shielded metal-arc processes. Gas metal-arc welding is used for joining sections more than ⅜ in. thick. Grooves in thick metal require a large amount of filler metal, and because of their bulk, such sections can withstand the heat input characteristic of the gas metal-arc process. Frequently, a root pass is made by gas tungsten-arc welding, and the filler passes by gas metal-arc welding. Submerged-arc welding is used, but the welding flux must be carefully selected to obtain adequate protection, and the welding conditions chosen must avoid excessive heat input. When welding metal more than 3 in. thick, shrinkage stresses will decrease ductility slightly, and a postweld stress-relieving treatment may be necessary.

Precipitation-hardenable alloys are susceptible to cracking in the weld metal or in the heat-affected zone unless they are properly heat treated before and after welding. The alloys containing columbium and tantalum, such as alloy 718, have a relatively slow hardening response and can be welded without undergoing spontaneous hardening during heating and cooling.

The nickel-chromium and nickel-molybdenum solid-solution alloys are readily welded in the annealed condition. No heat treatment is needed after welding to improve corrosion resistance, and generally the alloys do not become embrittled after long exposure at temperatures up to about 1500 F.

Table 2 lists general conditions for gas tungsten-arc welding of heat-resisting nickel-base alloys.

Table 2. Conditions for Gas Tungsten-Arc Welding of Heat-Resisting Alloys(a)

Base-metal thickness, in.	Diameter of filler metal, in.(b)	Electrode diameter, in.(c)	Shielding gas: Gas	Shielding gas: Flow rate, cfh	Welding current, amp(d)
0.010	0.020	0.040 to 0.060	Argon	12 to 15	10 to 15

(a) The data in this table are intended to serve as starting points for the establishment of optimum machine settings for welding workpieces on which previous experience is lacking. They are subject to adjustment as necessary to meet the special requirements of individual applications. These data are the result of experience in welding Hastelloy alloys B, C, C276, F, N and X; Inconel alloys 600, 625, 718, 722 and X-750; nickel-base alloy René 41; iron-base alloys A-286 and N-155; and cobalt-base alloys HS-25 (L-605) and HS-188. Torch-nozzle diameter was $\frac{7}{16}$ in.; nozzle had a gas lens. (b) Minimum wire diameters, where applicable. (c) EWTh-2 electrodes, tapered to a point. (d) Straight-polarity direct current with high-frequency arc starting. An increase of 10 to 20 amp may be needed for melt-through T-joints.

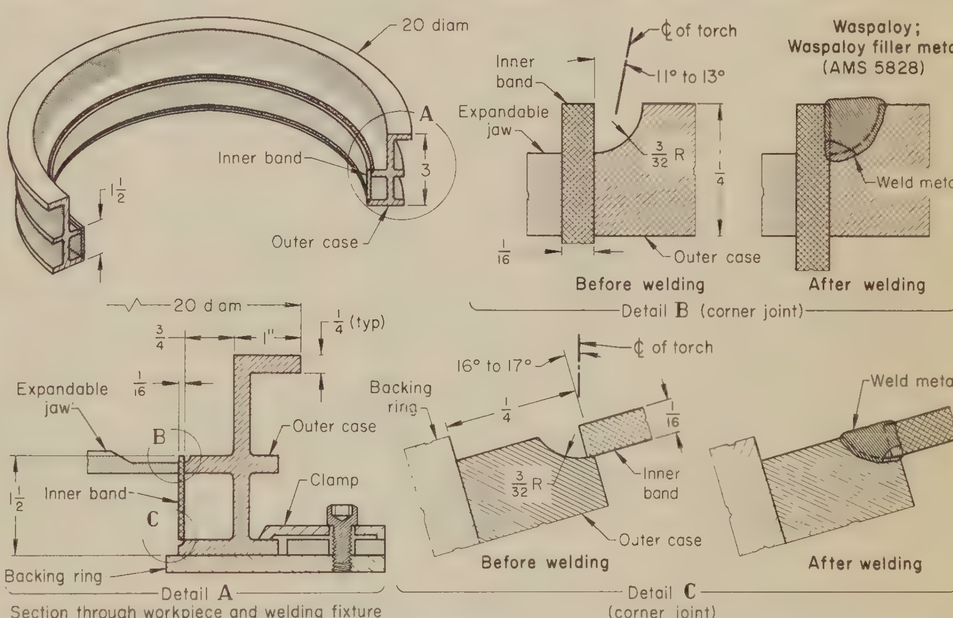
Joint Design for Nickel-Base Alloys

The same joint designs are used for both gas tungsten-arc and shielded metal-arc welding. Joint design for gas metal-arc welding requires special consideration, as discussed in the section on Gas Metal-Arc Welding of Nickel-Base Alloys, page 285. Unless it has been proven satisfactory by experience, a joint design that has been developed for another metal should not be used for nickel-base alloys.

Table 3 shows joint designs used in welding nickel-base heat-resisting alloys, and gives the sizes of grooves or welds in different metal thicknesses and the approximate amount of metal deposited. Nickel-base alloy weld metal does not flow as readily as steel weld metal does. Therefore, the molten metal will not penetrate as deeply as steel weld metal, and so the joints must be more open, to permit electrode or filler-metal manipulation and the placement of weld metal. Excessive puddling and heat input have a detrimental effect, inasmuch as loss of residual deoxidizers may result.

Preweld and Postweld Heat and Mechanical Treatments for Nickel-Base Alloys

The solid-solution (non-age-hardenable) alloys are welded in the annealed condition, sometimes after slight cold working. The precipitation-hardenable alloys usually are welded in the solution-treated condition, although test data indicate that welding René 41 in



Welding Conditions	
Joint type	Corner
Weld type	Single-J groove
Welding process	Automatic gas tungsten-arc
Power supply	200 to 300-amp transformer-rectifier, with drooping voltage
Torch	Water cooled
Electrode	$\frac{3}{32}$-in.-diam EWTh-2, tapered to 0.025-in. diameter
Electrode extension	$\frac{5}{16}$ in. max
Arc starting	High frequency
Filler metal:	
First pass	None
Second pass	0.032-in.-diam Waspaloy
Filler-metal feed	Adjustable at constant speed
Filler-metal speed	16 ipm
Shielding gas:	
At torch	Argon, at 30 to 35 cfh
On fixture	Argon, at 40 cfh; purge 5 min before welding
Edge preparation	Machine grooves in outer case; wipe both parts with methyl ethyl ketone

Corner Joint Shown in Detail B	
Current:	
First pass	100 to 105 amp, dcsp
Second pass	140 to 150 amp, dcsp

the overaged condition can help prevent strain-age cracking. If a high degree of deformation should occur during preweld forming, or if the alloy has a high work-hardening rate, process annealing on the formed workpieces, before welding, may be required. Usually, preheating of nickel-base heat-resisting alloys is neither needed nor recommended. A postweld thermal or mechanical treatment usually is needed, especially for the precipitation-hardenable alloys, to redistribute and relieve residual stresses resulting from weld-shrinkage strains. Often, both treatments are used on the same weldment.

Mechanical stress-relieving treatments include tensile stretching, roll planishing, and peening. Control of these treatments is erratic, and complete relief of residual stresses by mechanical techniques is difficult to accomplish. Mechanical stress relieving is most effective in redistributing residual stresses in a single direction. Effective stress relieving by roll planishing requires that the weld shape be uniform.

Heat treatments produce more uniform reductions in residual-stress patterns than do mechanical treatments and are preferred for stress relief. They can be combined with hot sizing, where required, to produce parts to close dimensional tolerances.

Weldments made of solid-solution alloys can be used as-welded or after stress relieving, depending on the alloy and application. Stress relieving in the range from 800 to 1600 F, depending on the alloy and its condition, can be used to reduce or remove stresses in work-hardened solid-solution alloys without producing a recrystallized grain structure, and a low-temperature stress-equalizing heat treatment (600 to 800 F) can be used to redistribute stresses without appreciably decreasing the mechanical strength produced by the previous cold working.

Precipitation-hardenable alloys are given a solution treatment after welding to relieve residual stresses, and then they are hardened by an aging heat treatment. If the normal aging time or temperature is exceeded, overaging will occur; it can result in loss of strength and increase in ductility.

In the following example, excessive distortion of the weldment was encountered during postweld solution treating, and the heat treatment was modified so that acceptable parts could be produced.

Example 273. Modification of Postweld Heat Treatment To Minimize Distortion (Fig. 3)

The gas-turbine shroud shown in Fig. 3 required two circumferential welds to join an outer case, a front case, and a flange, all made of Waspaloy. Single-pass welds were made by automatic gas tungsten-arc welding.

Waspaloy is susceptible to strain-age cracking. This type of failure can occur in service in the temperature range of 1200 to 1500 F. Weldment components, therefore, usually are solution treated prior to welding and, after welding, are again solution treated at about 1975 F for 1 hr and then aged at 1400 F for 16 hr. In this instance, excessive distortion was encountered during solution treatment, and therefore a modified heat treatment was developed that consisted in solution treating the components between rough and finish machining (prior to welding) and aging the weldments at 1600 F for 1 hr and at 1400 F for 10 hr.

Joint areas were cleaned by wiping with methyl ethyl ketone, and parts were handled with white gloves. The assembly was held together in a fixture with an expandable inside weld-backing ring that forced the assembly against an outside ring, as shown in Fig. 3. The inside ring was relieved at the roots of the joints for backing-gas flow, and the assembly was purged with argon gas for 5 min before welding was started. Welding details are summarized in the table that accompanies Fig. 3.

Welds were inspected for surface cracks before and after heat treatment by fluorescent-penetrant techniques, and for internal cracks by x-ray radiography.

Another unconventional heat treatment, which involved stress relieving René 41 weldments at 1000 F before age hardening, in order to prevent strain-age cracking, was successfully applied to test parts in an evaluation program. The results, which do not include service experience, are described in the example that follows.

Example 274. Stress Relieving a René 41 Weldment To Prevent Strain-Age Cracking (Fig. 4)

The wing-panel subassembly shown in Fig. 4 was made by joining a 0.020-in.-thick corrugated sheet, which had been cold worked by forming, and two 0.080-in.-thick side caps. The metal had been purchased in the solution-treated condition (AMS 5545, solution treated at 1975 ± 25 F) and was used as-received. The caps were manually gas tungsten-arc welded to the corrugated sheet, using the melt-through technique, a weld fillet being formed on both sides of the corrugated sheet. Filler metal was Hastelloy W (ERNiMo-6).

The weldment was stress relieved at 1000 F for 5 hr, furnace cooled to 500 to 600 F, air cooled to room temperature, age hardened at 1400 F for 16 hr, and air cooled. The 1000 F stress relief was advantageous because 25 to 35% of the contraction (normally, 0.001 in. per inch) expected during age hardening was achieved with little hardening. Thus, the assembly was able to deform plastically without cracking. This was especially significant because cold worked components and solution-treated components, with different rates of contraction, were joined. Also, the assembly

could be straightened after stress relieving and before age hardening, if necessary.

Although stress relieving René 41 at 1000 F before aging is unusual, because residual stresses are not substantially reduced at this temperature, the 1000 F heat treatment prevented strain-age cracks from occurring in the base metal. Also, the use of a solid-solution filler metal (Hastelloy W) instead of a precipitation-hardenable filler metal reduced strain-age cracking in the weld.

The welds were inspected visually and by the dye-penetrant method. A summary of the welding conditions is given in the table that accompanies Fig. 4.

Copper chill and hold-down bars, machined to the contour of the corrugations, were used for welding the cap to the sheet.

Overaging René 41. Recent tests conducted with circular-patch test specimens made of René 41 plate (0.60 in. thick) have indicated that this alloy is more resistant to strain-age cracking when preweld solution heat treated at 1975 F and overaged than when solution heat treated at 2150 F or when mill annealed at 1950 F and then aged at 1400 F for 16 hr. The preweld overaging treatment consisted of holding at progressively lower temperatures as follows:

1. Solution treat at 1975 F for ½ hr, cool at 3 to 8 F per minute to 1800 F
2. Hold at 1800 F for 4 hr, cool at 3 to 8 F per minute to 1600 F
3. Hold at 1600 F for 4 hr, cool at 3 to 8 F per minute to 1400 F
4. Hold at 1400 F for 16 hr, air cool to room temperature.

An alternative overaging treatment was simply to cool slowly (50 to 100 F per hour) from the 1975 F solution treating temperature. Although ductility was decreased slightly, the tensile and rupture strengths of René 41 were completely recovered by the conventional solution and aging heat treatment after welding.

Gas Tungsten-Arc Welding of Nickel-Base Alloys

Nickel-base heat-resisting alloys are readily weldable by the gas tungsten-arc process. Thin sections of aluminum-containing, precipitation-hardenable alloys are frequently joined without filler metal. The addition of filler metal is usually recommended for solid-solution alloys.

Straight-polarity direct current is recommended for both manual and machine gas tungsten-arc welding. The welding arc is started by a high-frequency current. An extension on the workpiece, which is machined off before the weldment is put into service, is frequently used to assure full-penetration welds and to minimize cracks in the weld metal caused by starts and stops. Heat input is kept as low as possible, to minimize the heat-affected zone. General conditions for gas tungsten-arc welding of nickel-base alloys are summarized in Table 2; specific conditions for welding three nickel-base alloys — Hastelloy X, Inconel 600 and Waspaloy — are given in Table 4.

For details of the gas tungsten-arc welding process, see the article that begins on page 113 in this volume.

Shielding Gas. Argon, helium, or a mixture of argon and helium is used as shielding gas. Helium produces a hotter arc, and frequently permits use of higher welding speeds. In Table 5, which suggests settings for welding nickel-base alloy 718 using argon and helium shielding, the recommended current is lower for helium, voltage is higher, and wire-feed rate is lower, for the same welding speed.

Welding grade argon and helium should be used; oxygen, carbon dioxide or nitrogen in the shielding gas usually will cause porosity and should not be present. An addition of about 5% hydrogen to argon acts as a reducing agent and is sometimes beneficial when the work metal has not been thoroughly cleaned. However, argon with 5% hydrogen should be used only for first-pass or single-pass welding, because porosity will result if this mixture is used for subsequent passes in multiple-pass welding.

In the following example, weld porosity due to inadequate cleaning was minimized by using an argon-helium-hydrogen shielding-gas mixture.

Example 275. Changing Composition of Shielding Gas To Control Porosity in Welds in Hastelloy C (Fig. 5)

Weld porosity due to inadequate cleaning was a problem in producing 3 to 12-in.-diam welded tubes from Hastelloy C sheet, 0.018 to 0.035 in. thick. A typical tube was 10 in. in diameter and 5 ft long. Tube seams were gas tungsten-arc welded in a seam welding machine that provided accurate joint alignment by clamping the joint edges between hold-down fingers and a backing bar, as shown schematically in Fig. 5(a). A Hastelloy C (ERNiMo-5) filler-metal wire was automatically fed. Originally, pure argon was used for shielding, both at the torch tip and in the backing groove. Torch travel was controlled by a motorized carriage operated by rack-and-pinion drive from a fixed overhead track.

Table 5. Conditions for Automatic Gas Tungsten-Arc Welding of 0.045-In.-Thick Nickel Alloy 718 Based on the Shielding Gas Used

Item	Shielding gas — Argon	Shielding gas — Helium
Current (dcsp), amp	80	40
Voltage, v	8 to 16	16 to 18
Welding speed, ipm	8	6 to 8
Filler-wire diam, in.	0.030-0.035	0.030-0.035
Wire-feed rate, ipm	12 to 15	8 to 9
Torch gas flow, cfh	20 to 24	20
Backing gas flow, cfh	4	4

Before welding, the joint edges were cleaned mechanically and chemically, but because the metal was resistant to chemical cleaning, joints still contained foreign material, which caused weld porosity. An investigation was carried out to determine if porosity could be avoided by using a different shielding gas. For the investigation, Hastelloy C test pieces were sheared from 0.026-in.-thick sheet and put through a slightly subnormal cleaning procedure to ensure that the test pieces would be susceptible to porosity. Then the test pieces were welded by the original procedure, except for the shielding gas used.

Shielding gas of high purity, premixed to various compositions, was purchased in tanks. On the assumption that a surface layer of oxide had been responsible for the porosity, a small amount of hydrogen, a reducing agent, was added to the shielding gas. In addition, helium was added to provide a hotter arc. An initial test using 98% argon, 2% hydrogen had given promising results and so a 5% hydrogen addition was tried with the argon and the various argon-helium mixtures. As helium content was increased from 0 to 45%, the porosity markedly decreased, until at 50% argon, 45% helium, 5% hydrogen, it was virtually eliminated (Fig. 5b). However, at this high helium concentration, the formability of the weld began to deteriorate (Fig. 5c).

The effect of welding speed was also investigated for the 50% argon, 45% helium, 5% hydrogen gas (Fig. 5d). Increasing welding speed from 10 to 30 in. per minute caused the porosity content of the weld to increase sharply. It appeared that by welding too rapidly, gas was trapped in the more rapidly solidifying welds.

The welds were examined by x-ray radiography and the number of pores was counted and recorded. Porosity (Fig. 5b and 5d) was expressed as the average number of pores per inch of weld metal in a minimum of 80 in. of weld.

Details of the welding conditions used in the investigation are summarized in the table that accompanies Fig. 5. As a result of the investigation, a shielding gas consisting of 60% argon, 35% helium and 5% hydrogen and a welding speed of 10 in. per minute were used for production welding.

Filler metals used with nickel-base heat-resisting alloys usually have the same general composition as the alloy

being welded. Because of the high arc currents and high welding temperatures, the compositions of the filler metals are often modified to resist porosity and hot cracking of the weld metal. Tack welding and root-pass welding frequently are done without filler metal. Table 6 gives the compositions of filler metals commonly used in gas tungsten-arc welding; several of these filler metals are used for welding metals other than nickel-base alloys.

For welding the precipitation-hardenable nickel-base alloys, either a precipitation-hardenable filler metal or a solid-solution filler metal may be used, depending on service requirements. Maximum mechanical properties, particularly in thick metal, are obtained when precipitation-hardenable filler metals are used, because most of the weld deposit is composed of filler metal. The solid-solution filler metals produce welds with lower mechanical properties, but they can be used where maximum strength is not needed. For example, when welding alloy 718 using filler metal René 41, alloy 718, GMR-235, or Hastelloy W (ERNiMo-6), weld specimens using the first three filler metals (precipitation-hardenable) gave tensile properties similar to those of the base metal, but Hastelloy W filler metal (solid-solution) gave weld tensile properties about 30% lower than those of the base metal.

Filler metal of the ERNiCr-3 classification (Table 6) is used for welding nickel-chromium-iron alloys to each other and to dissimilar metals, for high-temperature service and for nuclear applications.

Filler metal of the ERNiCrFe-5 classification is used to weld the nickel-chromium-iron alloys and Inconel 600. The columbium-plus-tantalum content minimizes hot cracking in the weld when high stress is developed, as when welding thick metal.

Filler metal of the ERNiCrFe-6 classification is used for welding some combinations of dissimilar metals. The deposited weld metal will respond to age-hardening treatments. When age-hardening response is not needed, ERNiCr-3 filler metal should be used.

Filler metal ERNiCrFe-7 contains aluminum, titanium, columbium and tantalum, and is used for welding the precipitation-hardenable alloys. The deposited filler metal will respond to aging treatments. The weldment must be stress relieved prior to aging.

Filler metals of the ERNiMo-4 and ERNiMo-5 classifications are intended for welding the nickel-chromium-molybdenum alloys.

Filler metal of the ERNiMo-6 classification has essentially the same composition as filler metal of the ERNiMo-4 classification, with 5% additional chromium. It is used for welding dissimilar metals, iron-nickel-chromium alloys, cobalt-base alloys, and nickel-base alloys. It is not precipitation hardenable, but it can be used to weld precipitation-hardenable alloys when high strength is not needed.

The filler metals listed in Table 6 by trade name have no applicable AWS classifications, but most have AMS designations, which are given in the table. These filler metals are primarily used for welding alloys of the same composition, although they are sometimes used for welding alloys of a different composition. For instance, René 41 and GMR-235 filler metals have been used to weld alloy 718.

(d) Effect of welding speed on porosity, using a mixture consisting of 50% argon, 45% helium, and 5% hydrogen as the shielding gas.

Fig. 5. Automatic welding of Hastelloy C tubing, and test results that prompted a change in shielding gas from pure argon to 60% argon, 35% helium, 5% hydrogen, using a welding speed of 10 in. per minute (Example 275)

Joint Design. All of the joints shown in Table 3 are weldable by the gas tungsten-arc process. When no filler metal is used, the sections to be joined must be held tightly together (zero root opening) to promote proper fusion. Table 3 gives the recommended groove dimensions for joints of each type and the amount of filler metal needed. Because nickel-base alloys have lower thermal conductivity than steel, when V, U or J-groove design is used, a slightly larger bevel angle than would be needed for steel is employed to ensure complete penetration. When welding nickel-chromium-iron alloys, V-grooves should be beveled to a 75° to 80° groove angle; U-grooves are beveled to a 30° groove angle, with a 3/16 to 5/16-in. radius. A J-groove should have a 15° bevel angle with a radius of at least 3/8 in.; a 1/2-in. radius is preferred. T-joints between members of different thickness should have bevel or J-grooves. When welding the nickel-chromium-molybdenum alloys, V-grooves are beveled to a groove angle of 60°; root opening is 1/16 to 3/32 in. for 1/4-in.-thick metal and 3/32 to 1/8 in. for 1/2-in.-thick metal.

A square-groove butt joint in metal up to 1/8 in. thick can be made by welding on one side only, by using the proper root opening to provide full penetration. A backing strip usually is needed to produce good back reinforcement. Although a square-groove butt joint can be made in metal up to 1/4 in. thick provided that a backing weld is used, metal thicker than 0.125 in. should preferably be beveled and welded from both sides. When this is not practical, the root opening should be increased and a backing strip should be used to ensure full penetration. When butt welding two pieces of different thickness, the heavier section should be machined to the thickness of the thinner section at the joint for ease of welding and for better stress distribution.

Nonuniform penetration can result in undesirable crevices and voids in the underside of the joint, and can create stress raisers that act as focal points for mechanical failure in service.

When pipe or tubing is used to carry corrosive materials, backing rings should be avoided if they cannot be removed after welding. Crevices between the backing ring and the tube are highly susceptible to stress corrosion, which may cause root cracking.

When a product made of a precipitation-hardenable nickel-base alloy cannot be heat treated after welding (because of size or shape), the following technique can be employed. Connecting pieces made of a solid-solution alloy, or one that is unaffected by the welding heat, are welded on the joint side of each component of the product, and the components plus connecting pieces are given an aging heat treatment. Welding of the final product is done at the connecting pieces. The composition and location of the connecting pieces must

be carefully selected so that welds are made in noncritical locations and so that service performance of the weldment is not adversely affected.

Corner and lap joints should be avoided if service temperatures are high or if service conditions involve thermal or mechanical cycling. When corner joints are used, a full-thickness weld must be made, such as that shown in Table 3. Usually, a fillet weld on the root side will also be required.

Joint design often affects selection of welding process and procedure. For example, when joining thin-wall tubes to tube sheets and tubes to flanged connections, and when welding bellows joints of various types, differential melting, caused by the varying heat-transfer capability of different base-metal thicknesses, may require special welding techniques. Sometimes, differential melting can be prevented by machining the thicker member to the same thickness as that of the thinner member or by suitable preheating of the thicker member. Directing the heat of welding to the thicker member is also beneficial. When these methods cannot be applied, a combination welding procedure may be successful, as in the example that follows.

Example 276. Use of Resistance Seam Welding Together With Gas Tungsten-Arc Welding To Produce a Leaktight Bellows Joint (Fig. 6)

A 10-in.-ID bellows assembly for a fuel duct for a rocket motor, shown in Fig. 6, consisted of a straight section of a 0.020-in.-thick bellows wall sandwiched between two 0.040-in.-thick rings, all made from alloy 718. A high-reliability seal weld was required. Originally, the joint was gas tungsten-arc welded, as follows: The acid-cleaned assembly was mounted on a rotating turntable and welded with 0.035-in.-diam alloy 718 (AMS 5832) filler metal under argon shielding gas. When the joint was tested hydrostatically under an internal pressure of 160 psi, the joint did not leak, but when it was tested with a helium mass spectrometer under an internal vacuum, significant leakage was detected.

After considerable investigation, it was determined that during welding the bellows wall melted back faster than the rings, so that weld metal was deposited at the edges of the rings only, resulting in a void that provided a leak path between the rings and the unintegrated surfaces of the bellows (see "After welding" view in detail A, Original method, in Fig. 6). One small void was enough to cause a leak.

The problem was solved by resistance seam welding and gas tungsten-arc welding the joint. The joint was first resistance seam welded (see Operation 1, Improved method, in Fig. 6) and then machined back to the edge of the seam weld. A gas tungsten-arc edge-flange weld was deposited as before (see Operation 2, Improved method, in Fig. 6). The completed combination weld was gastight under both methods of testing.

Conditions for gas tungsten-arc welding are summarized in the table with Fig. 6. Conditions for resistance seam welding are given in Example 386, in the article on Resistance Seam Welding.

Welding Techniques. When filler metal is used, the hot end of the wire must be kept under the shielding gas, and wire diameter should be no larger than work-metal thickness. The molten weld puddle must be kept as quiet as possible; otherwise, the deoxidizing elements will burn out.

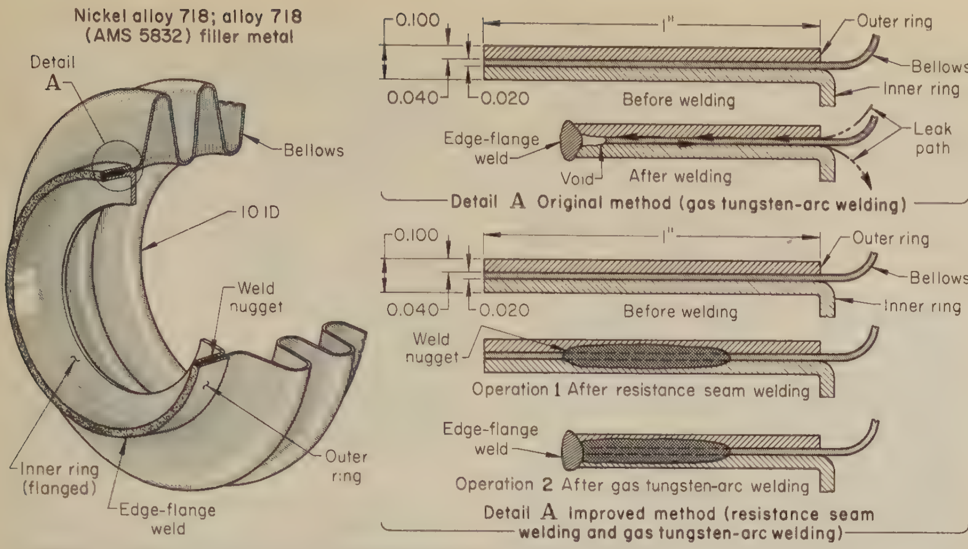
To ensure a sound weld, the arc must be maintained at the shortest possible length. When no filler metal is added, arc length should not exceed 0.05 in., and preferably should be 0.02 to 0.03 in. When filler metal is added, the arc will be longer, but it should be as short as possible, consistent with filler-metal diameter.

A greater-than-normal electrode extension will be needed for fillet welds and for the first few passes on heavy sections. Small-diameter filler-metal wires and more stringer passes may be used on welds made in other than the flat position, for adequate control of weld metal. When the back sides of butt welds do not show adequate penetration, they should be ground back to sound metal and back beads should be deposited. When possible, backing gas should be provided when welding the first side.

The following example describes procedures used to produce high-quality welds in a nuclear pressure vessel.

Example 277. Procedure for Making a Full-Penetration Circumferential Weld in Hastelloy X Pipe (Fig. 7)

A 6-in. elbow was manual gas tungsten-arc welded to the swaged end of a pressure vessel as shown in Fig. 7. The assembly, which was made entirely of Hastelloy X, was part



Conditions for Gas Tungsten-Arc Welding(a)

Joint type	Edge
Weld type	Three-member edge flange
Fixture	Rotating positioner
Power supply	300-amp transformer-rectifier
Electrode	0.040-in.-diam EWTh-2
Torch	300 amp, water cooled
Filler metal	0.035-in.-diam Inconel 718
Shielding gas	Argon, at 15 to 18 cfh
Current	50 to 55 amp, dcsp
Voltage	10 to 12 v
Arc starting	High frequency
Arc length	0.040 in. (approx)
Welding speed	60 ipm
Preweld cleaning	Immerse for 15 min in a solution of 30 to 40% HNO_3 and 2 to 5% HF

(a) For details of resistance seam welding, see Example 386, in this volume.

Fig. 6. Bellows joint of a rocket-motor fuel duct, and details showing how leaks occurred after gas tungsten-arc welding and how resistance seam welding together with gas tungsten-arc welding resulted in a leaktight joint (Example 276)

of a helium filter for the gas-cooled loop of a nuclear reactor. Fabrication was done in accordance with the ASME code for nuclear vessels and contract specifications.

The essential procedural conditions for welding are shown in Fig. 7 and described in the table that accompanies Fig. 7. Carefully selected practices were incorporated in the welding procedure to ensure high joint reliability, namely, for preweld cleaning, shielding, weld deposition, heat input control, and quality control.

Preweld Cleaning. Parts were received free of scale and with a bright finish. After the weld grooves had been machined (Fig. 7), the parts were immersed and scrubbed in unused, agitated acetone, and then wiped dry with a clean lint-free white cloth. No wire brushing or sanding was needed.

Shielding. In addition to torch shielding, a low positive-pressure argon flow was required for internal backing, to avoid oxidation at the weld root face and to limit root-face concavity to 3/32 in., as shown in Fig. 7. Before welding, the assembly was evacuated to 230 mm mercury, and then argon gas was introduced to bring the system up to atmospheric pressure. This was repeated five times to guarantee high purity of the argon during welding. Argon flows of 5 cu ft per hour at the root of the weld and 15 cu ft per hour at the torch were maintained during welding.

Positive internal pressure was assured by placing a plate with a ⅛-in.-diam hole over the open end of the elbow, and sealing the joint with tape. As welding advanced, the tape was removed about 3 in. ahead of the weld. Argon of certified welding quality (99.99% purity) was used. Any length of weld made during a cessation of gas flow was removed and rewelded. As an indication of adequate shielding, beads had to appear bright to dull gray after cooling.

Heat Control. To avoid any change in alloy phase distribution, and thus a change in alloy properties, heat input, interpass temperature, and postweld cooling were controlled. Heat input was controlled by depositing thin beads at low amperage. About 100 welding passes were needed to fill the joint. Interpass temperature was not allowed to exceed 150 F, and was measured by temperature-indicating crayons used on the base metal about ⅜ in. from the weld edge. Postweld cooling was assisted by water-cooling coils in which flow of the cooling water was regulated by a thermocouple placed inside the elbow near the weld and connected to a readout meter. When the joint became too warm, the water-cooling coils were activated.

Welding Technique. Arc-length control was important because of the sluggishness of the weld metal. A short arc had to be held at the weld puddle when filler metal was being deposited. High-frequency current was used for arc starting. Arc stops were made by leading the arc out of the groove to base metal, to avoid weld cracking. Slope control was used for regulating the current at the beginning and end of each weld pass. Tungsten electrodes were taper ground to a point and were maintained in a clean condition at all times.

Quality was ensured by: (*a*) procedure and welder qualification tests and other rules imposed by the ASME code for nuclear vessels; (*b*) dye-penetrant testing after the root pass and subsequent passes throughout the welding operation; (*c*) 100% radiographic inspection after the root pass and the final weld pass; (*d*) leak testing of the completed weld, using a helium leak-rate detector. The five joints welded by this procedure were acceptable.

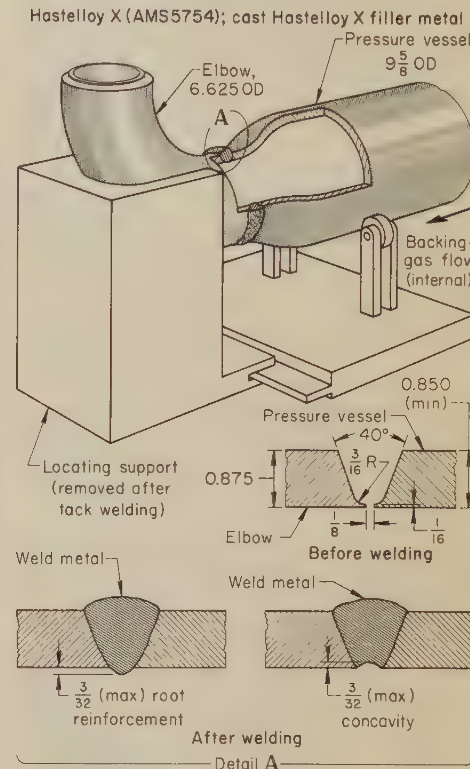
Gas Metal-Arc Welding of Nickel-Base Alloys

The solid-solution-strengthened nickel-base alloys and, with suitable welding procedures, many of the precipitation-hardenable alloys can be joined by gas metal-arc welding. Gas metal-arc welding is best suited to the joining of thick sections (more than about ⅜ in. thick) where high filler-metal deposition rates are desirable. For a description of this process, see the article on Gas Metal-Arc Welding, which begins on page 78.

Spray, globular, and short-circuiting metal transfer can be used. Optimum metal transfer is obtained when operating above the transition from globular to spray transfer. All of these methods employ electrode wire of comparatively small diameter. Incomplete fusion and oxide inclusions are likely to occur when the short-circuiting arc is used. Multiple-pass welds should be made by highly skilled welders only.

Reverse-polarity direct current should be used because the greater heating effect of reverse polarity assists in obtaining the required high melting rate.

Shielding gas for nickel-base heat-resisting alloys is argon or an argon-helium mixture. Gas flow rates range from 25 to 100 cu ft per hour, depending on joint design, type of metal transfer, and welding position. Gener-



Joint type	Butt

Welding process	Manual gas tungsten-arc
Power supply	500-amp constant-voltage transformer-rectifier, with slope control and gas preflow
Electrode	⅛-in.-diam EWTh-2 ground to a point
Torch	300 amp, water cooled; 7/16-in.-diam cup
Electrode extension	3/16 in. (approx)
Filler metal:	
Root pass	1/16-in.-diam cast Hastelloy X
Filler passes	3/32-in.-diam cast Hastelloy X
Shielding gas:	
At torch	Argon(a), at 15 cfh
Backing gas	Argon, at 5 cfh
Welding position	Horizontal-rolled pipe
Fixtures	Fit-up jig; turning rolls
Current	125 to 190 amp, dcsp (all passes)
Voltage	30 v
Interpass temperature	150 F max
Arc length	1/32 in. (approx)
Arc starting	High frequency(b)
Number of passes	100 (approx)
Travel speed	1 ipm
Preheat and postheat	None

(a) Welding grade, 99.997% pure. (b) Welding was terminated by leading the arc out of the groove to base metal. Slope control was used at beginning and end of each pass.

Fig. 7. Welding an elbow to a pressure vessel for a nuclear-reactor application, showing positioning of vessel for welding, joint design, and maximum root reinforcement and concavity (Example 277)

ally, flow rate is about 50 cu ft per hour. As the percentage of helium is increased, gas flow rate must be increased to give adequate protection.

Joint designs recommended for gas metal-arc welding are shown in Table 3. For the U-groove designs using globular or spray metal transfer, the root radius should be decreased by about 50% and the bevel angle should be doubled, compared with those shown in Table 3. When using a short-circuiting arc, the U-groove designs shown in Table 3 can be used without change.

Welding Techniques. Best results are obtained when the electrode holder is positioned at about 90° to the joint. Some inclination (up to about 15°) is permissible to permit a better view of the work, but excessive inclination can draw the surrounding atmosphere into the shielding gas, and porous or heavily oxidized welds will result.

Arc length is important. Weld spatter will occur if the arc is too short, and loss of control if the arc is too long.

The manipulation and electrode-holder angle used with pulsed-arc welding are similar to those used with shielded metal-arc welding. A slight pause at the limit of the weave is required in order to avoid an undercut.

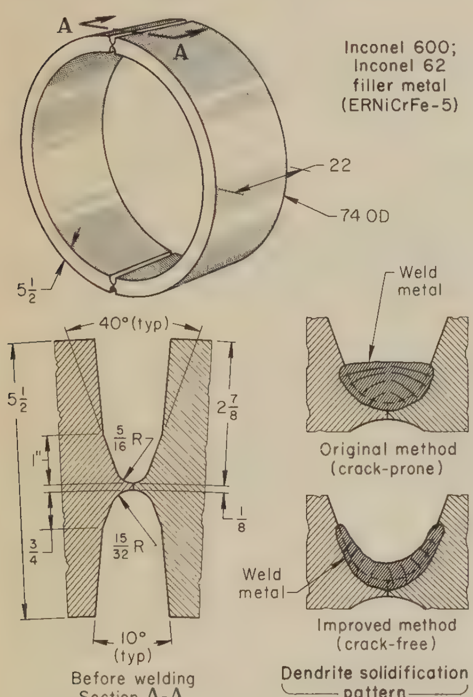
Electrode wire compositions for gas metal-arc welding are the same as those recommended for filler metals for gas tungsten-arc welding (Table 6). With globular and spray transfer, 0.035, 0.045 or 0.062-in.-diam wire is used. The short-circuiting arc generally requires wire 0.045 in. or less in diameter.

Production Examples. In the following example, thin weld beads covering the entire width of the groove were used to produce a crack-free weld. Because of the metal thickness, the design of the double-U groove was modified from that shown in Table 3.

Example 278. Prevention of Cracking in a Thick-Wall Cylinder by Using a Weaving Bead-Deposition Technique (Fig. 8)

Base-metal and weld-metal cracking were encountered in gas metal-arc welding of large 5½-in.-wall cylinders made of Inconel 600, because of hot shortness of the alloy and the solidification pattern produced by the welding technique (Original method, Fig. 8). By changing to a weave-bead technique, which produced a relatively wide, thin deposit, the direction of dendrite solidification was improved and heat concentration was decreased, resulting in crack-free base metal and welds. In deep, wide grooves, such as those shown in Fig. 8, section A-A, the amount of electrode holder oscillation and the travel speed were varied from layer to layer through the thickness of the groove, in order to produce optimum results.

Some welding conditions are given in the table that accompanies Fig. 8. With the aid of a skilled operator, the welds were produced by semiautomatic gas metal-arc welding.



Welding Conditions for Improved Method

Joint type	Butt
Weld type	Double-U groove
Welding process	Semiautomatic gas metal arc
Power supply	400-amp transformer-rectifier, with drooping voltage
Electrode	0.062-in.-diam Inconel 62
Shielding gas	Argon
Deposition rate	11 lb/hr, at 100% arc time

The wide, thin weld deposit produced by the weave-bead technique used in the improved method resulted in a lower heat gradient and a crack-free dendrite solidification pattern.

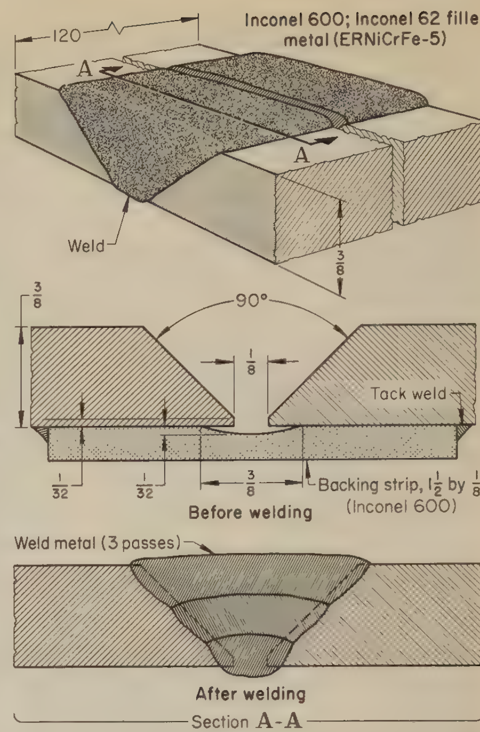
Fig. 8. Thick-wall cylinder that was welded by gas metal-arc welding. Joint design and original and improved solidification patterns. (Example 278)

In the next example, gas tungsten-arc welding was used for tack welding and gas metal-arc welding for root and filler passes in joining ⅜-in.-thick plate. The V-groove had an angle larger than the 80° angle suggested in Table 3.

Example 279. Use of Manual Gas Metal-Arc Welding for Joining ⅜-In.-Thick Plates of Inconel 600 (Fig. 9)

Because only a few welds were to be made and the available automatic equipment could not deposit a weaving bead, manual gas metal-arc welding was used to join 10-ft-long, ⅜-in.-thick plates of Inconel 600. A backing strip of Inconel 600 was temporarily tack welded, by manual gas tungsten-arc welding, to the back of the groove. Tack welds 1 in. long on 6-in. centers helped maintain the ⅛-in. root opening. The conditions for tack welding the backing strip and filling the groove are given in the table with Fig. 9.

A weaving technique was used for gas metal-arc welding to obtain a cellular type of weld solidification pattern (rather than dendritic), and thus to minimize the amount of segregation and provide good corrosion resistance.



Joint type	Butt
Weld type	Single-V groove
Welding process:	
Tack weld	Manual gas tungsten-arc
Groove weld	Manual gas metal-arc

Welding Conditions for Manual Gas Tungsten-Arc Tack Welding

Power supply	Transformer-rectifier, with drooping voltage
Electrode	3/32-in.-diam EWTh-2
Filler metal	0.045-in.-diam Inconel 62
Shielding gas	Argon, at 35 cfh
Welding position	Flat
Current	275 amp, dcsp
Voltage	27 to 29 v
Tack-weld spacing	1 in., on 6-in. centers

Welding Conditions for Manual Gas Metal-Arc Welding

Power supply	Constant-voltage transformer-rectifier
Electrode holder	Manual, water cooled
Electrode wire	0.045-in.-diam Inconel 62
Shielding gas	Argon, at 35 cfh
Current	275 amp, dcrp
Voltage	27 to 29 v
Welding position	Flat
Number of passes	Three
Setup and welding time per plate	1 hr, 50 min

Fig. 9. Plate of ⅜-in.-thick Inconel 600 that was welded by manual gas metal-arc welding, with joint design, backing strip and completed weld. The backing strip, tack welded in place by manual gas tungsten-arc welding, served as a fixture to maintain the root opening. (Example 279)

Shielded Metal-Arc Welding of Nickel-Base Alloys

Shielded metal-arc welding is widely used for joining the solid-solution nickel-base alloys, but is rarely used for joining the precipitation-hardenable alloys. The process is described in the article on Shielded Metal-Arc Welding, pages 1 to 23, this volume.

Reverse-polarity direct current is generally used to obtain optimum mechanical properties.

Joint design (see Table 3) must be such as to permit rapid travel and a minimum of weaving, in order to minimize heat input. Weaving is sometimes desirable, but the amount should not exceed three times the electrode diameter. Overheating can cause hot-short cracking in the weld metal or the base metal, and excessive carbide precipitation at grain boundaries in the heat-affected zone.

Electrodes for shielded metal-arc welding are listed in Table 6. Electrode composition should be similar to that of the base metal with which the electrode is to be used.

Electrodes of the ENiCr-1 classification are used for welding nickel-base alloys where high chromium content of weld metal must be maintained in spite of dilution by iron — for example, in welding nickel-base alloys to steel.

ENiCrFe-2 electrodes are used for welding dissimilar metals and alloys, and for welding the nickel-chromium-

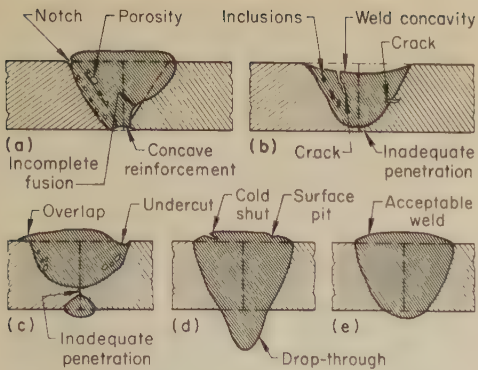


Fig. 10. Typical defects (views a through d) that occur in the arc welding of heat-resisting alloys. View (e) represents a weld with no defects and good reinforcement.

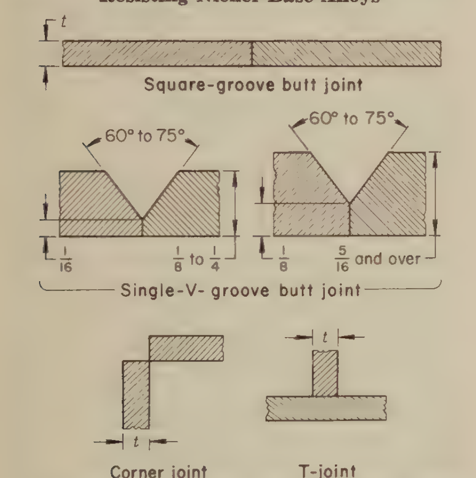
iron alloys to themselves. They are usually preferred for high-temperature applications. ENiCrFe-3 electrodes are not recommended for high-temperature service because they produce a weld metal that has a low stress-rupture strength.

ENiMo electrodes are used for welding the nickel-chromium-molybdenum alloys to themselves and to other metals. These electrodes are normally used only in flat-position welding.

Welding Conditions. Table 7 gives welding conditions for making butt, corner and T-joints in the solid-solution-strengthened nickel-base alloys by shielded metal-arc welding.

Table 7. Conditions for Shielded Metal-Arc Welding of Solid-Solution-Strengthened Heat-Resisting Nickel-Base Alloys



Metal thickness, in.	Number of passes	Current, dcrp(a), amp	Electrode diameter(b), in.
Square-Groove Butt Joints			
1/16	1	40 to 70	3/32
5/64	1	40 to 70	3/32
3/32	2	45 to 75	3/32
Single-V-Groove Butt Joints			
1/8	2	40 to 70	3/32
5/32	2	40 to 70	3/32

Corner Joints and T-Joints(c)			
1/16	1	40 to 70	3/32
5/64	1	40 to 70	3/32
3/32	1	40 to 70	3/32
1/8	1	40 to 70	3/32
5/32	1	40 to 100	3/32 to 1/8
3/16	1	40 to 100	3/32 to 1/8
1/4	2	40 to 130	3/32 to 5/32
3/8	3	40 to 130	3/32 to 5/32
1/2	6	40 to 130	3/32 to 5/32

(a) Current should be within the range recommended by the electrode manufacturer. (b) Where a range is shown, the smaller diameters are used for the first pass in the bottom of the groove, and the larger diameters are used for the final passes. (c) Fillet welds.

Causes and Prevention of Weld Defects

Weld defects such as cracks, porosity, inclusions and incomplete fusion usually are unacceptable in weldments made of heat-resisting alloys. Nondestructive inspection is used on almost all completed weldments; destructive inspection generally is limited to test samples. Various types of leak tests are used on weldments that are to be subjected to pressure in service. Thirteen types of defects that occur in arc welds are shown in Fig. 10.

Porosity. Proper cleaning of the joint area to remove surface contamination, interpass cleaning to remove all slag and oxides, and good welding technique will minimize porosity in welds. In Example 275, porosity that resulted from inability to clean the joint adequately was eliminated by a change in the shielding gas. Porosity is also caused by air or other gas being trapped in the weld.

Cracks and Fissures. Cracks are of three general types:

1. Transverse cracks in the base metal perpendicular to the weld
2. Longitudinal cracks in the base metal parallel to the weld
3. Microcracks and macrocracks in the weld metal.

Cracks of any type and size cannot be tolerated. The use of stringer beads helps to avoid cracking by minimizing heat input and weld stress.

Intergranular cracking or fissuring may be caused by grain-boundary segregation, which is likely to be excessive when the impurity content of the base metal is high and when large grains develop in the microstructure because the work metal is held at high temperature or the shielding is inadequate.

Cracking may occur in poorly designed weldments, such as those in which welded joints cross, creating complex, multiaxial stresses in the corner of the weld and an overlapping weld deposit.

In the following example, cracks in the base metal, perpendicular to the weld metal, were caused by shrinkage stress resulting from excessive weld size and high welding current. Oxide formation on the underside of the weld also was objectionable.

Example 280. Minimizing Cracking and Elimination of Oxide Formation in Welding Waspaloy Tubing (Fig. 11)

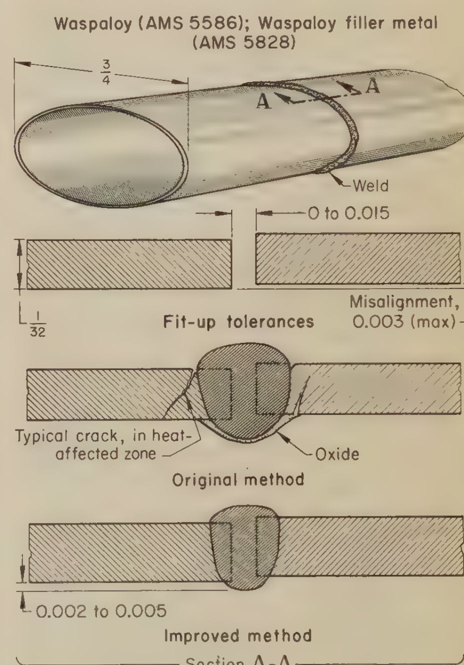
When Waspaloy (AMS 5586) gas-turbine nozzle segments were manual gas tungsten-arc welded, cracking occurred at both root and face sides of the weld in the heat-affected zone, and objectionable oxide formed on the underside of the weld. The parts to be welded were of elliptical shape, the long axis being ¾ in. A typical joint is shown in Fig. 11. Welding had been done carefully, using internal and external argon shielding, and Waspaloy filler metal (AMS 5828). Before welding, joint surfaces were prepared by grinding and cleaned by pressure washing with a detergent solution.

Investigation showed that cracking was directly related to excessive weld size, which had caused high shrinkage stress. A high welding current was responsible for the excessive size of the weld and more root reinforcement than was desirable. Insufficient internal argon pressure also contributed to excessive root reinforcement. Oxidation of the root surface had occurred, air having been pulled into the tube through various openings.

Welding procedures were changed as follows: current was reduced from 30 to 18 amp, and backing gas pressure and purity were increased by increasing the flow rate from 8 to 15 cu ft per hour and by taping all openings except a small exit port. As a result, root reinforcement was reduced to 0.002 to 0.005 in., and the smaller weld deposit and the lower heat input reduced shrinkage stresses so that rejections for cracking were decreased by 80%. Oxidation of the root surface was prevented.

Welding conditions are given in the table that accompanies Fig. 11. After welding, joints were inspected visually and radiographically, and then were tested at 100-psi hydrostatic pressure. Reducing the number of rejects by 80% represented the greatest improvement that had been made in 11 years of welding this heat-resisting alloy.

Strain-age cracking can occur in precipitation-hardenable nickel-base al-



Welding Conditions for the Improved Method

Joint type	Butt
Weld type	Square groove
Welding process	Manual gas tungsten-arc
Power supply	300-amp transformer-rectifier, with gas-and-water time delay, high-frequency and remote current control

Current	18 amp, dcsp
Voltage	15 to 20 v
Arc starting	High frequency
Arc length	1/8 in. (approx)
Number of passes	One

Fig. 11. Waspaloy nozzle segment, and joints welded by original and improved methods, showing size of weld and location of cracks (Example 280)

loys during the initial heat treatment after welding if the metal welded is in the aged condition and at least one area, such as the as-deposited weld metal, is in the solution-treated condition. Cracks that form under these conditions are relatively large, most of a crack being in the base metal. The metal is more likely to crack when an aged part is being repair welded. To minimize strain-age cracking, the following precautions should be taken:

1 Weld in the solution-treated (annealed) condition.
2 Weld with minimum restraint.
3 Do not preheat for welding.
4 Use as little heat input as possible.
5 Accomplish postweld solution heat treatment by heating as rapidly as possible through the aging temperature range.

Test data relating to René 41 exclusively indicate that overaging this alloy prior to welding is useful in avoiding strain-age cracking (see the discussion "Overaging René 41", on page 282).

Cold shuts and surface pits in a weld are possible evidence of a subsurface crack or of porosity that has emerged to the surface. Also, there may be lack of fusion between successive layers of weld metal or between adjacent weld beads. Cold shuts can occur between the weld metal and the base metal when hot metal runs ahead onto a cold metal surface and does not fuse properly. Cold shuts should be removed by grinding because they are possible sources of stress corrosion. Both visual and dye-penetrant inspection are used to locate cold shuts and surface pits.

Voids in welds can occur when air has been trapped in a groove or between two pieces of metal being welded. When welding a lining in a thick-wall vessel or when welding one tube inside another, entrapped air can cause a void if it does not have an easy escape path.

In the following example, a void occurred when two tubes of different wall thickness but the same outside diameter were welded together. The thick-wall tube was machined to fit inside the thin-wall tube.

Example 281. Elimination of a Void at the Root of a Joint (Fig. 12)

The elimination of a small tear caused by a small void at the root of a welded joint presented a problem in making the laminated resistance heating element shown in Fig. 12. A thin-wall Hastelloy X tube of high electrical resistance was welded to a heavier, pure nickel conductor tube. An inner tube, also of pure nickel, was separated from the outer tube by a layer of ceramic insulation, and completed an electrical circuit when joined to the Hastelloy X tube at the heater end. After welding, the weld metal was machined flush and the tube assembly was swaged to shape.

A small tear occurred in the weld metal after swaging, at the point on the circumference where the final joint closure was made. A small void found at the root of the joint was assumed to have weakened the weld sufficiently to cause the small rupture. It was concluded that the void was caused by a small amount of air (under pressure) trapped at the root of the joint. During welding, the air expanded and found an easy escape path through the unwelded portion of the joint, until the closure was made and the escape path was sealed off. There was no alternate route along the tube interlayers because of the close fit of components.

Special equipment	Vacuum pump

Fig. 12. Joint between resistance and conduction segments of a laminated, tubular resistance-heating element, location of void at root of weld, and joint design (Example 281)

To ensure evacuation of the tube, a small vacuum pump was connected to one end of the tube and the other end of the tube was sealed with a rubber stopper, leaving a path for escape of air through the interlayers. Pumping to obtain a low vacuum was carried out before and during welding. The tube was rotated manually during welding. The vacuum hose was long enough to be twisted through 360° of rotation without significant loss of vacuum. Using this procedure, no more tears occurred, and the problem was solved.

After swaging, the welded joints were tested by a helium mass spectrometer. The vacuum was applied to the end of the tube (as in welding) and helium test gas to the outside of the tube at the weld.

Inconel 82 (ERNiCr-3) filler metal was selected for this dissimilar-metal joint because of its strength and excellent ductility in the as-welded condition. Joint design consisted of a 90° single-V groove formed by beveling the 0.015-in.-wall Hastelloy X tube 45° and the 0.042-in.-wall nickel tube 45° to a depth of 0.015 in., which ensured a nickel backing for the joint (Fig. 12). The tubes were machined and washed in acetone before assembly for welding.

Manual gas tungsten-arc welding with argon shielding gas was used to deposit the weld metal in a single pass. No preheat was needed. Details of the welding procedure are summarized in the table that accompanies Fig. 12.

Notches are formed when the edge of the weld reinforcement is thick and does not blend smoothly into the surface of the base metal (see Fig. 10). Frequently, the edge of the reinforcement can be ground or machined to obtain suitable blending, but preferably welding practice should be changed to prevent the condition.

Iron-Nickel-Chromium and Iron-Chromium-Nickel Heat-Resisting Alloys

These iron-base heat-resisting alloys include strain-hardenable, solid-solution-strengthened, and precipitation-hardenable types. All contain appreciable amounts of nickel and chromium, with either one or the other of these elements constituting the principal alloying addition. Other alloying elements are generally added to increase hot strength (molybdenum, tungsten and cobalt), to act as stabilizers (columbium and tantalum), or to promote strengthening (aluminum, titanium, copper and boron).

The usual range of service temperature for these alloys (1200 to 1400 F) limits the selection of filler metals and preheat and postheat treatments for welding. Nominal compositions of the common Fe-Ni-Cr and Fe-Cr-Ni heat-resisting alloys are given in Table 1.

The 16-25-6 and 19-9 DL alloys are strain-hardenable and are easily joined by arc welding. Weld deposits can be made with an austenitic stainless steel filler metal, with a nickel-base alloy filler metal, and with a filler metal of the same composition as the base metal. Generally, preheating and postheating are used.

The solid-solution-strengthened alloys, such as N-155, are easily welded by the shielded metal-arc, gas metal-arc, and gas tungsten-arc processes; however, the heat input should be kept low, and the welds should be cooled rapidly to maintain weld ductility.

Some precipitation-hardenable alloys, such as A-286, are considerably more difficult to weld. These alloys are extremely sensitive to intergranular hot cracking in the weld metal and in the heat-affected zone. Cracking is most likely to occur when aged metal or highly restrained parts are joined. Cracks in root passes or crater cracks can be minimized by using suitable welding procedures and techniques to control heat input during welding. Microcracking (microfissuring) can occur in the weld metal and in the heat-affected zone and must be controlled by proper preweld and postweld heat treatment and by selection of the most suitable filler metal.

Nevertheless, high joint efficiency can be obtained in arc welding A-286 sheet up to 0.094 in. thick. Joints in thicker sections are more difficult to weld and require special techniques such as automatic welding, a single pass, or the use of weld back cooling.

In all the precipitation-hardenable alloys, the aluminum, columbium or titanium may combine with either the iron or the major solid-solution elements to form a low-melting eutectic phase in the grain boundaries. Melting of this grain-boundary phase, often called incipient melting, occurs at the fusion line during welding, and thermal stresses incidental to weld cooling

cause the grains to separate. Grain separation produces gross subsurface cracks or microfissures which are difficult to detect by available nondestructive inspection methods.

Joint design for iron-base heat-resisting alloys depends on the welding process, the application, and the filler metal used. For some applications, joint designs similar to those used for stainless steels are appropriate (see Table 4 in the article on Arc Welding of Stainless Steel); for other applications, joint designs similar to those shown for nickel-base alloys are used (Table 3 here), except that the included angle of V-grooves is usually 60° — for shielded metal-arc welding, it may be from 75° to 90°. Although square-groove butt joints are usually used for metal up to ⅛ in. thick, in Example 282, a zero-root-face V-groove was ground in 0.080-in.-thick A-286 sections. Because nickel-base alloys have low fluidity, wider joint bevels and openings are sometimes required when welding with nickel-base filler metal.

Preweld and Postweld Heat Treatment. The strain-hardenable alloys usually are welded in the hot-cold worked condition. The metal in the heat-affected zone is essentially solution treated by the welding heat, resulting in a decrease in hardness and strength. Although the strain-hardenable alloys frequently are preheated for welding, the preweld heat treatments must be done in a limited temperature range to avoid annealing the metal. This same restriction on heat treating temperature applies to postweld treatments of these alloys.

The solid-solution-strengthened alloys generally are welded in the solution-treated condition and are used without postweld heat treatment. These alloys have a small zone of grain growth adjacent to the weld, but this does not appreciably reduce weld strength.

The precipitation-hardenable alloys are welded in the solution-treated condition because the greater ductility of the base metal in this condition permits some relaxation of the shrinkage stresses associated with welding. Postweld heat treatment generally includes a re-solution treatment and an aging treatment.

Gas Tungsten-Arc Welding of Iron-Nickel-Chromium and Iron-Chromium-Nickel Alloys

Gas tungsten-arc welding is the most widely used process for joining Fe-Ni-Cr and Fe-Cr-Ni heat-resisting alloys, especially in thin sections, because the welding operation can be observed and controlled easily and because of the high percentage of alloy transfer that is characteristic of the process. The minimum heat input that is appropriate to work-metal thickness and to filler-wire diameter should be used, to reduce the temperature gradient in the heat-affected zone. The amount of heat input is particularly important in welding of the precipitation-hardenable alloys, because these alloys are subject to grain-boundary melting.

Straight-polarity direct current is used for welding the Fe-Ni-Cr and Fe-Cr-Ni alloys. Thoriated tungsten electrodes (EWTh-2) are most commonly employed.

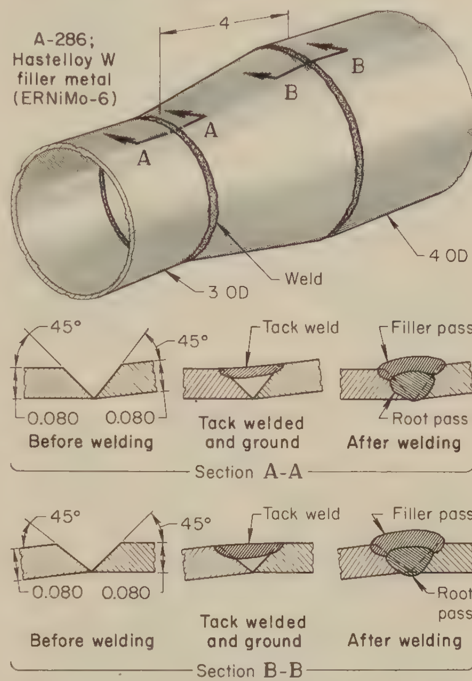
Conditions for manual gas tungsten-arc welding of A-286 and Incoloy 800 are given in Table 8.

Argon shielding gas at a flow rate of 15 to 20 cu ft per hour is used at the torch. Argon is also used for purging before welding and as a backing gas.

If shielding is inadequate, aluminum and titanium, which are present in the precipitation-hardenable alloys, are likely to combine with oxygen in the air to form refractory oxides on the surface of the weld bead being deposited. These oxides may result in oxide inclusions or otherwise interfere in the production of a sound weld. In multiple-pass welding, surface oxides must therefore be removed after each welding pass, preferably by grinding.

Filler metals that will produce weld metal with a composition that is the same as, or similar to, that of the base metal are usually selected. Wire of the same composition as the base metal, austenitic stainless steel wire, and nickel-base alloy wire are used (see Table 6). Because the heat-resisting alloys have relatively high strength at elevated temperature, the solidifying weld metal frequently is severely stressed. Hastelloy W (ERNiMo-6), a nickel-base filler metal that has good hot strength and sufficient ductility to prevent cracking during weld solidification, is recommended for joining many of the Fe-Ni-Cr and Fe-Cr-Ni alloys. This filler metal is not age hardenable, but its as-welded mechanical properties are satisfactory for many applications. For high-stress applications of the precipitation-hardenable iron-base alloys, a filler metal that responds to age hardening, and thus develops the highest joint efficiency, is recommended.

Production Example. Procedures for gas tungsten-arc welding of thin workpieces of a precipitation-hardenable alloy are described in the following example. Filler metal, joint preparation, method of purging the weld, and welding technique were carefully selected to prevent weld or base-metal cracking.



Joint type	Butt
Weld type	Single-V groove (see figure)
Welding process	Manual gas tungsten-arc
Power supply	300-amp transformer-rectifier, with high-frequency arc starting and automatic time delay for gas and water
Electrode	$\frac{1}{16}$-in.-diam EWTh-2, tapered to a sharp point
Torch	Water cooled
Filler metal	$\frac{1}{16}$-in.-diam Hastelloy W
Shielding gas:	
At torch	Argon, 10 to 15 cfh
Backing gas	Argon, at 10 cfh
Welding position	Horizontal-rolled pipe position
Fixtures	V-block; turning rolls
Current	70 amp, max, dcsp(a)
Voltage	Not controlled
Arc starting	High frequency

(a) Foot-operated remote control was connected with low-range circuit of power supply.

Fig. 13. Gas tungsten-arc welded A-286 fuel duct for which special welding techniques were used to prevent cracking (Example 282)

Example 282. Welding Procedures That Prevented Cracks in A-286 Aerospace Fuel Ducts (Fig. 13)

Special techniques were needed to weld sections of A-286 fuel ducts to meet radiographic inspection requirements. The chief concern in welding this alloy was to prevent cracking, which was likely to occur in the weld metal, in the underbead region, and in the heat-affected zone.

The reducing section (Fig. 13) was welded to the two straight-side tube sections in two passes for each weld, using manual gas tungsten-arc welding, Hastelloy W (ERNiMo-6) filler metal, and argon gas for external and internal shielding. The welding conditions are summarized in the table that accompanies Fig. 13.

Material Condition. The components were welded in the solution-treated condition. If a part was cold worked after solution treatment, it was re-solution treated before welding.

Joint Preparation and Fit-up. Section ends were beveled 45° to a featheredge

Table 8. Conditions for Manual Gas Tungsten-Arc Welding of 0.062-In.-Thick Alloy A-286 and Incoloy 800

Item	Alloy A-286	Incoloy 800
Joint type	Square butt(a)	Square butt(a)
Electrode	$\frac{3}{32}$-in.-diam EWTh-2(b)	$\frac{3}{32}$-in.-diam EWTh-2(b)
Filler metal	0.062-in.-diam Hastelloy W (ERNiMo-6)	0.062-in.-diam ERNiCrFe-5
Number of passes	One	One
Welding speed, ipm	2 to 3	2 to 4
Current (dcsp), amp	70 to 85	65 to 80
Voltage, v	10 to 12	10 to 12
Arc starting	High frequency	High frequency
Shielding gas:		
At torch	Argon, at 15 to 20 cfh	Argon, at 15 to 20 cfh
Backing gas	Argon, at 5 to 10 cfh	Argon, at 5 to 10 cfh
Preheat and postheat	None	None

(a) Zero root opening for welds from ¼ to 2 in. long; $\frac{1}{32}$ to $\frac{3}{64}$-in. root opening for welds from 2 to 4 in. long. (b) Electrode tapered to $\frac{1}{64}$-in. diameter.

(zero root face) by grinding and disk sanding (see Fig. 13). Extreme care was needed to prevent burning or overheating of the featheredges.

Sections to be joined were vapor degreased. After fit-up, and just before welding, joints were again cleaned, using a stainless steel wire brush. Accuracy of fit-up was important: overlaps, misalignment, and root openings were not permitted.

Filler Metal. Hastelloy W filler-metal wire was used for tack and groove welding, in preference to A-286 filler-metal wire, because deposition proceeded more smoothly, with less drop-through and better wetting of the groove faces; the incidence of cracking in the weld metal (as detected by dye-penetrant inspection) was lower, and the Hastelloy W wire was easier to handle.

Tack Welding. During fit-up, tack welds were placed at ½-in. intervals around the joint, each tack being carefully deposited across the top of the groove instead of at the root. This procedure (contrary to normal practice) was necessary to avoid oxidizing or overheating the root of the joint; internal gas purging was not used during tack welding, except when fit-up at the featheredge was poor, leaving a small gap. The tack welds were ground flush with the tube wall, leaving a thin web of tack-weld metal, which was consumed during the intermittent root pass. For tack welding and for the initial welding pass, the parts were supported in a V-block.

Argon Purging. After tack welding, purging dams fitted with small-diameter pipe fittings were placed at both ends of the assembly. A hose attached to one dam provided an argon flow of 10 cu ft per hour. In the dam at the opposite end, an exit orifice was made by placing adhesive masking tape over the fitting and puncturing the tape with a 3/32-in.-diam electrode.

Welding. The root pass was made by depositing intermittent welds 1 to 1¼ in. long separated by intervals of about the same length. Each end of the weld bead was then ground back approximately ⅛ in. to a featheredge, using a small grinder fitted with a 1-in.-diam by 1/32-in.-thick wheel. When the joint was cool enough to handle with bare hands, the root pass was completed by filling the intervals.

Intermittent welding was used during the root pass to reduce heat input and cumulative shrinkage stress. The ends of the weld beads were ground to remove possible cracks at these stress points and to reduce heat buildup on making the tie-ins.

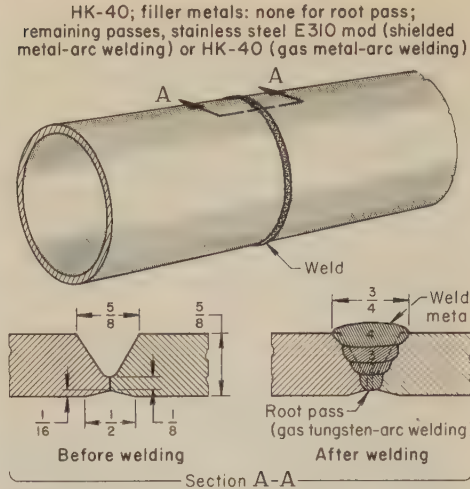
During welding, current was regulated by a foot-operated remote control switch that was connected with the low-range circuit of the power supply. A low welding current (70 amp, max) was used because excessive heat would have caused cracking.

After it was cooled to room temperature, the root bead was cleaned with a power-operated stainless steel wire brush and inspected visually and by a dye-penetrant method for cracks, especially at tie-in points. Cracks were removed by grinding, and the areas to be repaired were blended in before being carefully rewelded.

The second (filler) pass was made while the duct was being rotated on turning rolls. This prevented heat buildup, which was likely to occur if the operator had to stop to turn the workpiece during welding. Stops and starts caused root cracking that was not detectable by dye-penetrant inspection but that was evident in radiographs. If the duct could not be automatically rotated, the second pass was made by intermittent welding.

Gas Metal-Arc Welding of Iron-Nickel-Chromium and Iron-Chromium-Nickel Alloys

Gas metal-arc welding is sometimes used for these heat-resisting alloys when sections are more than about ½ in. thick, where joint design and work-



Joint type	Circumferential butt

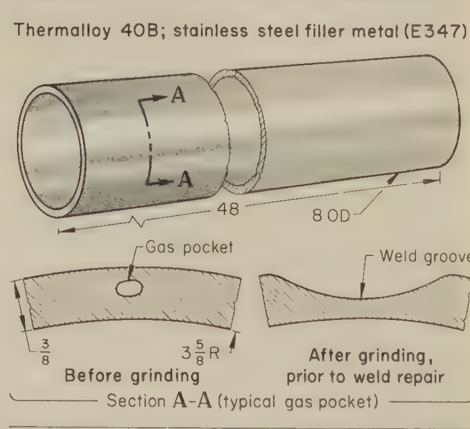
piece size can compensate for the high heat input. In general, it is not recommended for wrought heat-resisting alloys, but it is used for castings.

Electrode material is selected to match the composition of the base metal and to suit service conditions.



Revised Welding Conditions

Weld type	Repair
Welding process	Shielded metal-arc
Power supply	400-amp transformer-rectifier
Electrode	⅛-in.-diam E347-16
Current	100 amp, dcrp
Voltage	32 v
Preheat and postheat	None

Fig. 15. Cast Thermalloy 40B calcining tube, and preparations for weld repair of gas pocket (Example 284)

The following example describes an application in which gas metal-arc welding was used to build up a weld after the root pass had been deposited by gas tungsten-arc welding.

Example 283. Use of Gas Metal-Arc Welding for Filler Passes on a Circumferential Joint in ⅝-In.-Wall Cast Tubing (Fig. 14)

The ⅝-in.-wall tubing shown in Fig. 14 was originally joined by gas tungsten-arc welding for the root pass and shielded metal-arc welding for the filler passes. This practice was changed so that filler passes were welded by the automatic gas metal-arc process, because it was faster and offered improved control. In addition, wire brushing and grinding after each pass were eliminated, and less skill was needed.

The HK-40 tubing (25% chromium, 20% nickel, 0.35 to 0.45% carbon) was beveled as shown in Fig. 14, section A-A. A gas tungsten-arc root pass without filler metal gave a smooth, continuous weld bead on the inaccessible interior of the circumferential joint and provided a sound surface for the weld that was made from the other side. As a result, visual inspection, using a boroscope, was easily accomplished and interpretation of radiographs was simplified, compared with a weld in which a backing strip was used.

The filler passes were made with automatic gas metal-arc welding. Weld metal was deposited by a modified weaving technique to ensure uniform deposition across the groove, low residual stresses in the weld metal, and rapid weld-metal deposition. The final bead extended 1/16 in. beyond the edge of the weld groove.

The root bead and the final bead were inspected for surface discontinuities by the dye-penetrant method. Welded joints were examined radiographically in accordance with paragraph UW-51, Section VIII, ASME Boiler and Pressure Vessel Code, except that 10% random sampling was used.

Shielded Metal-Arc Welding of Iron-Nickel-Chromium and Iron-Chromium-Nickel Alloys

Shielded metal-arc welding can be used for joining Fe-Ni-Cr and Fe-Cr-Ni heat-resisting alloys when gas tungsten-arc welding equipment is not available or when it is not practical to use the gas tungsten-arc process.

Reverse-polarity direct current produces the best mechanical properties in the welds. When joint design permits, rapid travel with as little weaving as possible is preferred, to minimize heat input. To avoid overheating when starting and when stopping a weld, welding currents that are consistent with the metal thickness or the size of the components should be used. Striking the arc on a starting tab adjacent to the joint will help prevent cracking at the beginning of the weld bead. The arc can be broken on a similar tab at the end of the weld, but doubling back on the bead with a slant arc is also acceptable. Whenever possible, welding should be done in the flat position.

Electrodes for shielded metal-arc welding usually are selected so that the composition of the deposited weld metal is close to that of the base metal. Service requirements, such as operating temperature or the need for crack-free weld metal, often influence selection of electrode metal. For example, for applications in which service temperature is above 1650 F, welding electrode Inconel 112 is recommended

for joining Incoloy 800. For applications in which service temperature is below 1650 F, welding electrode Inco-Weld A (ENiCrFe-2) is recommended. When service temperature is below 1000 F and the weld metal must meet stringent fissure specifications, Inconel 182 (ENiCrFe-3) is recommended.

The compositions of electrodes used for welding Fe-Ni-Cr and Fe-Cr-Ni heat-resisting alloys appear in Table 6.

Production Example. Repair of casting defects is a typical application of shielded metal-arc welding. In the following example, the base metal, the electrode material, and the preheating practice were carefully evaluated to assure satisfactory results.

Example 284. Change in Welding Procedure To Avoid Intergranular Corrosion in Cast Thermalloy 40B Tubes (Fig. 15)

X-ray inspection showed scattered gas pockets in cast tubes of Thermalloy 40B, and repair welding was required. The tubes, used in a calciner that operated at 1400 F to convert uranyl nitrate to uranium oxide, were 8 in. in outside diameter, with a ⅜-in. wall, and 48 in. long.

Because of a misunderstanding as to alloy composition, the first repair welding procedure attempted resulted in carbide precipitation in the grain boundaries and failure of the welded areas by intergranular corrosion within three months. The original repair procedure was as follows: The defective tubes were cleaned in hot trichlorethylene vapor and rinsed in hot water, and the defects were ground out, using a hand grinder. Before welding, the tubes were furnace heated to 600 F, and around each defect, an area about 4 in. in diameter was heated to 1100 F with a torch. The defects were repaired by shielded metal-arc welding, using a ⅛-in.-diam austenitic stainless steel electrode, E309-16, and a welding current of 100 amp (dcrp). The tubes were then wrapped in an asbestos blanket to obtain slow cooling.

Because of the poor performance as a result of the first welding procedure, a new procedure was tried. Tubes were cleaned for welding in the same manner as before, preheating was eliminated, a columbium-tantalum-stabilized stainless steel electrode, E347-16, was used, and the tubes were cooled in air after welding. Elimination of the high preheat and the slow cooling reduced carbide precipitation in the heat-affected zone of the base metal, although the higher rate of cooling did cause some cracking. The columbium-tantalum-stabilized electrode also inhibited carbide precipitation in the weld. Although tubes failed from intergranular corrosion after approximately three years of service, the failures were not associated with the weld repairs.

Details of the revised welding procedure are given in the table with Fig. 15.

Submerged-Arc Welding of Iron-Nickel-Chromium and Iron-Chromium-Nickel Alloys

Submerged-arc welding of these heat-resisting alloys normally is limited to applications involving thick sections, where high deposition rate is desired. For some alloys, the lack of a suitable flux prevents the use of this process.

The types of joints and groove designs are similar to those used for submerged-arc welding of low-carbon steel. The composition of the weld metal is often critical when joining Fe-Ni-Cr and Fe-Cr-Ni heat-resisting alloys, and so careful selection of the electrode and of the flux is needed. The electrode is generally of a composition that will produce weld metal of the same composition as the base metal. Modified stainless steel electrodes are used for welding castings. Hastelloy W (ERNiMo-6) can be used where joint strength is not a critical requirement and a weld metal of good ductility is needed.

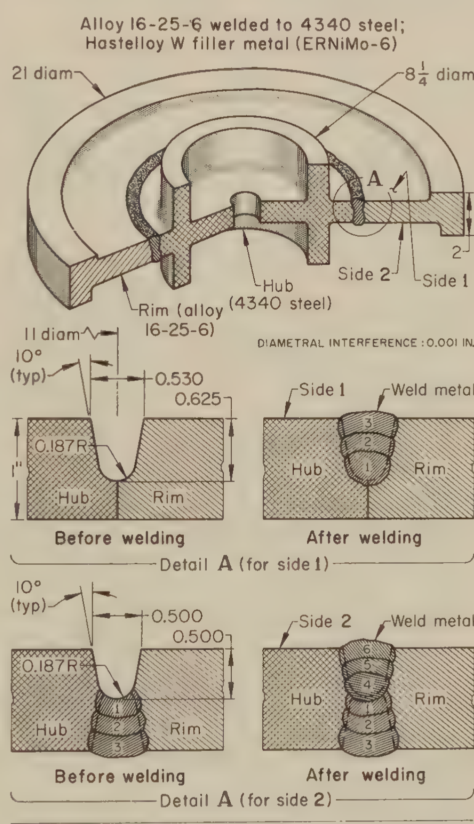
Production Example. In the following example, submerged-arc welding was used for joining a strain-hardenable alloy to an alloy steel. Filler metal, groove design, preheating, and postweld heat treatment were selected to preserve the mechanical properties of both alloys.

Example 285. Joining Heat-Resisting 16-25-6 Alloy to 4340 Steel in Gas-Turbine Wheels (Fig. 16)

Turbine wheels for aircraft gas-turbine engines had a 4340 steel hub and a 16-25-6 alloy rim that were joined by welding, as shown in Fig. 16. Submerged-arc welding was selected for the 1-in.-thick joint because of its high deposition rate and the consistent weld quality obtainable.

A 3⁄16-in.-diam electrode wire made of Hastelloy W (ERNiMo-6) was selected for filler metal, because of its good weld-crack resistance in joining dissimilar metals. The tabulation that follows shows how its composition compares with that of 16-25-6 alloy and 4340 steel:

Element	16-25-6 (rim)	Hastelloy W (filler metal)	4340 (hub)
Carbon	0.07	0.12	0.41
Manganese	2.00 max	1.00 max	0.75
Silicon	1.00 max	1.00 max	0.27
Chromium	16.00	5.00	0.80
Cobalt	...	2.50 max	...
Molybdenum	6.00	24.5	0.25
Nickel	25.00	Rem	1.80
Vanadium	...	0.60	
Phosphorus	0.030	0.040	0.015
Sulfur	0.030	0.030	0.015
Nitrogen	0.15	...	...
Copper	0.50	...	...
Iron	Rem	5.50	Rem



Joint type	Butt
Weld type	Double-U groove(a)
Welding process	Submerged-arc
Power supply	1000-amp transformer
Electrode	3⁄16-in.-diam Hastelloy W (ERNiMo-6)
Flux	Neutral
Current	518 amp, ac (all passes)
Voltage	28 to 35 v (all passes)
Stickout	1¼ in.
Travel speed	13.3 ipm (all passes)
Wire feed	Automatically controlled
Fixture	Turntable

(a) The first U-groove was filled with weld metal before the second groove was cut.

Fig. 16. Section through a bimetal gas-turbine wheel showing location of weld joining the two alloys, joint design, and sequence of operations in groove cutting and weld-metal deposition (Example 285)

Before welding, the 16-25-6 rim was conditioned for optimum strength by hot-cold working at 1260 F during the final forging operation. (Because of this treatment, subsequent heat treatment of the weldment was limited to 1200 F max.) Rim hardness was Rockwell C 22 to 30.

The 4340 steel hub was quenched and tempered to a hardness range of Rockwell C 26 to 32.

Although the butt joint was designed for what ultimately became a double-U-groove weld, as shown in Fig. 16 (detail A for side 1), the groove on the first side was completely welded before the groove on the second side was cut.

The rim and hub were machined for a shrink fit, and mating edges of the side that was to be welded first were beveled, degreased and wiped with acetone. After furnace preheating the rim to 850 F and the hub to 650 F, the two parts were assembled and mounted for flat-position welding on a rotating positioner, with a circular gas burner located under the joint for preheat control. The parts were dimensioned for diametral interference of 0.001 in. at room temperature. This permitted assembly with an easy sliding fit after furnace preheating, and gave a light interference fit after the temperature became equalized at 550 F.

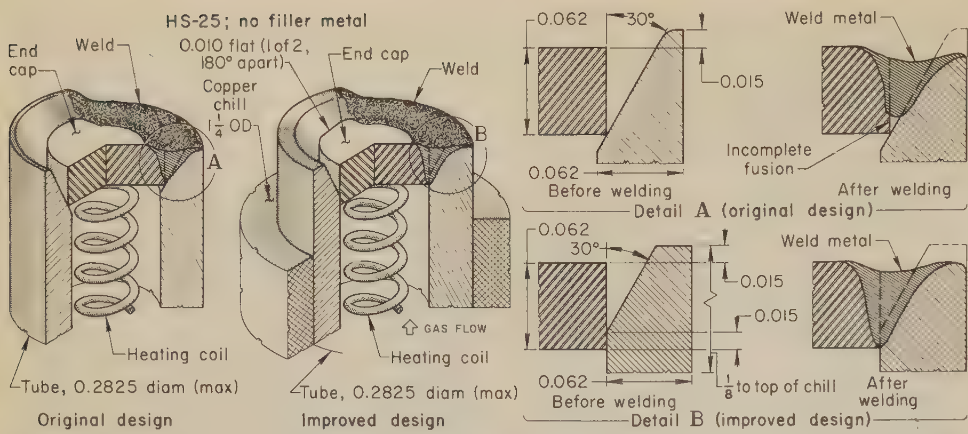
After the first-pass bead was deposited, using the settings shown in the table that accompanies Fig. 16, the weld metal was cleaned of slag and wire brushed. Interpass temperature was adjusted to 575 F. Passes 2 and 3 were deposited using the same settings as for the first pass. The part was immediately transferred to a furnace at 600 F, heated to 1065 F (at a maximum rate of 100 F per hour), held for 6 hr, furnace cooled to 500 F (at a maximum rate of 100 F per hour), removed from the furnace, and air cooled.

A groove was then cut on the second side to be welded (Fig. 16, detail A for side 2). The part was preheated in a furnace to 650 F, transferred to the welding positioner, temperature equalized at 550 F, and welding was completed using the same technique as before. Immediately after the final pass, the part was placed in a furnace at 600 F and held for 4 hr; the remainder of the postweld heat treatment was the same as for the weld on the first side.

After machining off 1⁄32 in. of weld metal and across the base metal in the weld area, the joint was inspected by radiographic, magnetic particle, and fluorescent-penetrant techniques. Hardness surveys taken across the joint were as follows:

4340 hub base metal	28 Rc
4340 heat-affected zone	24 to 25 Rc
Hastelloy W weld metal	20 to 24 Rc
16-25-6 heat-affected zone	20 to 22 Rc
16-25-6 rim base metal	25 to 26 Rc

Joint tensile strength averaged 113,000 psi; yield strength, 68,000 psi; elongation in 2 in., 9%; and reduction of area, 16%. Failure in tests occurred in the weld metal. In addition to helping to preserve mechanical properties of the base metals, the preheat and the heat treating cycles were successful in preventing the formation of untempered martensite in the heat-affected zone of the 4340 hub, thus eliminating this potential source of cracking.



Joint type	Corner
Weld type	Single-bevel groove
Welding process	Automatic gas tungsten-arc
Power supply	200-amp, dc motor-generator
Electrode	0.040-in.-diam EWTh-2, tapered to 0.015-in. diameter
Torch	110 amp, air cooled
Filler metal	None
Welding position	Flat

Current	45 amp, dcsp
Shielding gas:	
At torch	Argon, at 20 cfh
Backing gas	Argon, at 2 cfh
Fixtures:	
Workpiece	Copper chill ring, turntable mounting
Torch	Clamped to swing-arm mount
Arc starting	High frequency
Arc length	1/16 in.
Production rate	65 pieces per hour

Fig. 17. End-closure detail of sheathed heating-element assembly, and original and revised joint design (Example 286)

Cobalt-Base Heat-Resisting Alloys

Cobalt-base heat-resisting alloys (see Table 1) are available in both cast and wrought forms. Generally, the cast alloys are more difficult to weld than are the wrought alloys but, other than repair welding, there is little need to weld most such castings.

Where the application requires very high reliability of welds, only gas tungsten-arc and gas metal-arc welding are recommended; otherwise, shielded metal-arc welding is used.

Joint design and weld grooves for the cobalt-base alloys are essentially the same as for the nickel-base alloys (see Table 3).

A square-groove butt joint is used for sheet metal up to about 7/64 or 1/8 in. thick, a V-groove for plate up to 3/8 in. thick, a double-V groove or a double-U groove for thicknesses of 3/8 to 5/8 in., and a double-U groove for thicknesses over 5/8 in. Where T-joints are used, the same groove limitations apply as for butt joints. Corner-joint welds should be backed by a fillet weld if possible. This type of joint should be avoided where high stresses are likely to occur.

V-grooves should have a 60° groove angle for gas tungsten-arc welding.

The weld grooves should be machined to assure proper fit-up. The edges of a sheared plate should be ground or machined back 1/16 in. to remove stressed metal. Gas and arc cutting and beveling are not recommended.

All joints should be designed to ensure full penetration. In the following example, improved joint design and use of argon backing gas resulted in 100% penetration and prevented oxide formation at the root of a joint.

Example 286. Changes in Joint Design, Shielding, and Heat Extraction That Eliminated Defects in Welds in HS-25 (Fig. 17)

The end closure for a sheathed heating-element assembly required welding a disk-shape HS-25 end-cap stamping to the open end of a 0.2825-in.-diam HS-25 tubular sheath (Fig. 17). Earlier, the end cap had been welded to a wire coil that served as the heating element of the assembly. After the end cap was welded on, the tube was packed with ceramic insulation material, and swaged to reduce the diameter approximately 16%, thus compacting the insulation. Tests were made for leaktightness and for electrical properties.

The original welding procedure consisted of fitting the end cap with its welded-on heating coil into the beveled end of the tube as shown in Fig. 17, original design and detail A. Then the tube was mounted vertically on a turntable and rotated under a fixed gas tungsten-arc torch. The shielding gas was argon. Weld metal was obtained by melting down the protruding tube wall.

The customer's specification of 100% joint penetration (with a joint design not conducive to complete penetration) required the use of excessive heat, which being conducted to the heating coil attached to the end cap, caused the joint between the heating coil and the end cap to become softened and to fail during the swaging and assembly operations that followed. A second defect was the formation of oxides (because of inadequate shielding and trapped air) on the interior of the tube and at the root of the joint. The oxides that formed on the inside of the tube caused short circuiting during final testing and those at the root of the joint caused incomplete fusion. To eliminate these conditions, a new procedure was developed, which is described below.

First, the depth of the bevel on the tube was reduced to provide a root face of 0.015 in. (see detail B in Fig. 17), and the diameter of the end cap was decreased to provide a press fit into the tube. Two flats were ground on the end cap to allow the escape of air and thus permit the use of argon gas for shielding the back of the weld. An O-ring that held the tube in the rotating fixture also served as a seal for the argon backing gas, which flowed through the rotating fixture and into the tube. This procedure was successful in preventing oxide formation on the inside of the tube and at the weld root, but new difficulties developed: the heat produced by welding caused the O-ring to break down and the end cap to become overheated. Both of these difficulties were corrected by placing a copper ring on the tube to act as a heat sink.

The sequence of operations finally adopted was as follows:

1 Degrease parts; solution heat treat the tube under vacuum, which also cleaned the tube.
2 Press fit end cap assembly into tube.
3 Mount tube in rotatable fixture.
4 Place copper heat sink around tube.
5 Purge air from tube interior with continuous flow of argon.
6 Move swing-mounted torch into position (1/16 in. above, and centered on, tube wall).
7 Start gas flow, arc and turntable rotation. After two weld passes, terminate arc, rotation and gas flow in half a rotation.
8 Retract torch, unclamp heat sink, and remove assembly with a special hand tool.
9 Test assembly for leaks by holding under water for 10 sec while pressurized with air at 100 psi.

This procedure produced 100% joint penetration when used with the welding conditions given in the table that accompanies Fig. 17. Rejects after swaging amounted to less than 1%, compared with more than 20% previously. Electrodes were changed two or three times during an 8-hr shift, because the points became misshaped. After each electrode change, the first piece welded was sectioned and polished to check for penetration and defects.

Cleaning. The weld joint and the adjacent area must be thoroughly cleaned before welding. All foreign matter should be removed by grinding, machining or scrubbing with a suitable solvent. Shot or sand blasting should not be used because iron and sand particles embedded in the work-metal surface can cause serious contamination. Wire brushing should be done with stainless steel or copper brushes; carbon steel brushes can contaminate the base metal.

If the alloys are heat treated in an oil-fired furnace, fuels of low sulfur content must be used to avoid sulfur contamination and subsequent detrimental effect on mechanical properties and corrosion resistance.

Gas Tungsten-Arc Welding. Straight-polarity direct current is preferred for gas tungsten-arc welding of cobalt-base alloys. A thoriated tungsten electrode (EWTh-2) of the smallest diameter that will carry adequate current is recommended. Use of electrodes too small in diameter, at high current densities, can cause excessive electrode erosion and result in tungsten inclusions in the weld metal.

To ensure sound welds, argon gas at a flow rate of 15 to 25 cu ft per hour for weld-puddle shielding and 5 to 10 cu ft per hour for backing is recommended.

In the following example, long, ductile crack-free welds were required in a cylinder made of thin metal. Microcracks appeared in the heat-affected zone when the cylinders were welded by the original method, but were eliminated when the backing bar was chromium plated.

Example 287. Elimination of Microcracks in the Heat-Affected Zone of an HS-25 Weldment (Fig. 18)

A bellows 25 in. in diameter and 30 in. long was formed from a cylinder 72 in. long made of 0.012-in.-thick HS-25 sheet. Two longitudinal welds were required in fabricating the cylinder (Fig. 18). The welds had to be ductile and crack-free so that the bellows convolutions could be formed without cracking and without adversely affecting the mechanical properties of the welds.

Originally, the cylinders were welded by the gas tungsten-arc process, without filler metal, using a welding positioner with cop-

per hold-down fingers and a copper backing bar. Transverse microcracks, up to about 0.10 in. long, through the work metal, appeared in the heat-affected zone. All attempts to eliminate the cracks, including increasing the welding speed, decreasing the clamping force, changing the shielding gas from argon to 25% argon – 75% helium and then to 95% argon – 5% hydrogen, and decreasing arc voltage, were unsuccessful.

When 0.030-in.-diam Hastelloy W filler-metal wire was used (instead of no filler metal), cracking was reduced to one or two repairable cracks in four or five welds, provided that the weld was less than 0.065 in. wide. However, at higher welding speeds, such as 60 in. per minute, it was difficult to feed the limited amount of wire needed to make the narrow weld. In addition, the occasional cracks that did occur were difficult to repair.

Because satisfactory welds had been made in tests on short lengths of HS-25 using no fixturing, methods of reducing tooling effect while maintaining alignment were considered, and a step taken was to plate the backing bar with 0.001 in. of hard chromium. Welds were made, with and without filler metal and with different welding currents, and all of the welds were crack-free. It was not known whether the cracks were initially caused by copper contamination of the weld metal or by heat dissipation due to the higher thermal conductivity of the copper, but the cracking was eliminated by chromium plating of the backing bar.

Forming of the convolutions was done with no cracking, indicating no significant adverse effect on the mechanical properties of the welds.

Welding conditions are given in the table that accompanies Fig. 18.

In the following example, gas tungsten-arc welding was used for repair of cracks in cobalt-base alloy castings.

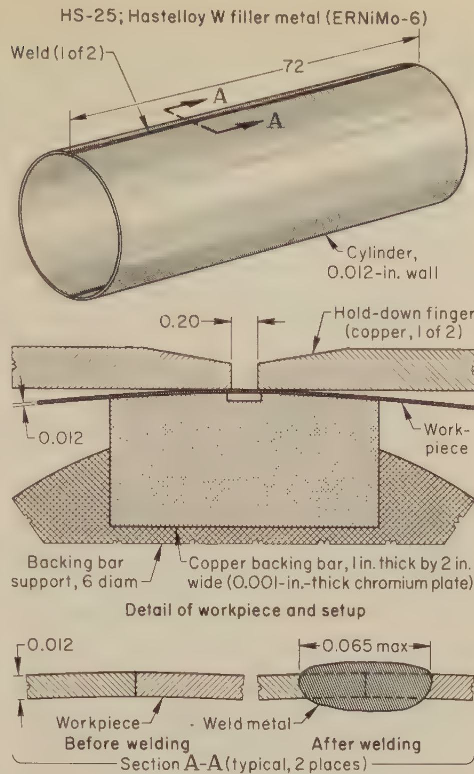
Example 288. Repair of Cracks in Cast HS-21 Gas-Turbine Nozzles (Fig. 19)

During gas-turbine overhaul, cracks were often detected in the vanes and shrouds of nozzles, most often appearing on the trailing edges of vanes. A section of a typical 9-in.-diam second-stage nozzle is shown in Fig. 19. Most of the defective nozzles were returned to service after repair by manual gas tungsten-arc welding. The repair procedure was as follows:

1. Remove heavy carbon coating and other surface contaminants by wire brushing and vapor degreasing.
2. Remove residual carbon by a proprietary chemical process, using strong alkaline cleaners and oxidizers, followed by light wet blasting of tough scaly areas or porous surfaces.
3. Heat treat castings at 2150 F for 15 min in a vacuum furnace, for final cleaning and solution treating.
4. Inspect castings by the fluorescent dye-penetrant method and mark cracks, using a special felt marker in which the ink is solvent soluble.
5. Grind out all cracks, using a small grinding wheel to cut slots (weld grooves) as shown in detail A of Fig. 19.
6. Fill the weld grooves by depositing HS-25 filler metal (AMS 5796) with low welding current and argon shielding.
7. Grind the weld surfaces to the proper contour.
8. Visually inspect ground surfaces.
9. Re-solution treat castings at 2150 F in a vacuum furnace.
10. Inspect welds, using fluorescent dye-penetrant method as before.
11. Wet blast all ground and blended areas for final finish.

The thickness of the vanes varied from 3⁄16 in. at the leading edge to 1⁄16 in. at the trailing edge. Hence, the weld beads had to be deposited with special care, using a foot-operated current control. Slotted areas were gradually built up by welding around the groove edges until the area was filled sufficiently to finish to size. It was not possible to weld the vanes from both sides. A small water-cooled torch with a 3⁄8 or 7⁄16-in.-diam cup and a 1⁄16-in.-diam gas lens was used for manipulating the 1⁄16-in.-diam tungsten electrode.

Parts repaired by this method proved acceptable after 25 hr of testing at various loads and a large number of cycles. In service, gas turbines with extensive casting weld repairs have exceeded 400 hr of service without failure.



Welding Conditions for Improved Method

Joint type	Butt
Weld type	Square groove
Welding process	Automatic gas tungsten-arc, automatic arc voltage with 0.25 sensing range
Power supply	300-amp transformer-rectifier
Electrode	0.045-in.-diam EWTh-2
Filler metal	0.030-in.-diam Hastelloy W
Torch	Water cooled
Shielding gas:	
At torch	Argon, 25% argon – 75% helium, or 95% argon – 5% hydrogen, at 15 to 25 cfh
Backing	Same gas as above, at 3 to 5 cfh
Welding position	Flat
Current	10 to 30 amp, dcsp
Voltage	11 to 19 v
Arc starting	High frequency
Travel speed	15 to 90 ipm
Wire feed	Automatically controlled
Fixture	Hold-down fingers and backing bar

Fig. 18. HS-25 cylinder that was welded without microcracking in the heat-affected zone when the backing bar was chromium plated (Example 287)

Gas Metal-Arc Welding. The wrought cobalt-base alloys can be welded automatically by gas metal-arc welding, using reverse-polarity direct current. The speed of welding, inherent to this process, can be an advantage in some applications, but care should be used to ensure that high heat input does not cause weld-metal cracking.

The shielding gas usually is argon, but argon with 1% oxygen is sometimes used. The electrode material selected should be compatible with the base metal and service requirements. Typical conditions for gas metal-arc welding are given in Table 9.

Shielded metal-arc welding can be used for joining cobalt-base alloys when service conditions permit and when it is not feasible to weld by a gas-shielded method. Reverse-polarity direct current results in the best mechanical properties. Welding should be done in the flat position, with rapid travel and as little weaving as possible.

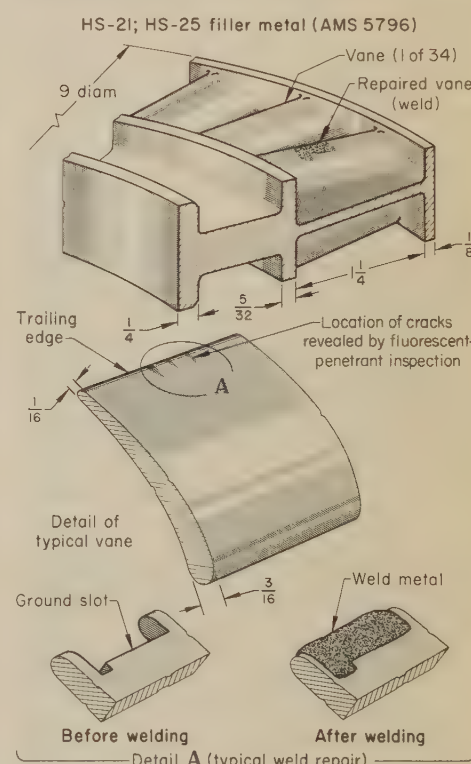
Table 9. Typical Conditions for Gas Metal-Arc Welding of Cobalt-Base Heat-Resisting Alloys

Base-metal thickness	1⁄8 to 3⁄8 in.
Filler-metal diameter	0.035 in.
Welding current	130 to 160 amp, dcrp
Voltage	22 to 25 v
Shielding gas	Argon + 1% oxygen; 40 cfh
Travel speed	30 ipm

Types of joint and proportions of weld grooves are the same as those used for nickel-base alloys. Cobalt-base alloys are welded in the solution-treated condition with electrodes that have a composition similar to that of the base metal being welded.

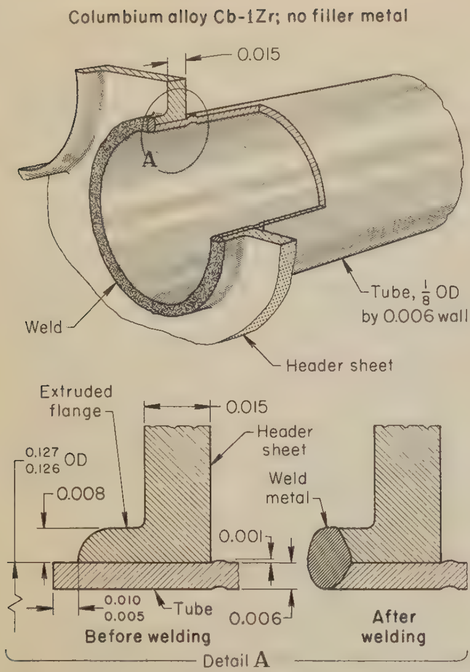
Refractory Metals

The refractory metals (columbium, tantalum, molybdenum and tungsten) can be welded by the gas tungsten-arc and electron beam processes. These metals must be welded in high-purity inert gas or in high vacuum to minimize contamination of the weld.



Weld type	Repair
Welding process	Manual gas tungsten-arc
Power supply	300-amp transformer-rectifier, with high-frequency current and time delay for gas and water
Electrode	1⁄16-in.-diam EWTh-2
Torch	Water cooled, with gas lens
Filler metal	1⁄16-in.-diam HS-25 (AMS 5796)
Shielding gas	Argon, at 10 to 15 cfh
Welding position	Flat
Current	12 to 70 amp, dcsp
Voltage	Not controlled
Arc starting	High frequency

Fig. 19. Section of a gas-turbine second-stage nozzle showing steps in the repair welding of a crack in the trailing edge of one of the vanes (Example 288)



Joint type	Edge flange
Torch	Light-duty, pencil type, air cooled(a)
Electrode	0.020-in.-diam EWP(b)
Filler metal	None
Shielding gas	Argon, in chamber
Current	20 to 25 amp, dcsp
Voltage	8 v
Welding speed	4.3 ipm
Welding time per tube	5.5 sec

(a) Mounted on a locating and guiding fixture. (b) Taper ground to a needle point.

Fig. 20. Joint between columbium alloy tube and header that was welded by the automatic gas tungsten-arc process (Example 289)

Preweld Cleaning. The refractory metals are susceptible to weld porosity, and sometimes to weld cracking, if not properly cleaned before being welded. Degreasing by wiping with acetone, followed by chemical cleaning, is necessary. After chemical cleaning, the work metal should be handled with clean cotton gloves and welded as soon as possible.

A procedure recommended for cleaning molybdenum alloys is as follows:

1. Immerse for 5 to 10 min in a warm (150 to 180 F) solution of (by weight) 10% sodium hydroxide and 5% potassium permanganate in distilled water.
2. Rinse in tap water, scrubbing off loose smut.
3. Immerse for 5 to 10 min in a room-temperature solution of (by volume) 15% concentrated sulfuric acid and 15% concentrated hydrochloric acid in distilled water, plus 6 to 10% (by weight) chromic acid.
4. Rinse in tap water and dry in air.

Glass or porcelain enameled containers are preferred for both solutions; stainless steel containers are unsatisfactory. If the work is not cleaned satisfactorily by the first cycle, the four steps can be repeated as necessary. Areas that resist treatment can be cleaned by pouring concentrated hydrochloric acid on them immediately after removal of the work metal from the smut-removing bath (step 3).

The same procedure can be used for cleaning tungsten, but reaction rates will be much slower and results not completely satisfactory.

Molybdenum and tungsten may also be cleaned by etching with a solution of (by volume) 90% concentrated nitric acid and 10% concentrated hydrofluoric acid. Reaction is vigorous, and the noxious gases emitted require forced-draft ventilation.

Tantalum alloys can be cleaned by immersing in a hot chromic dip or by chemically polishing in a solution of five volumes of 95% sulfuric acid, two volumes of 70% nitric acid, and two volumes of 48% hydrofluoric acid.

Columbium alloys may be cleaned with the following solutions:

1. 40% (by volume) HNO_3, 5% HF, remainder distilled water
2. 60% (by volume) HNO_3, 40% HF
3. 15% (by volume) H_2SO_4, 22% HF, remainder distilled water.

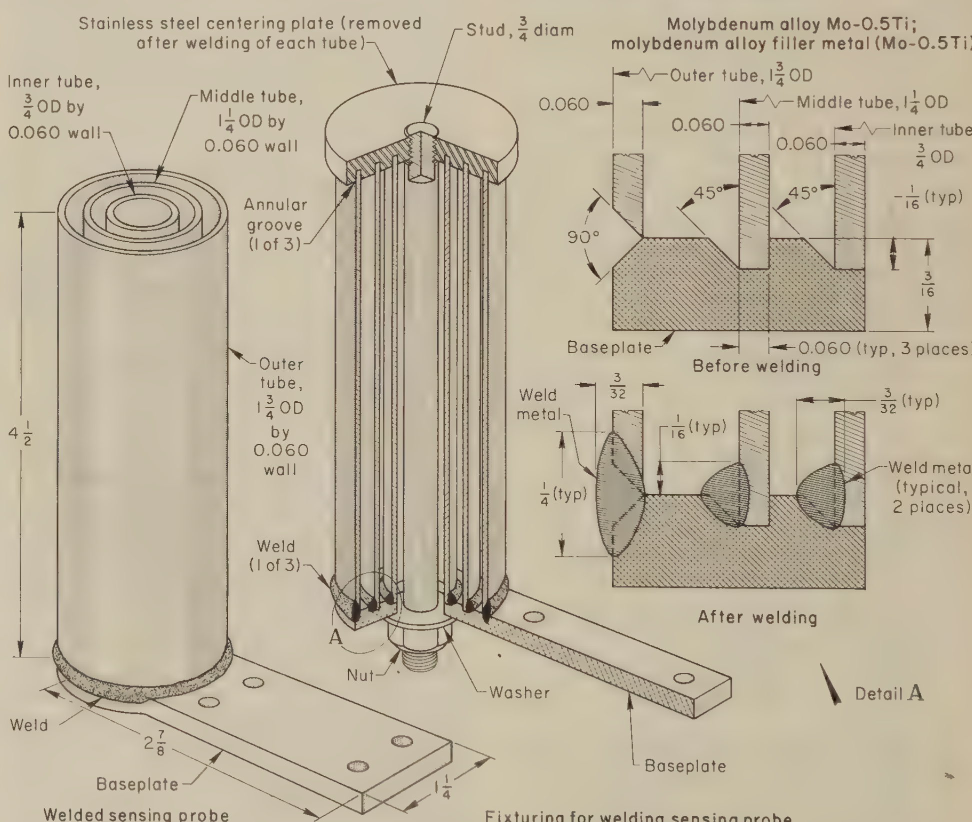
Columbium and Tantalum. Welds in pure columbium and tantalum are soft and ductile; they have very low ductile-to-brittle transition temperatures. During welding of columbium and tantalum alloys that contain carbon, rapid cooling from welding temperatures hardens the matrix of the weld zone and may give rise to brittleness at or near room temperature. The welded joint may age in service at elevated temperatures, with a loss in ductility. Postweld overaging treatments may be used to overcome aging embrittlement in service by increased precipitation of carbides or oxides, or both.

In the following example, the columbium alloy Cb-1Zr was edge welded by the gas tungsten-arc process.

Example 289. Gas Tungsten-Arc Welding of Edge Joints Between Columbium Alloy Cb-1Zr Tubes and Header (Fig. 20)

In the production of small heat exchangers for a high-temperature aerospace application, the ends of ⅛-in.-OD by 0.006-in.-wall tubes were edge-flange welded to a 0.015-in.-thick header. The tubes and header were made of columbium alloy Cb-1Zr, and were welded in the annealed condition. As shown in Fig. 20, each tube hole in the header had an extruded flange 0.008 in. thick that provided tube support as well as a low-restraint edge for welding. After the tubes and header were degreased and pickled, the tubes were inserted, with the ends protruding 0.005 to 0.010 in., and were expanded to the 0.126/0.127-in. inside diameter of the holes in the headers, and to provide each tube with a small embossed bead opposite the weld joint, which positioned the tube in the header (Fig. 20).

The assembly was gas tungsten-arc welded in a controlled-atmosphere chamber, under dry argon. Dry argon was used because of the embrittling effects of oxygen, nitrogen and hydrogen on the high-temperature properties of columbium alloys. Gas tungsten-arc welding was selected over electron beam welding mainly because the electron beam process would have entailed more expensive equipment, fixturing and tooling. Preliminary welds were made manually; the operation was later mechanized by mounting the torch on a locating and guiding fixture. Welding conditions are given in the table with Fig. 20.



Joint types	Outer tube, corner; middle and inner tubes, T
Weld types	Outer tube, single-V groove; middle and inner tubes, single-bevel groove
Electrode and filler metal	⅛-in.-diam EWTh-1 electrode; 0.060-in.-diam Mo-0.5Ti wire filler metal
Shielding gas	Reactor-grade helium, in a purge chamber
Current and voltage	250 amp, dcsp; 17 v(a)
Preheat(b)	1200 F (approx)

(a) From a 400-amp power supply. (b) Supplied by welding arc.

Fig. 21. Pressure and temperature-sensing probe made of molybdenum alloy Mo-0.5Ti and welded by the manual gas tungsten-arc process (Example 290)

Molybdenum and Tungsten. When molybdenum and tungsten are cooled from the molten state, or from temperatures near the melting point, interstitial impurities are rejected, usually to the grain boundaries, as oxides, nitrides and carbides. During welding, the interstitial compounds go back into solution, and during cooling are again rejected to the grain boundaries. Also, grain growth occurs, which decreases grain-boundary surface area. As a result, the weld metal and the metal in the heat-affected zone are weaker and less ductile than the base metal. Welds that are ductile at room temperature have been made in molybdenum but not in tungsten, because molybdenum is less sensitive to interstitial impurities than tungsten. The ductility of the weld is closely related both to the amount of interstitial impurities present and to the resulting grain size.

Welded joints are extremely notch sensitive; therefore, whenever possible, the weld metal should be finished smooth and faired gradually into the base metal. Notches at the root of the weld must be avoided.

Welds made in the molybdenum alloy Mo-0.5Ti have ductility comparable to welds in unalloyed molybdenum of similar interstitial content.

In the following example, the assembly was welded in a helium-filled chamber, with the use of a filler metal. The chamber was purged with the inert shielding gas, instead of by evacuating the chamber and then backfilling it with the inert gas.

Example 290. Joining Molybdenum Alloy Mo-0.5Ti Tubes to a Baseplate by Manual Gas Tungsten-Arc Welding (Fig. 21)

The tubes and baseplate that comprised the pressure and temperature-sensing probe shown in Fig. 21 were made of molybdenum alloy Mo-0.5Ti, and were joined by manual gas tungsten-arc welding. Welding was done in a purge chamber using reactor-grade helium as the shielding gas. The welding arc, manually traversed along the joints, provided preheating to about 1200 F.

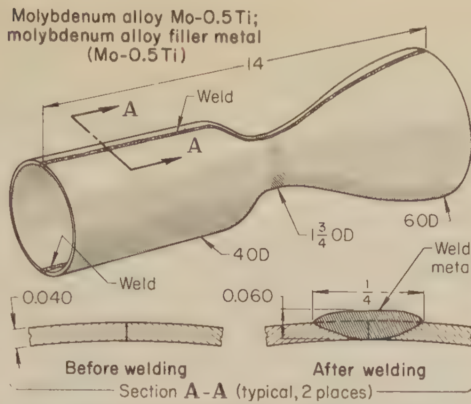
Before welding, all joint surfaces were machined, degreased with acetone, and chemically cleaned. The three tubes were located and held in place for welding by mating annular grooves machined in the Mo-0.5Ti alloy baseplate and a stainless steel centering plate; a nut and washer on a stud held the assembly together during welding (see Fig. 21).

The welding sequence for each joint, starting with the inner tube, was:

1 Displace air in the chamber by purging.
2 Test atmosphere purity using a test weld on a scrap piece of Mo-0.5Ti alloy (absence of discoloration indicated that atmosphere was satisfactory).
3 Preheat joint area to dull red color (about 1200 F) with welding arc.
4 Weld each joint in one pass, adding Mo-0.5Ti filler metal as needed.
5 After welding each joint, stress relieve the weldment in a dry hydrogen atmosphere (−75 F dew point) at 1900 ± 25 F for 1 hr.

After welding, the joints were inspected by the dye-penetrant method. Welding conditions are given with Fig. 21.

The two examples that follow describe the use of gas tungsten-arc welding in the production of nozzles from 0.040-in.-thick molybdenum alloy Mo-0.5Ti. In the first example, a filler metal was used but no fixture was needed. In the second example, no filler metal was used but fixtures and backing gas were needed.



Joint type	Longitudinal butt
Weld type	Square groove
Torch	Water cooled
Electrode	⅛-in.-diam EWTh-1
Filler metal	Mo-0.5Ti strips $\frac{1}{16}$ in. thick by ⅛ in. wide
Shielding gas	Argon, in a purge chamber
Current	150 amp, dcsp(a)
Voltage	17 v
Welding position	Flat
Fixture	None
Preheat(b)	1200 F (approx)

(a) From a 400-amp power supply. (b) Supplied by welding arc.

Fig. 22. Transpiration-cooled nozzle made of molybdenum alloy Mo-0.5Ti and joined by manual gas tungsten-arc welding (Example 291)

Example 291. Manual Gas Tungsten-Arc Welding of Mo-0.5Ti in a Purge Chamber, Using the Torch for Both Preheating and Welding (Fig. 22)

Figure 22 shows a transpiration-cooled nozzle that was produced as a weldment of two formed halves of 0.040-in.-thick molybdenum alloy Mo-0.5Ti. The two longitudinal joints were welded by the manual gas tungsten-arc process, in an atmosphere of argon in a purge chamber. Preheat of about 1200 F was provided by the welding arc, which was manually traversed.

Before welding, the joint edges were machined, and the two nozzle halves were chemically cleaned. No fixture was used during welding; instead, the two halves of the nozzle were held together by tungsten wires wrapped around the assembly and tightened by twisting the ends. During welding, Mo-0.5Ti filler metal was added as needed. Other welding conditions are given in the table that accompanies Fig. 22.

After the assemblies had been welded, the welds were dye-penetrant inspected; then the nozzle was stress relieved in dry hydrogen (−75 F dew point) for 1 hr.

Example 292. Automatic Gas Tungsten-Arc Welding of Mo-0.5Ti, Using Backing Gas and Copper Backing Fixtures (Fig. 23)

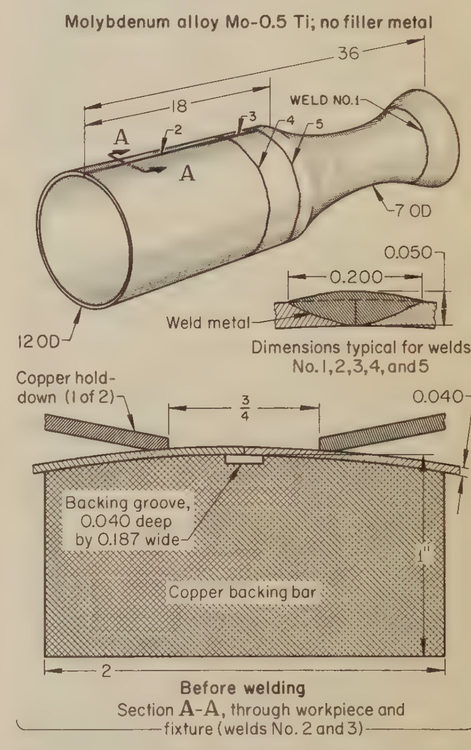
The ramjet combustion-chamber and exit-nozzle assembly shown in Fig. 23 was formed from molybdenum alloy Mo-0.5Ti sheet 0.040 in. thick, and was joined by automatic gas tungsten-arc welding. Reactor-grade helium at a flow rate of 20 cu ft per hour was used as leading and trailing shielding gas at the torch, and as backing gas for two joints. Argon backing gas at 3 cu ft per hour was used for three joints.

The components of the weldment were formed at 400 to 800 F from cross rolled stress-relieved sheet. Surface contamination and imperfections were removed by precision belt grinding 0.005 in. from each surface of the sheet before forming. The edges of the square-groove butt joints were machined and the components were degreased with acetone and then chemically cleaned.

Separate fixtures were used for each of the five welds shown in Fig. 23. The fixture for the circumferential throat weld (weld 1 in Fig. 23) was a copper backing ring with a groove for the argon backing gas. The fixture for the two longitudinal welds (welds 2 and 3 in Fig. 23) consisted of a copper backing bar, which also had a groove for the backing gas, and copper hold-down strips. A low-carbon steel fixture positioned the components for the circumferential welds in the combustion chamber (welds 4 and 5 in Fig. 23). Backing-gas protection for these welds was provided by the use of a counterbalanced floating shield matching the inside diameter of the chamber and extending over an arc of about 75°.

The metal at the joints for welds 1, 2 and 3 was preheated to 400 F by resistance heating elements embedded in the copper backing ring and bars. The metal at the joints for welds 4 and 5 was preheated to 325 F by quartz lamps. Postweld stress relieving at 1900 ± 25 F for 1 hr in dry hydrogen (−75 F dew point) was done after completion of each of the welds 1, 2, 3 and 5 (welds 4 and 5 were stress relieved by the same heat treatment).

Weld quality was checked by radiographic and dye-penetrant inspection methods. Welding conditions are given in the table with Fig. 23.



Joint type	Butt (longitudinal and circumferential)
Weld type	Square groove
Welding process	Automatic gas tungsten-arc
Torch	Mechanically held, water cooled
Electrode	$\frac{3}{32}$-in.-diam EWTh-1
Filler metal	None
Shielding gas	Helium and argon(a)
Current(b)	Welds 1, 2 and 3, 225 amp, dcsp; welds 4 and 5, 170 amp, dcsp
Voltage	16 to 16.5 v
Welding position	Flat
Preheat	Welds 1, 2 and 3, 400 F; welds 4 and 5, 325 F
Welding speed	40 ipm
Edge preparation	Machining, acetone degreasing, and chemical cleaning

(a) Reactor-grade helium, at 20 cu ft per hour, was used as leading and trailing shield at the torch, and as backing gas with a floating shield for welds No. 4 and 5. Welding-grade argon, at 3 cu ft per hour, was used as backing gas in grooves of backing ring for weld No. 1 and backing bar for welds No. 2 and 3. (b) From a 400-amp power supply.

Arc Welding of Aluminum Alloys

*By the ASM Committee on Welding of Aluminum Alloys**

GAS METAL-ARC and gas tungsten-arc welding have almost entirely replaced other arc welding processes for aluminum alloys. These gas-shielded arc welding processes result in optimum weld quality and minimum distortion, and they require no flux. As a result, difficult-to-reach places and completely inaccessible interiors of welded assemblies are left free from flux residues that could be a potential source of corrosion. Furthermore, welding can be done in all positions, because there is no slag to be worked out of the weld by gravity or by puddling.

Visibility is good. The gas envelope around the arc is transparent, and the weld puddle is clean. A welder doing a hand welding job can make a neat, sound weld because he does not have to contend with smoke and fumes and can see what he is doing.

Base Metals

Most aluminum alloys can be joined by either gas metal-arc or gas tungsten-arc welding, and the weldabilities of aluminum alloys are essentially the same for both processes. The most common alloys are grouped by weldability rating in Table 1; nominal compositions are given in Table 2.

Wrought alloys most easily welded by gas-shielded arc processes are those of the non-heat-treatable 1*xxx*, 3*xxx* and 5*xxx* series; the alloys in the heat treatable 6*xxx* series are also easily welded. Alloys of the 4*xxx* series and of the high-strength, heat treatable 2*xxx* series can also be arc welded, but special techniques may be required and somewhat lower ductility may be obtained. Of the high-strength heat treatable 7*xxx* series, alloys 7075, 7079 and 7178 are weldable, but have brittle heat-affected zones, and therefore welding is usually not recommended, but alloys 7005 and 7039 were developed specifically for welding and have good weldability. Alloys 7005 and 7039 are of special interest for large structures in which the welds must be of high strength, because welds will age naturally to 70 to 90% of the strength of the heat treated base metal (depending on the chemical composition of the weld deposit) within 30 to 90 days after welding.

The heat of welding removes part or all of the effects of strain hardening; in consequence, the yield strength of the heat-affected zone of a weld in a non-heat-treatable alloy may not exceed that of the annealed alloy. The size of the low-strength zone will depend primarily on the speed of welding and the amount of strain hardening. On the whole, weldments exhibit good joint efficiency and ductility.

Table 1. Weldability of Aluminum Alloys by the Gas Metal-Arc and Gas Tungsten-Arc Processes (a)

Readily Weldable

Casting alloys: 122, 142, 220

(a) Wrought alloys are listed here by Aluminum Association designations; casting alloys, by industry designations. See Table 2 for nominal compositions of all alloys listed, and for Aluminum Association designations of casting alloys. (b) See Table 14 on page 877 in Volume 1 of this Handbook for strength and ductility of gas metal-arc welded joints in many of these alloys and combinations of these alloys, using various filler metals.

When a heat treated alloy (T4 or T6 condition) is arc welded, its strength in the as-welded condition is slightly less than that of the unwelded alloy in the T4 condition. This decrease in strength is attributed to the comparative weakness of the heat-affected zone. The zone normally consists of an area of solution-annealed material adjacent to the weld, an area where partial annealing has occurred, and an overaged area. Because of the high strength of the base metal and the low strength of the heat-affected zone, weldments of alloys in the T6 condition have a low as-welded joint efficiency and often a lack of ductility. Solution heat treatment and aging after welding may restore much of the strength, but little improvement in ductility occurs. After postweld aging alone, the strength may be no higher, and the ductility can be lower, than those of some non-heat-treatable alloys. To obtain optimum properties of weldments, it may be preferable to weld in the annealed condition, and to solution heat treat and age afterward.

There is little difference between the strengths of welded and unwelded heat treatable and non-heat-treatable alloys in the annealed condition.

Casting Alloys. Most casting alloys can be gas-shielded arc welded if they are given the correct edge preparation. Aluminum sand and permanent mold castings are welded to repair foundry defects, to repair items broken in service, or to join cast fittings to wrought members. Formerly, die-cast fittings were seldom used where welded construction was required, because they often contained porosity, but recent advances in casting technique, such as vacuum die casting, have resulted in improved quality; die castings are now satisfactorily welded for some applications, such as irrigation tubing.

(a) Wrought alloys are identified by Aluminum Association designations. (b) Casting alloys are identified first by industry designations, and then parenthetically by Aluminum Association designations.

loys are given in Table 3. In addition, filler metals having the same composition as the base-metal alloy are often used for repairing casting defects.

Selection of Filler Metal. Common criteria to be considered in selecting a filler metal are ease of welding, strength, ductility, resistance to corrosion of the filler metal – base metal combination, color match with the base metal after anodizing, and service at elevated temperature. The filler metals listed in Table 3 have been developed to satisfy these requirements. A guide for selection of the filler metal that gives the optimum combination of these criteria for general welding of a selection of alloy combinations is shown in Table 4. Tables 5 and 6 rate filler metals for specific welding criteria — namely, ease of welding, as-welded joint strength and ductility, corrosion and heat resistance, and color match after anodizing.

Joint Design and Edge Preparation

In general, joint design for aluminum alloys is similar to that for steel (see the illustrations in the article on Recommended Proportions of Grooves for Arc Welding, beginning on page 148 in this volume). The fact that the fluidity of aluminum during welding is higher than that of steel makes for some differences: for example, in thin sheet, the root opening is smaller. Recommended butt-joint designs for gas-shielded arc welding are shown in Fig. 1. When using straight-polarity direct-current gas tungsten-arc welding, the root face can be thicker and the grooves narrower. Some butt-joint designs used for gas metal-arc welding are shown in Fig. 6 and Table 9.

Lap joints are used more often for aluminum alloys than for most other metals. The efficiency of lap joints is 60 to 80%, depending on the alloy and temper. Lap joints offer the advantages of no edge preparation being required and ease of fit-up, but have the disadvantage that inspection of the weld is difficult. Preferred types of lap joints are shown in Fig. 2.

T-joints are also widely used. Beveling is seldom required, but it is used on thick material to reduce welding costs and to minimize distortion.

Welding a lap joint or a T-joint on one side only is not recommended. It is better to use a small continuous fillet weld on each side of the joint.

Edge Preparation and Assembly. Material up to about ⅜ in. thick can be sheared to a reasonably square edge that can be cleaned readily. Shear blades should be kept free of oil and foreign material; the aluminum should be degreased before shearing if there is excessive lubricant on the surface.

Band sawing, using a stick-wax lubricant, can be employed for edge preparation of metal several inches thick. After sawing, all lubricant should be removed from the sawed surface.

Usually, no lubricant is used when machining joint edges. When a lubricant must be used, sharp cutting tools of correct design should be employed. Dull or improperly designed tools result in prepared edges that can trap lubricant, which can cause weld porosity.

The extra time needed to ensure a close fit is often less than the extra time required in welding an improperly prepared assembly. Better fit and uniformity of the joint are required for automatic and out-of-position welding than for semiautomatic and flat-position welding. Automatic gas tungsten-arc welding of aluminum less than ⅛ in. thick requires that joint fit-up should be held within 0.003 to 0.010 in., depending on metal thickness. A very close fit of the edges is also essential when gas tungsten-arc welding without the addition of filler metal.

Aluminum alloy extrusions are sometimes produced with edge designs that facilitate welding. Besides edge preparation, the design may include (*a*) self-aligning mechanical fitting (see Example 294); (*b*) integral weld backing (see Example 311 and section F-F in Fig. 36); or (*c*) an increase in section thickness at the joint area to make welding easier, or (as in Example 319) to compensate for the lower unit strength of the weld area than of the base metal — which is especially valuable in butt welds in heat treatable alloys used in structures too large for most furnaces used for postweld heat treating.

Preweld Cleaning

Preweld cleaning of aluminum is essential for optimum weld quality. Precleaning requirements are especially stringent prior to straight-polarity direct-current gas tungsten-arc welding, because under such conditions the arc exerts no cleaning action. However, the highest-quality welds are not always needed. Where service requirements permit, many aluminum parts are welded with no preweld cleaning at all.

Surface contaminants that should be removed from the base metal include dirt, metal particles, oil and grease, paint, moisture, and heavy oxide coatings. Another source of contamination is oxide film on the filler metal. Base metals such as 1100 and 3003 have a relatively thin oxide coating as-fabricated, and the 5*xxx* and 6*xxx* series al-

NOTE: All filler metals shown here are covered by AWS specification A5.10-69, prefixed by the letters "ER". Throughout this table, the prefix has been omitted, to conserve space. Filler metals 5356, 5556 and 5654 are not suitable for sustained service at temperatures higher than 150 F. Other service conditions, such as immersion in fresh or salt water or exposure to specific chemicals, may also limit the choice of filler metal. Where no filler metal is listed, the base-metal combination is not recommended for welding.

(*a*) Base metals 5254 and 5652 are used for hydrogen peroxide service. Filler metal 5654 is used for welding both alloys for service at temperatures of 150 F and below. (*b*) 4043 may be used for some jobs. (*c*) 4047 may be used for some jobs. (*d*) 4145 may be used for some jobs. (*e*) 5183, 5356 or 5556 may be used. (*f*) 1100 may be used for some jobs. (*g*) 2319 may be used for some jobs. (*h*) 5183, 5356, 5554, 5556 and 5654 may be used. In some cases they provide improved color match after anodizing treatment, highest weld ductility, and higher weld strength. Filler metal 5554 is suitable for service at elevated temperature. (*j*) Filler metal of the same composition as the base metal is sometimes used. (*k*) 5039 may be used for some jobs.

(a) F = flat; H = horizontal; V = vertical; O = overhead. (b) For design 8, $t_1 = t$ for t less than 3/8 in., and t_1 = 3/8 in. for t greater than 3/8 in.

Fig. 1. Recommended butt-joint designs for the gas metal-arc welding (dcrp) and gas tungsten-arc welding (ac) of aluminum alloys. Joints 2, 3, 4, 5 and 6 should be back gouged to solid weld metal before applying a pass on the root side.

loys generally have a thick, dark oxide coating. The thicker the oxide, the greater its adverse effect on weld-metal flow and solidification and the greater the risk of porosity. Any foreign material that remains on the surfaces to be welded is a potential source of unsound welds. For best results, all cleaning and oxide removal should be done immediately before welding.

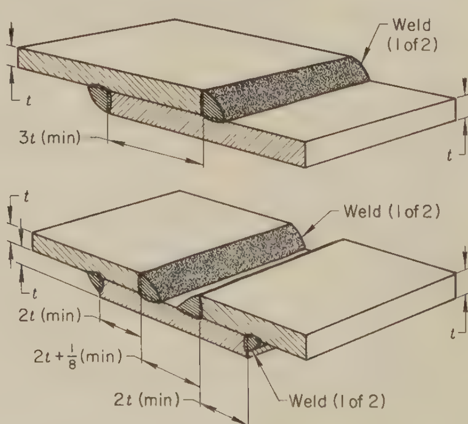

Fig. 2. Preferred types of lap joints for arc welding of aluminum alloys

First, the work-metal surface should be cleaned of contaminants. The following manual cleaning methods can be used for small production runs. Dirt can be removed easily by washing and scrubbing with a detergent solution; an effective drying procedure is necessary to ensure that no moisture is present on the surfaces to be welded. Removal of grease and oil can be accomplished by swabbing with solvent-soaked cloths. Suitable solvents include

Footnotes for Table 5

(a) Rating applies particularly to fillet welds. All filler alloys rated will develop presently specified minimum strengths in butt welds. (b) Rating based on continuous or alternate immersion in fresh or salt water. (c) Rating based on free-bend elongation of weld.

(d) Filler alloy 5183 has the same ratings as 5556, except that welds made with 5183 are slightly more ductile and, in cases where the filler metal controls the weld strength, slightly less strong than welds made with 5556. Because of its lower strength, 5183 filler metal is not recommended for welding 5456.

(e) Filler-metal alloys 5356 and 5556 are not recommended for corrosion resistance in welding alloy 1100, 3003 or 3004 to bare alloy 3003 or 3004, but are rated B for corrosion resistance in welding alloy 1100 or 3003 to alclad 3003 or 3004, and rated C for corrosion resistance in welding alloy 3004 to alclad 3004. (f) Ratings do not apply when heat treated after welding.

Table 5. Filler Metals Commonly Used in Arc Welding Combinations of Aluminum Alloys
(Ratings are relative, in decreasing order of merit, and apply only within a given block. Combinations having no rating are not recommended.)

Alloys to be welded	Ease of welding						Strength of welded joint (as-welded)(a)						Corrosion resistance(b)						Service at sustained temp above 150 F						Color match after anodizing						Ductility(c)

For footnotes, see facing page.

butyl alcohol, naphtha, acetone, carbon tetrachloride, and trichlorethylene. Butyl alcohol, naphtha and acetone must be used with care, because they are flammable; carbon tetrachloride and trichlorethylene should be used only with effective ventilation, and well away from the welding area, because they decompose and produce toxic fumes when contacted by the arc.

Next, heavy oxide layers should be mechanically removed with a wire brush, steel wool, mill file, portable milling tool, or a scraper. The use of abrasive paper or grinding disks alone is not recommended, because particles of the abrasive may become embedded in the aluminum and, unless subsequently removed, can cause inclusions in the weld. Wire brushes should have sharp bristles and should be kept free of oil and other foreign material; bristles preferably should be 0.012 to 0.016 in. in diameter and of stainless steel, to minimize iron oxide pickup.

Motor-driven wire brushes should be used carefully. If excessive pressure is applied, a burnishing action in which the oxide is rolled into the freshly exposed surface will result, and the weld may be of poorer quality than one made without wire brushing. However, enough pressure has to be used to cause the sharp bristles to break the oxide from the surface of the aluminum alloy.

Chemical removal of oxides can be accomplished by immersion in solutions of the butyl alcohol – phosphoric acid type. After the chemical treatment, the parts should be washed thoroughly with water and dried with hot air.

For thick and persistent oxide coatings, immersion in a 5% sodium hydroxide solution at 150 F for about 30 sec is recommended. This treatment leaves a dark smut on the surface. To remove the smut, the treatment should be followed by a cold water rinse, immersion in a solution containing equal parts of commercial nitric acid and water at room temperature, a final water rinse (preferably hot) and hot air drying. Heavy-etching caustic solutions are not recommended, because the rough surface that they produce is likely to collect hydrocarbons and foreign material.

It is preferable that degreasing and chemical cleaning be done before the parts are assembled for welding. Cleaning after assembly can result in retention of foreign material and solutions between abutting edges and lapped areas of the joint, and porosity and dross entrapment in the weld are likely to result.

Freshly machined and freshly filed surfaces are the cleanest and are often specified when the ultimate in weld quality is demanded.

Occasionally, special precleaning methods are used to solve a specific problem, as in the following example:

Table 6. Guide to Selection of Filler-Metal Alloys for Arc Welding Various Combinations of Heat Treatable Aluminum Alloys

(Ratings are relative, in decreasing order of merit, and apply to a given base-metal combination and postweld condition. The use of base metals as filler metals, or of combinations indicated here by dashes as having no ratings, is not recommended.)

Alloys to be welded(a)	Postweld condition(b)	Ease of welding						Strength(c)						Ductility(d)						Corrosion resistance(e)

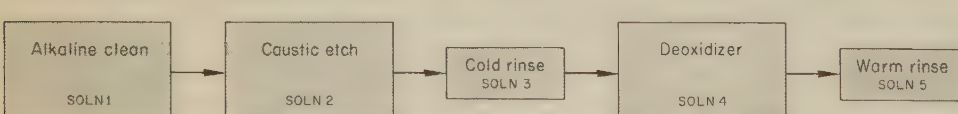
(a) Ratings for both bare and alclad materials are the same. (b) X = naturally aged for 30 days or longer; Y = postweld solution heat treated and artificially aged; Z = postweld artificially aged. (c) Ultimate strength from cross-weld tensile test. (d) Ratings based on free-bend elongation of weld. (e) Ratings based on continuous or alternate immersion in fresh or salt water. (f) 5183 and 5356 have the same ratings as 5556. (g) Filler alloy 5554 is suitable for welding 6061, 6063 and 7005 prior to brazing. (h) Filler alloy not recommended because of possible susceptibility to stress-corrosion cracking when postweld heat treated.



Solution Number	Solution Type	Composition	Operating temperature, F	Immersion time, minutes
1	Nonsilicated alkaline cleaner	3 to 4 oz/gal of water	140 to 150	5 to 10
2	Caustic soda etch	3 to 4 oz/gal of water	145 to 150	4 to 6
3	Cold water rinse	Water(a)	70	1 to 3
4	Chromic acid deoxidizer	11 to 13 oz/gal of water	70 to 90	6 to 10
5	Warm water rinse	Water(b)	135 to 145	1(c)

(a) Rinse should be overflowing, with air agitation. (b) Rinse should be overflowing, to remove the acid and warm the part for quick drying. (c) Minimum.

Fig. 3. Flow chart for five-step cleaning process used for parts to be welded to make a fuel-storage tank (Example 293)

Example 293. Preweld Cleaning of Parts for Fuel-Storage Tanks (Fig. 3)

Preweld cleaning required special attention in the fabrication of fuel-storage tanks for M-60 combat tanks from 80 individual parts, because the welded joints had to have optimum ductility and fatigue strength to withstand the severe vibrational stress to which the fuel-storage tanks were subjected in service.

Original preweld cleaning practice called for: (*a*) vapor degreasing (when necessary) to remove most of the foreign matter; (*b*) dipping in a caustic etching solution; (*c*) rinsing; (*d*) dipping in a nitric acid deoxidizing solution; and (*e*) rinsing. This method of cleaning, however, was unsatisfactory because:

1. The metal surfaces reoxidized after a few hours, which necessitated the recleaning of many parts and subassemblies during the welding of a tank.
2. During the caustic etch, the amount of metal removed from threaded parts was enough to cause the threads to be out of tolerance.
3. Use of nitric acid created a safety hazard.

A special chemical cleaning method consisting of five steps was therefore developed. The process is shown in Fig. 3 and described in the accompanying table. Parts with drawing compound or heavy soils were vapor degreased prior to step 1.

To prevent contamination of the chemical solutions, back rinsing was not permitted. Solution strengths were checked daily by titration and were kept in the composition ranges listed in the table.

Work metal was ⅛-in.-thick alloy 5086-H32 sheet, alloy 5083-H112 extrusions, and alloy 6061-T6 fittings. The design of the vehicle utilized every available cubic inch of space between the engine and the tank hull, and in consequence the left-hand and right-hand fuel tanks, composed of 50 subassemblies (80 parts), were of dissimilar and complex shapes. Although the irregular shapes were formed, wherever possible, by bending, approximately 20 ft of gas metal-arc tack welding and 200 ft of gas tungsten-arc welded seams were required per fuel tank. The details for tack welding are given in Example 305; joint-welding details are given in Example 311.

The special precleaning method produced a more stable surface on the aluminum alloy parts, which permitted a longer elapsed time between cleaning and welding, and permitted, under normal conditions,

complete welding of an assembly without recleaning. Solution 2 was bypassed when parts that were to be cleaned contained threads (as the etchant affected thread dimensions) and when recleaning was required for dusty parts and parts whose welding had been delayed.

Chemical recleaning could not be used on the subassemblies before final welding of the assembly because capillary action would have caused entrapment of reagents in the seams on some of the parts, which would have caused sputtering during welding. Therefore, these joints were recleaned mechanically with power brushes having stainless steel wire bristles.

Preheating

In gas-shielded arc welding of aluminum alloys, preheating of parts to be welded is normally employed only when the temperature of the parts is below 15 F or when the mass of the parts is such that the heat is conducted away from the joint faster than the welding process can supply it. Preheating may be advantageous for gas tungsten-arc welding with alternating current of parts thicker than about 3/16 in. and gas metal-arc welding of parts thicker than about 1 in. Gas tungsten-arc welding with reverse-polarity direct current is limited to thin material, and preheating is not necessary with this process. It is also not necessary to preheat thick parts when gas tungsten-arc welding using straight-polarity direct current, because of the high heat input provided to the work.

Preheating can also reduce production costs because the joint area will reach welding temperature faster, thus permitting higher welding speeds.

Various methods can be employed to preheat the entire part or assembly to be welded, or only the area adjacent to the weld can be heated by use of a gas torch. In mechanized welding, local preheating (and drying) can be done by gas or tungsten-arc torches installed ahead of the welding electrode.

The preheating temperature depends on the job. Often 200 F is sufficient to ensure adequate penetration on weld starts, without readjustment of the current as welding progresses. Preheating temperature for wrought aluminum alloys seldom exceeds 300 to 400 F, because the desirable properties of certain aluminum alloys and tempers may be adversely affected at higher temperatures. Aluminum-magnesium alloys containing 4.0 to 5.5% Mg (5083, 5086 and 5456) should not be preheated to between 200 and 450 F, because their resistance to stress-corrosion cracking will be reduced by this treatment.

Large or intricate castings should be preheated to approximately 800 F to minimize thermal stresses and to facilitate attainment of the welding temperature. After welding, such castings should be cooled slowly to minimize the danger of cracking. Castings that are to be used in the heat treated condition should be welded before heat treatment or should be reheat treated after welding. Preheating (and the heat of welding) may affect the corrosion resistance of some alloys — for instance, alloy 220 — unless welding is followed by heat treatment.

Preheating for weld repair of a plate is described in Example 307, and for a casting on page 318.

Fixtures

Design of fixtures is based on the expectation that dimensional changes in welding aluminum alloys will be twice as great as in the welding of steel. The coefficient of expansion of aluminum is about twice that of steel, and its melting point is about half that of steel. Thus, the change in dimensions from welding heat is in the same range as that for steel. However, the thermal conductivity of aluminum is greater. In general, the amount of expansion is inversely proportional to the speed of welding.

When butt welding aluminum sheet, the fixture should enable the sheet to be clamped with a uniform force of approximately 200 lb per linear inch of

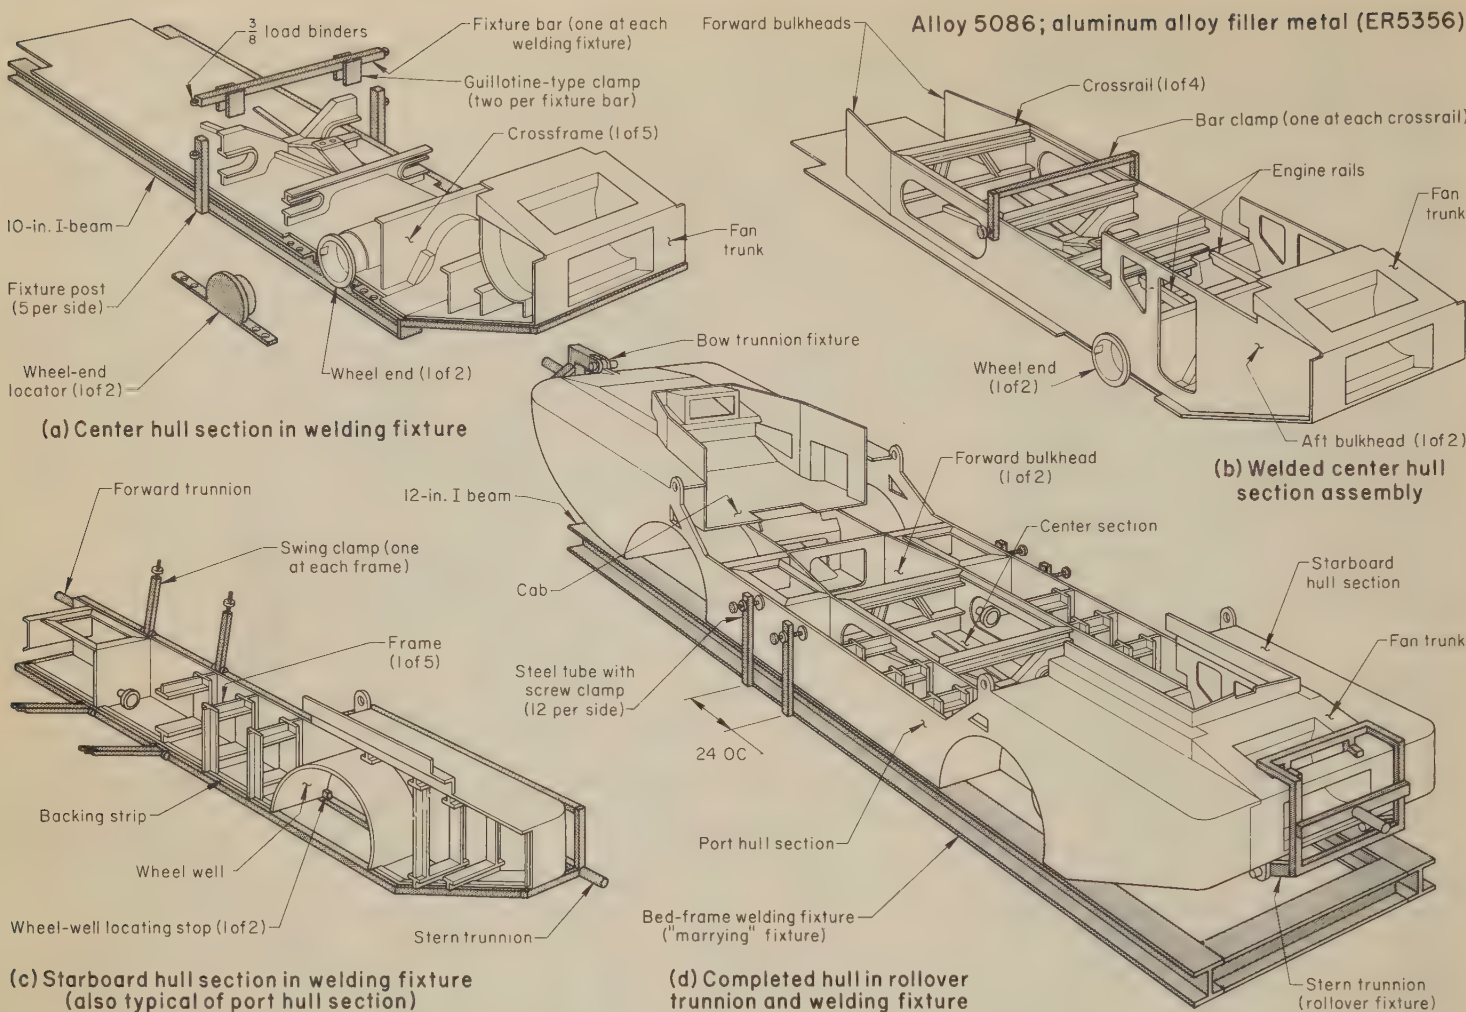

Fig. 4. Fixtures used for welding center hull section of an amphibious lighter to port and starboard hull sections (see also Example 297)

seam. This amount of force will usually ensure against movement of the sheet during welding. To guard against deflection of the arc, nonmagnetic materials, such as austenitic stainless steel, copper and aluminum, should be used for those parts of a fixture within 4 in. of the arc, and must be used for fixture parts within 2 in. of the arc.

Although rigid clamping reduces distortion, the inability of the weldment to contract, caused by the restraint, may induce residual stress as high as the yield strength of the base metal and may also result in cracking. To keep distortion to the minimum, the joint should be designed with minimum separation between members, and welding should be done in the minimum number of passes.

The several fixtures required for welding a 418-in.-long amphibious lighter are shown in Fig. 4. The fixtures included guillotine-type clamps for use with load binders, bar clamps, multiple swinging clamps, rollover trunnion adapters, I-beam bed plates with steel tubes around the outside edge (the basic "marrying" fixture), and screw clamps. The rollover feature was adopted to avoid out-of-position welding, as when a weld had to be made on the outside of the bottom of the hull. (Welding the center hull section to the port and starboard sections is described in Example 297.)

A fixture used in welding long pipelines is described in Example 298.

Because many aluminum alloy weldments incorporate extruded products, self-fixturing can often be employed. In the following example, the extrusions were designed so that the joints were self-aligning, thereby reducing both the assembly time and the cost of fixtures.

Example 294. Use of Extruded Shapes for Self-Alignment of Parts for Welding (Fig. 5)

By the use of self-aligning extruded shapes throughout, the modular instrument enclosure shown in Fig. 5 could be made as cheaply from aluminum as from steel. In this application, strength and seal-tightness were not important. Material costs were 60% higher for aluminum than for steel, but welding costs and overhead costs were lower, and less welding skill was needed. In addition, aluminum enclosures were lighter, required less maintenance, and had better corrosion resistance.

The enclosures were made of alloy 6061-T6. The roof, sides, base and doors were subassembled by means of interlocking mechanical joints, and then were assembled and welded only in strategic places, as shown in Fig. 5. The interlocking joints along the sides of the panel extrusions were left unwelded. The joints in the roof were calked with sealant, to make them dust-tight.

The self-aligning feature of the design can be seen in the corner detail in Fig. 5. A blank plate was used to maintain square alignment of the door opening.

Welding was done by the gas metal-arc process, using an electrode holder having an integral wire-feed drive from a 1-lb spool. The electrode holder, control unit, and power supply were a coordinated package. Initial voltage was set by the operator, and further adjustment was made by a wire-feed-rate dial on the electrode holder, which automatically adjusted welding current to the proper level. Additional information is given in the table with Fig. 5.

In later production, the original electrode holder was replaced by one having a pull-type wire feed from a 10-lb spool that was separate from the electrode holder. By using 10-lb spools instead of 1-lb spools, wire cost was reduced by approximately $1 per pound.

Electrode-wire selection was important from the standpoint of color match, because completed enclosures were not painted. ER4043 and some other electrode wires darkened in service. Preferred electrode was ER5154 wire having a bright finish, but ER5356 also met the color-match requirements and was used later.

Precleaning was not required, because the material was sufficiently clean and free of oil in the as-received condition.

Gas Metal-Arc Welding

The ability of gas metal-arc welding to deposit large quantities of weld metal in a short period of time has played a large part in the increased use of aluminum since the late 1940's. Typical conditions for gas metal-arc welding of aluminum alloys are given in Tables 7 through 10. Figure 6 shows

butt-joint designs for the conditions given in Table 10.

Thicknesses of aluminum alloys commonly joined by gas metal-arc welding range from ⅛ in. up to the maximum plate thickness available (several inches). In this thickness range, gas metal-arc welding is capable of high-quality weld deposits — for example, those meeting requirements of the ASME Boiler and Pressure Vessel Code. With the use of pulsed-current power supplies, some types of joints can be gas metal-arc welded in aluminum as thin as 0.030 to 0.040 in.

Welding speeds up to 55 in. per minute are obtained with semiautomatic welding, and speeds for machine and automatic welding can be as high as 180 in. per minute. Maximum welding speeds commensurate with the application are always desirable when welding aluminum alloys. The rapid cooling after welding, which results from high welding speeds, produces fine-grain weld deposits and retards the formation of low-melting constituents at the grain boundaries.

Power Supply and Equipment. Only reverse-polarity direct current (electrode positive), which gives good penetration and a cathodic cleaning action at the work surface, is used in gas metal-arc welding of aluminum alloys. The steady and pulsed direct-current power supplies, and the wire-feed systems, electrode holders, and control systems used for gas metal-arc welding of aluminum alloys, are the same as those used for gas metal-arc welding of other metals (see the article on Gas Metal-Arc Welding, on page 78). Push-type wire-feed systems can handle aluminum wire down to 0.045 in. in diameter, but for smaller wires, a pull-type or a push-pull system must be used. Grooved drive rolls are preferred; knurled rolls and serrated rolls are likely to chip off small particles of metal, which can enter the wire conduit and slow down or stop wire feed. Wire conduits, inlet guides, guide liners, and bushings for aluminum electrode wire should be of all-nylon or all-Teflon construction.

Shielding Gases for Gas Metal-Arc Welding

Argon, helium, and mixtures of the two, are used as shielding gases in gas metal-arc welding of aluminum alloys. Table 11 lists the preferred gases for various thicknesses of aluminum alloy to be welded.

Argon is generally preferred when welding thinner metal, mainly because of its lower arc heat. In addition, argon results in a smoother and more stable arc than helium, and thus much less weld spatter is obtained.

Helium, because of its greater arc heat, is capable of producing the deep penetration desirable in weld deposits in thicker metal. The bead profile with helium shielding is wider and less convex than with argon shielding, and the penetration pattern has a broader underbead. Welding with pure helium produces welds of darker appearance with some spatter. Helium is lighter than argon, requires higher flow rates, and it is more expensive. Therefore, helium is seldom used alone. However, in some jobs the use of higher currents, higher welding speeds and fewer passes can more than compensate for the higher cost of helium.

Argon-Helium Mixtures. To take advantage of the higher arc heat of helium without the disadvantages associated with using the pure gas, mixtures of argon and helium are usually used for out-of-position welding and in joining thick metal. Although users have individual preferences, mixtures ranging between 25 and 75% helium are most widely used. A helium-rich mixture, such as 75% helium and 25% argon, is frequently employed when welding workpieces more than 2 in. thick and is usually employed for out-of-position gas metal-arc welding. For workpieces more than 3 in. thick, helium-rich mixtures will maximize weld penetration and minimize porosity. When welding workpieces 1 to 3 in. thick in the flat position, increasing the current or voltage, or both, enables the helium content to be decreased.

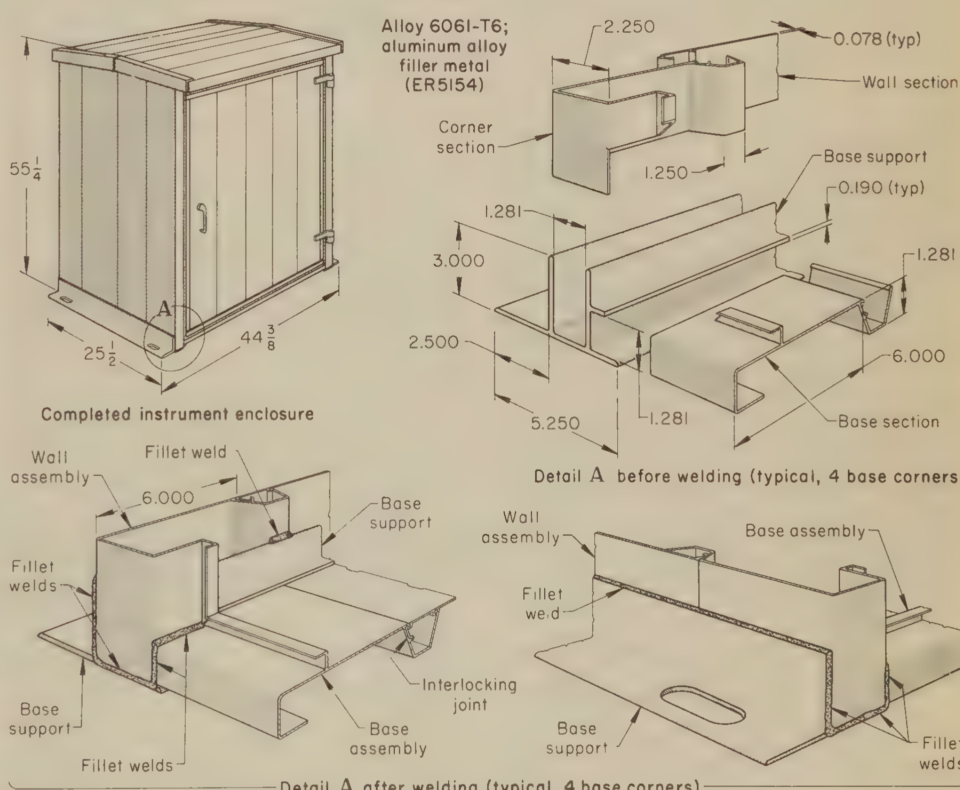
Oxygen Additions. Small percentages of oxygen are sometimes added to pure argon or to argon-helium mixtures. For some jobs they have been found to improve arc stability and make out-of-position welding easier. For example, in out-of-position welding thin sheet of alloys 1100 and 3003, a small amount of oxygen added to the argon shielding gas was found to improve solidification of the weld puddle. A drawback to the addition of oxygen to the shielding gas is that the welds are likely to contain a larger amount of entrapped oxide.

Nitrogen shielding gas plus a small amount of argon introduced separately through the contact-tube bore of the electrode holder results in an extremely hot, penetrating arc and has been used to produce welds of lowest cost and adequate strength and quality in EC electrical bus conductor.

Flow Rates. Typical shielding-gas flow rates for gas metal-arc welding of aluminum and aluminum alloys are given in Table 12. Note that helium requires about twice the flow of argon. The rate should not be greater than that which will have laminar flow.

Arc Characteristics in Gas Metal-Arc Welding

Increasing the welding current from low to high changes the arc from one producing short-circuiting metal transfer to one producing globular metal transfer and then to one producing spray metal transfer (see Fig. 2, page 79, in the article on Gas Metal-Arc Welding). Spray transfer produced by



Conditions for Semiautomatic Gas Metal-Arc Welding

Joint types	T, lap	Electrode wire	0.035-in.-diam ER5154(a)
Weld type	Fillet	Shielding gas	Argon, at 20 cfh
Power supply	200-amp, constant-voltage transformer-rectifier	Electrode stickout	¼ in.
		Current	130 amp, dcrp
Wire-feed system	Adjustable speed	Voltage	24 v
Electrode holder	200 amp, air cooled	Number of passes	One

(a) ER5154 is a former AWS classification that has been replaced by ER5654. ER5356, which met color-match requirements as well as ER5154, was used in later production.

Fig. 5. Modular instrument enclosure fabricated of extruded aluminum shapes. Note the self-aligning feature of the assembly. (Example 294)

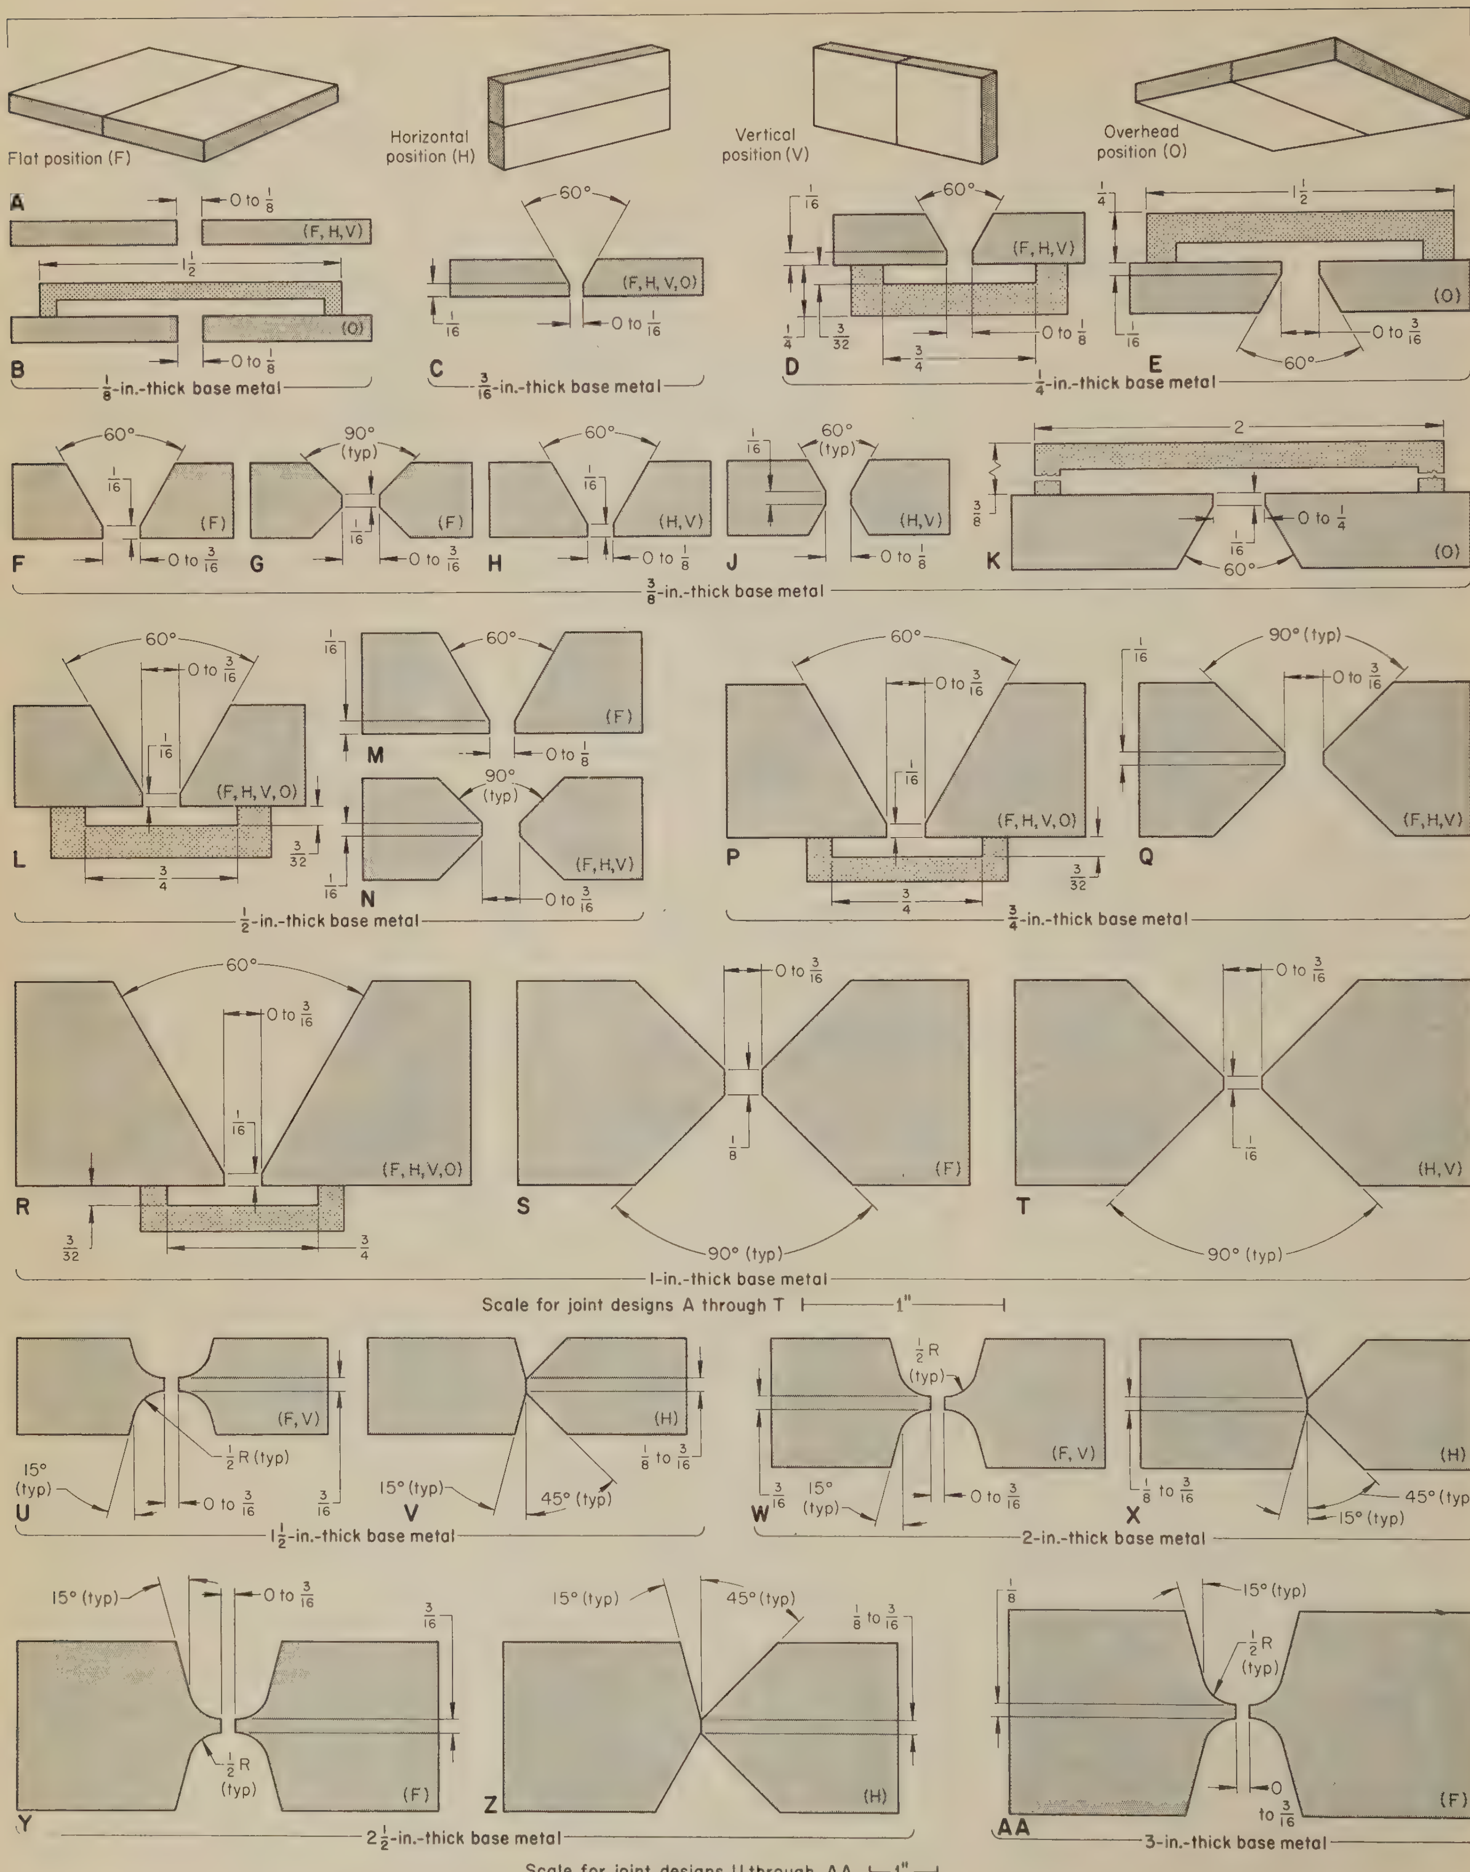


Fig. 6. Butt-joint designs for which applicable welding conditions are given in Table 10

either a steady-current arc or by a pulsed-current arc is used for almost all gas metal-arc welding of aluminum alloys. In some special applications, globular transfer and steady current are used instead.

To obtain spray metal transfer from steady-current arcs requires extremely high current densities when welding aluminum alloys. It is not uncommon to employ current densities ranging from 50,000 to 300,000 amp per square inch of electrode cross section. In contrast, current densities for gas tungsten-arc welding of aluminum alloys and for gas metal-arc welding of steel are about 10,000 amp per square inch.

The steady-current and current-density ranges in which the transition from globular to spray transfer takes place depend on the electrode size and the arc voltage employed. For a 3⁄64-in.-diam electrode and 22 to 31 volts, the change in type of transfer occurs at about 120 amp, or about 70,000 amp per square inch. Increasing the electrode diameter to 3⁄32 in. increases the transition current to about 220 amp, but decreases the current density to about 30,000 amp per square inch. When electrode diameters are larger than standard, the current density for the transfer transition is further reduced. The steady currents and wire-feed rates at which transfer transition takes place for electrodes of standard sizes are shown in Fig. 7. Pulsed currents must be used in order to achieve spray transfer at lower average currents and wire-feed rates.

Spray Transfer. Two of the notable characteristics of the spray-transfer arc are its stiffness and its narrowness; these advantages are described below:

Arc Stiffness for Deep Penetration. There is no lack of weld penetration when using spray transfer. Even in the low range of welding currents, the use of high current density and small-diameter electrode wire establishes a stable arc column with a well-defined pattern on the workpiece. To ensure fusion at the root of a butt joint, a minimum amount of root reinforcement is required, usually 1⁄32 to 3⁄16 in., depending on metal thickness and joint design.

Arc Stiffness for Out-of-Position Welding. When using spray transfer, the transfer follows the direction in which the electrode wire is pointed, which makes this type of transfer suitable for out-of-position welding. It can be an advantage when complicated parts require welding in several positions, such as in Examples 297 and 305. Spray transfer is also used to make a circumferential weld around a part too large to rotate, such as the welding of pipeline in Example 298.

Arc Narrowness for Small Fillet Welds. The spray arc has a narrow stable core, which concentrates the heat. This property enables fully fused small fillet welds to be made in relatively thick material.

In one application, corner joints having a minimum amount of weld metal and a minimum heat-affected zone were welded in thick alloy 5083 plate at minimum welding cost. Two basic joints were developed for near-minimum penetration (Fig. 8). Either a constant-current or a constant-voltage heavy-duty power supply was used, along with a heavy-duty wire-feed system and a water-cooled electrode holder. The electrode wire was 3⁄32-in.-diam ER5356. This wire size was chosen because the base metal was thick enough to prevent melt-through, it cost less per pound than smaller-diameter wire, and it was the largest diameter that could be deposited in all positions with semiautomatic equipment.

(a) Letters refer to joint designs in Fig. 6. When joint designs V, X and Z are used in the horizontal welding position, the 15° bevel should be on the bottom plate. (b) F = flat; H = horizontal; V = vertical; O = overhead. (c) Based on 100% arc efficiency at electrode-wire feed shown.

Very small fillet welds can be made in thinner workpieces, such as between the 1⁄4-in.-thick liner ring and the 1⁄8-in.-thick truncated cone shown in Fig. 9. In this application, using 3⁄64-in.-diam ER5183 electrode wire, it was not difficult for the welding operator to maintain a small weld bead and thus to hold to a minimum any distortion that could have taken place had the weld been larger.

Arc Narrowness for Square-Groove and Narrow-Groove Butt Joints (High-Current-Density Welding). The concentrated heat of the spray arc can also be used to weld butt joints with square or narrow grooves, thus reducing the amount and cost of the electrode wire required to make the joint.

Techniques have been developed to extend the usable current densities into the high range (to 300,000 amp per square inch), to take advantage of the very narrow penetrating arc. (At these high current densities, the characteristic hissing noise of the arc is replaced by a crackling noise.) These techniques are especially suitable

Table 11. Shielding Gases and Gas Mixtures Commonly Used for Gas Metal-Arc Welding of Aluminum Alloys

Work-metal thickness, in.	Shielding gas or mixture
0 to 3⁄4	100% argon
3⁄4 to 2	100% argon
	75% argon, 25% helium
	50% argon, 50% helium
2 to 3	50% argon, 50% helium
	25% argon, 75% helium
Over 3	25% argon, 75% helium

when making square-groove butt joints in base metal from ¼ to ⅝ in. thick. Welding is often accomplished in two passes, one from each side, at a much greater speed than is possible at lower current densities. Back gouging is rarely required, and welding in one pass instead of several stringer-bead passes greatly reduces the total heat input. The reduction in heat input results in less distortion and, in heat treatable alloys, produces better as-welded properties. Most welds made with the "square-butt" and "high-current" techniques are of better quality than standard radiographic requirements demand.

Thicknesses greater than ⅝ in. can also be welded with a square-groove butt joint, but the amount of reinforcement may be excessive. Where reinforcement must be minimized, V-grooves can be machined in both sides of the joint to the amount required. Figure 10 shows how two 1¾-in.-thick plates of alloy 5083 were joined, using only one pass from each side, with 450-amp welding current, 28 volts, 100 cu ft per hour of argon for shielding, and 1/16-in.-diam ER5356 electrode wire.

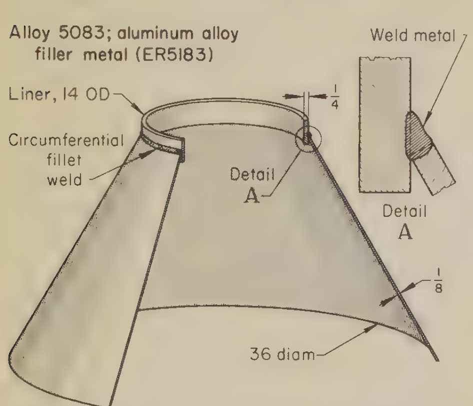

Fig. 9. Cone and liner ring that were joined by a small fillet weld to minimize distortion

The degree of bevel required with high-current-density welding is considerably less than with conventional welding. The root face is quite thick — usually about half the thickness of the plate. Joint preparation is not critical; machining need not be as accurate as for conventional joints.

Good results can be achieved with either a constant-current or a constant-voltage power supply. Argon should be supplied at 60 to 100 cu ft per hour, without excessive turbulence. The electrode holder and welding machine must have suitable current-carrying capacity. At present, high-current-density welding is normally used for automatic welding in the flat position where the welding conditions can be closely controlled. See Table 13 for conditions.

Table 14 presents the results obtained in tension and bend tests on single-V-groove joints made by conventional methods and typical square-groove butt joints made by high-current-density methods. The economic advantage of high-current-density welding with square grooves is evident.

Pulsed-arc transfer is a type of spray transfer that occurs in pulses at regularly spaced intervals. In the time interval between pulses, the welding current is reduced and no metal transfer occurs. The low average current and low heat input associated with pulsed-arc welding have allowed the advantages of spray transfer to be extended to the welding of sections thinner than can be spray-transfer welded using conventional steady-current power supplies. (Previously, short-circuiting transfer was used to gas metal-arc weld sheet of this lower thickness.)

In addition to enabling the spray-transfer welding of aluminum 0.030 to 0.125 in. thick, pulsed-arc transfer offers other advantages. One is the option of using larger-diameter electrode wires, which cost less per pound, are easier to feed, have fewer current-transfer problems in the contact tube, and have a lower probability of weld porosity from surface contamination on the wire because of the lower surface-to-volume ratio of the larger wire.

Another advantage is that sheet can be welded to heavier plate, even when the joint has a poor fit. A layer of metal is progressively built up on the thicker section until the gap is bridged.

Well-formed root beads and finishing beads are easily made on thin aluminum with pulsed-arc welding, whereas the beads made by short-circuiting transfer have high crowns, which consume more filler metal, can cause distortion due to the unbalanced cross section of single-pass welds, and have poor appearance. Also, adjusting welding conditions to obtain good fusion with short-circuiting transfer is difficult. This type of transfer has been largely replaced by pulsed-arc transfer.

Globular Transfer. The type of arc that produces metal transfer by a large drop of molten metal is seldom used when welding aluminum alloys because with conventional steady-current power supply the transfer is likely to be erratic. But, because the arc penetration is shallower and the heat input is lower at the current densities that produce this type of transfer, globular transfer has occasionally been used when welding metal thinner than that normally welded with spray transfer and steady current (⅛ in. and less).

Globular transfer was successfully employed in joining the side of about 1200 ft of 1-in.-OD, 0.065-in.-wall alloy 3003 tubing to the surface of ⅛-in.-thick alloy 3003 sheet with a single-flare bevel-groove weld. A steady current of 120 to 130 amp and a voltage of 19 to 19½ volts were used with a constant-voltage power supply, a shielding-gas mixture of 75% argon and 25% helium, and 0.020-in.-diam ER4043 electrode wire. Welding speed was 15 in. per minute, using manual manipulation of the electrode holder. Only two

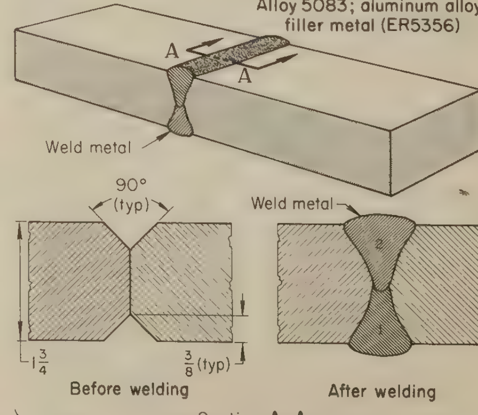

Fig. 10. Edge preparation for high-current-density welding of aluminum plate 1¾ in. thick, with one pass from each side

leaks, both caused by excessive melt-through, needed to be repaired.

Electrode Wires for Gas Metal-Arc Welding

Classifications and compositions of electrode wires are given in Table 3. Standard wire sizes are available in 1-lb and 10-lb spools in sizes from 0.030-in. to 0.040-in. diam and in 1-lb and 15-lb spools in sizes from 3⁄64-in. to 1⁄8-in. diam. Deposition and wire-feed rates obtained with two common electrodes in the standard sizes are shown in Fig. 11 for various welding conditions.

Electrode-wire feed should be selected so that the wire is consumed as fast as it emerges from the electrode holder, without extending more than 3⁄8 in. beyond the shielding-gas nozzle. The electrode holder is tilted not more than 10° forehand. The arc length that should be used is governed by the metal thickness, the type of joint, and the welding current. When making small fillet welds and welding narrow-groove butt joints, a short arc is preferred. Arc length is usually 1⁄8 to 3⁄8 in.

The wire size chosen for each application depends on the requirements and welding conditions for that application. The following example describes the successful semiautomatic gas metal-arc welding of one of the aluminum-copper alloys, using a fairly small-diameter electrode wire and a special joint design.

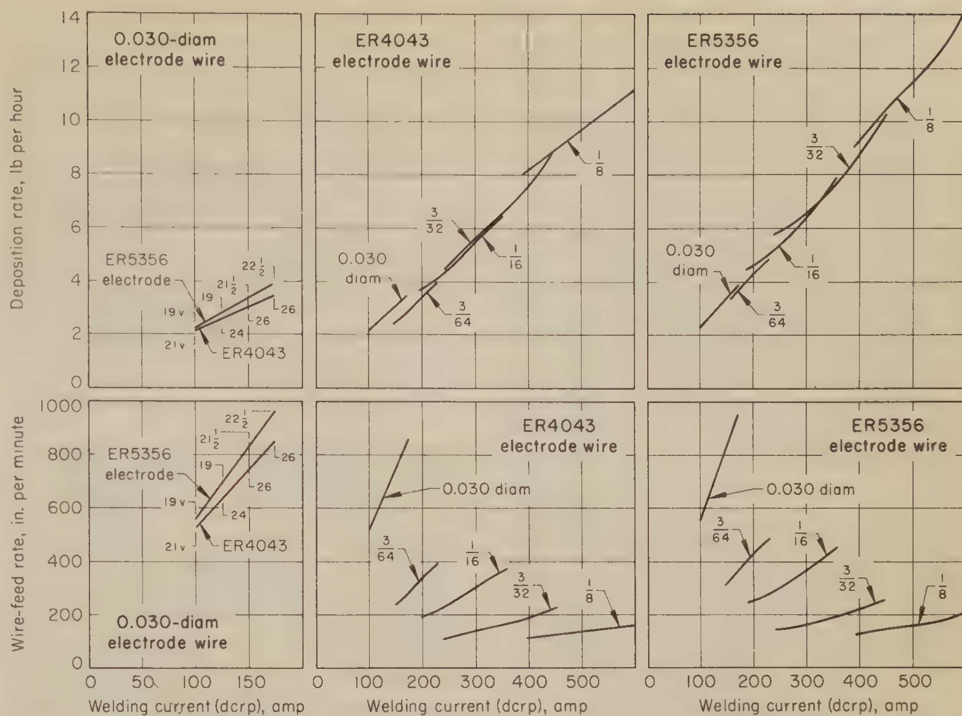

Fig. 11. Typical deposition rates and wire-feed rates for gas metal-arc welding with ER4043 and ER5356 electrode wire, under argon shielding

Example 295. Semiautomatic Gas Metal-Arc Welding of 1⁄4-In. 2014-T6 Plate, Using a "Step-Down" Joint and 3⁄64-In.-Diam Electrode Wire (Fig. 12)

Alloy 2014-T6 plate 1⁄4 in. thick was butt welded in two passes by semiautomatic gas metal-arc welding, using a special step-down joint, an electrode wire of smaller diameter, a helium-argon atmosphere, and a special backing insert.

The purpose of the step-down joint (Fig. 12) was to ensure uniform root penetration and a smooth contour on the root surface. This joint was superior to a V-groove joint because the arc produced by the conventional power supply used might have wandered on the groove face of a V-groove joint; this undesirable wandering does not occur in a step-down joint. A further advantage was the ease with which a uniform land could be machined into the plate edges.

Use of the 3⁄64-in.-diam electrode wire, rather than the 1⁄16-in.-diam wire normally used with 1⁄4-in. plate, allowed a lower welding current while maintaining a high current density and a uniform metal transfer (spray type). The step-down joint enabled a relatively low welding current to be used for the root pass to avoid melt-through. The smaller-diameter wire also resulted in a more concentrated plasma cone and faster welding, which helped to reduce the width and severity of the heat-affected zone. The 3⁄64-in.-diam wire was used for both passes. ER4043 filler metal was chosen for its low crack sensitivity.

A 75% helium, 25% argon gas mixture was used for shielding, primarily so that the cover pass would be wider and the weld could be completed in two passes.

The weld backing bar contained a grooved insert that was made of either a metal with low thermal conductivity (such as stainless steel) or one with high thermal conductivity (such as copper), depending on the heat flow encountered in each

Table 14. Typical Test Results and Cost Factors for Gas Metal-Arc Welds in 1⁄2-In. Alloy 5356 Plate

(a) High-current-density welding. (b) Standard is 6⅔t.

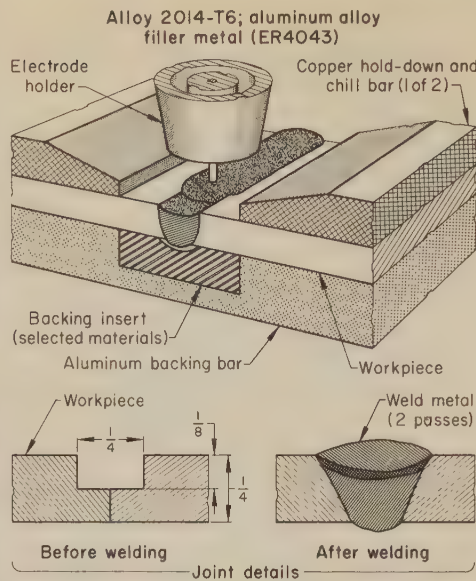
individual welding job. Use of a low-conductivity metal insert was likely to produce a smoother contour at the root surface than use of the high-conductivity metal insert. However, the risk of melt-through was somewhat greater when using the low-conductivity insert, and the cooling of the weld area was slower, which somewhat increased the width and severity of the heat-affected zone.

Before assembly for welding, joint surfaces were chemically cleaned by brush application of a commercial cleaner, wiping the joint clean, and then drying it with a clean cloth. After completion of the root pass, the face of the weld was cleaned with a rotary stainless steel wire power brush, in preparation for the cover pass.

Conditions for welding are given in the table that accompanies Fig. 12.

[In addition to the technique described above, pulsed-arc welding may be used with a V-groove joint to join ¼-in.-thick alloy 2014-T6 plate.]

As a rule, electrode wires from 0.030 to 3/32 in. in diameter are used with semiautomatic and automatic welding. The ⅛-in.-diam size is normally used only with automatic welding, as in the following application.



Semiautomatic Gas Metal-Arc Welding

Joint type	Butt
Weld type	Step-down groove
Joint tolerances	0.025-in. max root opening; ±0.005-in. max mismatch
Welding position	Flat
Power supply	500 amp, constant voltage
Fixtures	Copper hold-down and chill bars; aluminum backing bar with grooved insert
Electrode holder	500 amp, water cooled
Electrode wire	3/64-in.-diam ER4043
Shielding gas	75% helium, 25% argon, at 100 cfh
Number of passes	Two

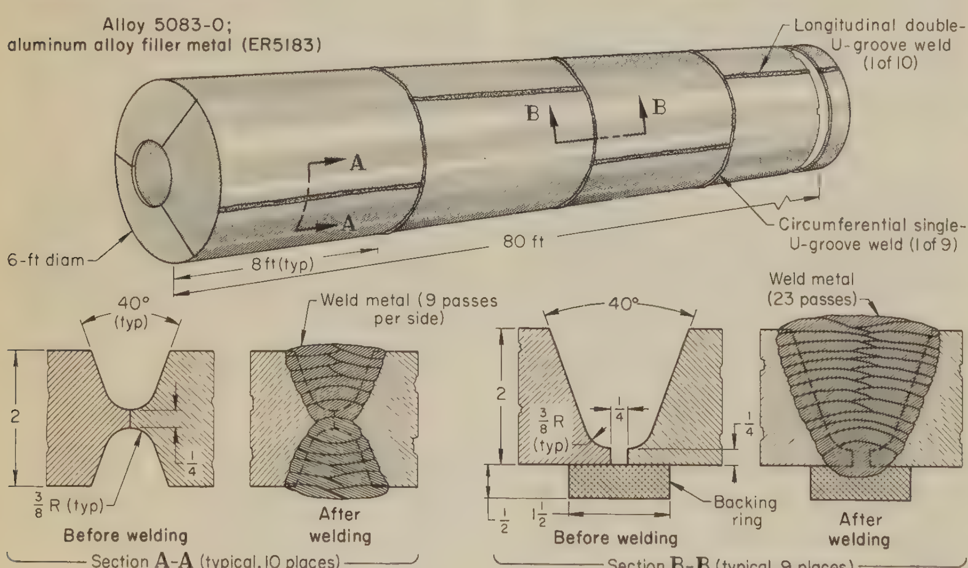
	First pass	Second pass
Current (dcrp), amp	215	140
Voltage, v	28	30
Welding speed, ipm	29	15

Fig. 12. Welding setup, showing special step-down joint design and backing bar with insert for varying cooling effect (Example 295)

Example 296. Use of ⅛-In.-Diam Electrode Wire and Automatic Welding To Decrease Welding Time for Large Heat Exchangers (Fig. 13)

Several heat exchangers, 6 ft in diameter and 80 ft long, were constructed by welding 2-in.-thick alloy 5083-O formed plate sections by the gas metal-arc process. Because of the size of the heat exchangers and the thickness of the metal, welding conditions that would keep welding time to the minimum were desirable.

Double-U grooves were machined on the plates for longitudinal welds, where welding could be done from both sides, and single-U grooves were machined for circumferential welds, where welding could be done from one side only. The single-U grooves were permanently backed with aluminum rings. Design of the two types of grooves is shown in Fig. 13.



Conditions for Automatic Gas Metal-Arc Welding

Joint type	Butt
Weld type:	
Longitudinal welds	Double-U groove
Circumferential welds	Single-U groove
Power supply	1000 amp, constant voltage
Electrode holder	800 amp, water cooled
Electrode wire	⅛-in.-diam ER5183
Shielding gas	75% A, 25% He, at 60 cfh
Welding position (all welds)	Flat
Current	460 to 480 amp, dcrp
Voltage	35 v
Welding speed	18 to 20 ipm
Number of passes, longitudinal welds	18
Number of passes, circumferential welds	23

Fig. 13. Heat exchanger that was welded by automatic gas metal-arc welding, joint design, and welding-pass sequence (Example 296)

The double-U grooves were filled with fairly small beads by making five passes on one side, back gouging the root and making all nine passes on the other side and then making the last four passes on the first side; the single-U grooves were filled in 23 passes. The small size of the individual beads resulted in a weld having good ductility, but because of the high welding speed used the total welding time was no more than would have been needed to fill the grooves by using fewer passes and producing larger weld beads.

The flow rate of the 75% argon, 25% helium gas was great enough (60 cfh) to ensure adequate shielding at all times; increasing the flow would not have been necessary had field erection been required.

Use of ⅛-in.-diam electrode wire, instead of the 3/32-in.-diam wire often used to weld 2-in. plate, reduced the number of passes that were needed by about one-half, and fully automatic welding permitted higher welding speeds. Use of automatic welding also ensured good control of weld quality. No peening or other in-process treatment was required during welding, and porosity was at an acceptable level. Welding conditions were the same for both types of joints and are given in the table that accompanies Fig. 13.

Welding With Large-Diameter Electrode Wires. The current density required for spray transfer with steady current is reduced for electrode sizes larger than standard. Current densities of 12,000 to 30,000 amp per square inch are used for welding with 5/32, 3/16, and 7/32-in.-diam electrode wires, compared with 30,000 to 100,000 amp per square inch for welding with 3/64 to ⅛-in.-diam wires. Using the larger-diameter wires, deposition rates of 15 lb per hour are readily obtained, compared with 5 to 10 lb per hour for standard sizes of wire, making this a method for low-cost welding of thick aluminum plate in the flat position. Most gas metal-arc equipment is designed for use with electrode wires not exceeding ⅛ in. in diameter, and this equipment may not be suitable for welding with large-diameter wires. However, suitable equipment can usually be made by converting submerged-arc equipment. Constant-current motor-generator power supplies are preferred, although rectifiers have been used.

When welding with large-diameter electrodes, somewhat different techniques are required to ensure 100% fusion to the sidewalls of grooves. In general, double-V grooves with fairly wide included angles (45° to 90°) are preferable to deep, narrow grooves. Shorter arc lengths, which give more fusion at the sidewalls, must be used. The arc should be shortened until the characteristic hissing disappears and is replaced by a popping sound. The welding speed should always be low enough to allow the arc to impinge on the molten puddle. Although 100% argon can be used for most applications, the addition of helium to the argon increases penetration. Conditions for welding butt joints in metal thicknesses from ¾ through 3 in. are given in Table 15; Table 16 summarizes conditions for welding corner joints with fillets sized from ½ through 1½ in. Every procedure listed in the tables has met the requirements of Section IX of the ASME Boiler and Pressure Vessel Code. Thick-wall spheres, large cranes and other massive structures have been welded by this method.

Weld Backing for Gas Metal-Arc Welding

Backing bars are commonly used for gas metal-arc welds in butt joints, as this permits welding to be accomplished at higher speed, with less operator skill and with less control of welding conditions, especially when using spray transfer for joining thin sections. Steel is the material most commonly used for temporary backing of welds in aluminum alloys. Carbon steel is often used, but stainless steel is used when lower thermal conductivity is required in the backing. Copper and aluminum may be used when higher thermal conductivity is needed. Backing made of magnetic material sometimes deflects the arc and interferes with welding. When this occurs, nonmagnetic materials such as austenitic stainless steel, copper and aluminum should be used instead.

Austenitic stainless steel backing bars have reasonable life against arc damage and do not produce arc blow; their use minimizes the possibility of iron or rust pickup in the root bead. When copper backing is used, copper pickup must be prevented. Local deposition of copper or copper-aluminum alloy can result in corrosion in service. Life of copper backing is somewhat less than that of stainless steel, especially under direct arc impingement. Chromium plating of copper backing has been used to reduce copper pickup and increase backing life. Aluminum backing with a hard anodic coating will provide adequate chilling; an added advantage is that the arc will not strike the aluminum backing and cause damage, because the anodic coating is an excellent dielectric.

Backing bars may be temporary, permanent, or integral. Temporary aluminum backing is removed by chipping after welding. It is not necessary that a butt weld be completely fused to the temporary aluminum backing, provided that the root pass is back gouged to sound metal after the backing bar has been removed. Temporary backing should be grooved to allow the root surface of the weld to protrude beyond the plane of the back surface of the workpiece, thereby ensuring adequate penetration. This groove should be shallow (0.010 to 0.030 in.) and wider than the width of the root surface of the weld. Too wide a groove will give insufficient support to the metal under the hold-down clamps.

Although the chilling effect of the backing bar may be advantageous at times, at other times it may be a disadvantage, and then it is common practice to place sheets of asbestos between the backing bar or clamps, and the work metal. The asbestos sheets should not be placed directly beneath the joint. Properly placed strips of asbestos will provide a backing groove and will eliminate the need for a groove in the backing bar.

Temporary backing bars may be seen with the butt welds in Fig. 6. Example 295 describes how backing inserts of different metals can be used to slow down or accelerate the cooling of a joint during welding.

When permanent aluminum backing is used, it is necessary to obtain complete fusion between the backing, the root faces and the root layer of the weld. This is facilitated by using a greater root opening than is employed with temporary backing. Mechanical and magnetic oscillation can be used to help achieve fusion to both root faces in a single pass. Permanent backing bars are shown with the five welds in Table 17. Service conditions do not always permit the use of permanent backing, but by eliminating the back gouging required when temporary backing is used, the use of permanent backing (when permitted) can reduce costs, as in the following example.

Example 297. Use of Permanent Backing Strips for Sounder Welds and Savings in Labor (Fig. 14)

Permanent backing strips were used in joining the starboard and port hull sections to the center hull section of an amphibious lighter made of 3⁄16-in.-thick alloy 5086 sheet. The strips, 1 in. wide by 3⁄16 in. thick, were tack welded to the inside seam edge of both the starboard and port hull sections while they were still in the subassembly fixture (Fig. 4c). The tack welds were 2 in. long on 6-in. centers. The starboard and port hull sections were then hoisted into the final assembly fixture (see Fig. 4d), and tack welded to the center section. Bulkheads and braces were welded in place and the bow was joined to the hull. Finally, the trunnions were fastened in place and the hull was turned over in the fixture

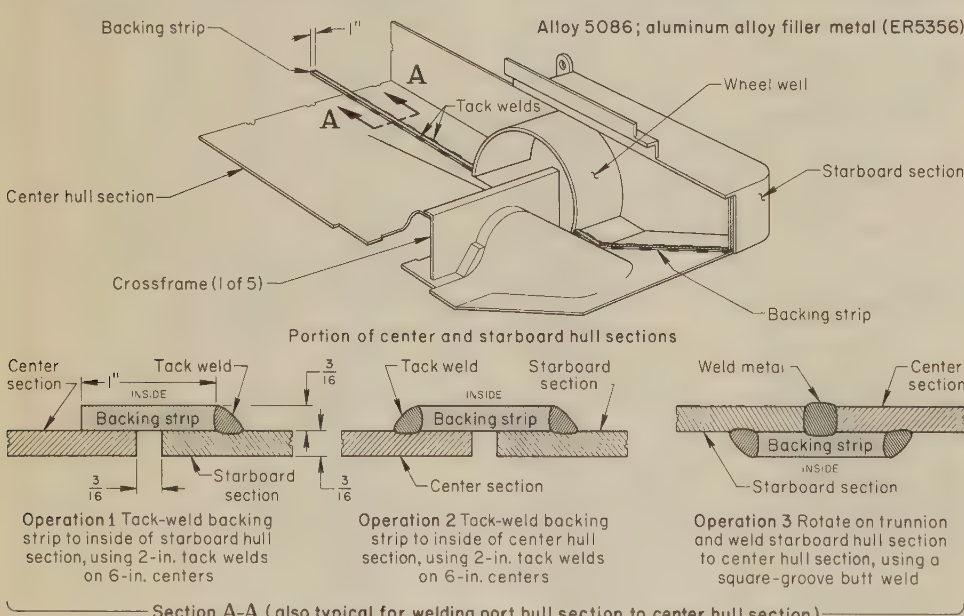
to make the longitudinal weld on the outside. One welding pass was needed for one-third of the length and two passes for the other two-thirds. The placement of the backing strip and the welding sequence for attachment of the strip are shown in Fig. 14. The welding conditions are given in the table that accompanies Fig. 14.

The procedure originally used involved no backing strips. The first weld was made on the inside of the hull, the assembly was rotated, the root of the weld was back gouged by grinding, and two more passes were made on the outside of the joint.

The use of backing strips resulted in a saving of 8 hr of welding and back-gouging time at a cost of ½ hr to install the backing strips and an added material cost of $5.00. Because the welds using the improved method were subject to less rework based on the results of radiographic inspection, there was an added saving in reduced repair time. These improvements led to improved material flow, eliminated the need for one of the two trunnion fixtures, thus gaining 200 sq ft of floor space, and freed two machines for other welding.

Warpage was a serious imperfection, irrespective of the welding method and was never completely eliminated. Welding with a wandering sequence was helpful, but was at the discretion of the operator.



Conditions for Semiautomatic Gas Metal-Arc Welding

Joint type	Butt
Weld type	Square groove
Welding positions	Flat, vertical
Power supply	300-amp, constant-voltage transformer-rectifier
Fixtures	Assembly and clamping, mechanical shield jigs, permanent backing strip (see Fig. 4)
Precleaning	Wire brush, wipe with acetone
Electrode holder	Manual, water cooled
Electrode wire	3/64-in.-diam ER5356
Shielding gas	Argon, at 35 to 45 cfh
Current	220 to 250 amp, dcrp
Voltage	26 to 27 v
Welding speed	About 14 ipm
Number of passes	One, for flat position; two, for vertical position

Fig. 14. Section of amphibious lighter, showing use of backing strip for joining starboard and port sections to center hull section (Example 297)

Butt joints in extrusions can be designed so that the weld backing is an integral part of the extrusion. Integral backing is not recommended in environments where the nonwelded portion of the backing can promote crevice-type corrosion.

Multiple-Pass Gas Metal-Arc Welding

When welding joints in thin-wall vessels, it is sometimes desirable to use two passes rather than one, to avoid leakage due to porosity; gases can escape more easily from the smaller weld puddles, the second pass can fill some of the porosity that may exist in the first-pass weld bead, and there is little probability that any remaining pore in the first-pass bead will line up with a pore in the second-pass bead to produce a through hole.

For butt welding sections ⅜ in. thick or thicker, common practice is to weld from both sides when possible. Whether or not the first weld penetrates to the underside, the bead should be back gouged into sound fused weld metal before depositing the backing bead. Back gouging removes entrapped oxide film at the base of the weld bead. Proper depth is attained by gouging to the point where the chip no longer splits along the oxide film entrapped at the original face of the joint. Back gouging can be accomplished by a pneumatic hammer and knife-edge chisels of proper design, or by machining. Oil should not be used when back gouging, or it should be removed prior to welding. Disk grinders should not be used. Portable back-gouging equipment that employs shaped milling cutters is available. Regardless of method, the back-gouging groove should be of uniform shape, with no torn metal, sharp corners, or crevices from which oil or foreign material cannot be removed.

It is advisable to check that all defects extending to the gouged surface have been removed before depositing the backing bead. This check may be done by dye-penetrant inspection or, for the ultimate in weld quality, by radiographic inspection (as in Example 307) or ultrasonic inspection.

The shells of most aluminum vessels are thick enough to require at least two welding passes. In the feed-gas cooler shown in Fig. 15, 45 passes, made in the horizontal welding position, were required to complete the joining of a 3-in.-thick tube sheet to a 1½-in.-thick by 18-in.-OD pipe, both made from alloy 5083-O plate. In order to facilitate welding, the cooler was placed on turning rolls and rotated. Two welders worked simultaneously on the job; one at the 12 o'clock position and the other at the 6 o'clock position. The electrode holders were hand held, but were provided with supports to minimize operator fatigue. A constant-voltage power supply, a shielding-gas mixture of 75% argon and 25% helium, and ER5183 electrode wire were selected. A 1/16-in.-diam wire was used, allowing maneuverability of the electrode holder. None of the welded coolers failed the mass-spectrometer leak test.

Conditions for making multiple-pass welds in butt, corner and T-joints in ¼ and ⅜-in.-thick alloy 6061-T6 are given in Table 17. A multiple-pass technique was used in Example 298, for welding of pipe, and in Example 306, where leaktight joints were required.

Automatic Gas Metal-Arc Welding

When the size of the production run warrants the installation cost and setup time, the use of automatic gas metal-arc welding equipment offers several advantages, among which are better quality on a more consistent basis and higher welding speed than can be obtained with manual manipulation of the electrode holder. An application where the higher welding speed greatly reduced welding time is described in the following example.

Example 298. Use of Automatic Gas Metal-Arc Welding of Pipe To Greatly Reduce Welding Time (Fig. 16)

Joining lengths of alloy 6351-T4 pipe in the field by automatic gas metal-arc welding was found to be economical for lengths of five miles or more for a 6-in.-diam pipe (Fig. 16).

The U-groove joint with ends butted tightly, as shown in Fig. 16, was essential for the process. After cleaning the joint by wiping with solvent, alignment and backing for the root bead were accomplished by an internal tool that could be expanded and collapsed manually by means of an extension handle. Use of the alignment tool made tack welding unnecessary. The alignment tool was withdrawn as soon as the root bead was completed; it was used to align the next joint while welding of the previous joint was continued.

Welding was accomplished with an air-cooled electrode holder (with electrode-wire spool attached) mounted on a machine that rotated it around the pipe. In this way, a six-pass weld was finished without

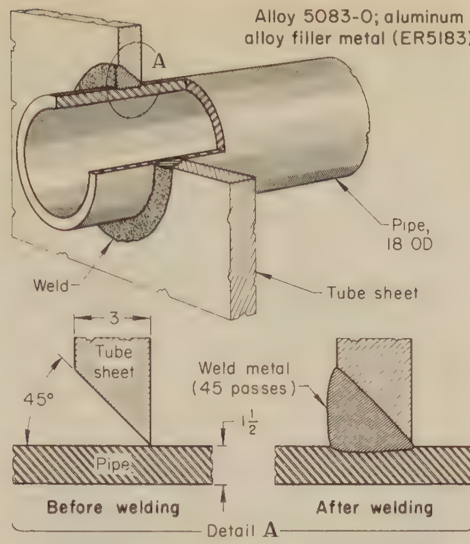


Fig. 15. Leak-free joint between tube sheet and pipe in an aluminum feed-gas cooler

stopping. Welding began near the top of the pipe and continued until the six passes were completed (Fig. 16). The electrode holder was adjusted for bead location and depth, and the direction of rotation was reversed after passes 2 and 5 without extinguishing the arc, to ensure adequate penetration and fusion, and correct weld-bead shape. Welding speed was fairly high (100 ipm), welding current was high (200 amp), and an electrode wire of small diameter (0.035 in.) was used. Welding conditions are given in the table with Fig. 16.

The estimated production rate, allowing for normal downtime, was 12 welds per hour per machine. The estimated production rate for welding with a manually manipulated electrode holder was five welds per hour per operator.

In the next example, the cost savings made possible by the higher welding speed helped overcome the high raw material cost of using aluminum rather than steel for the application.

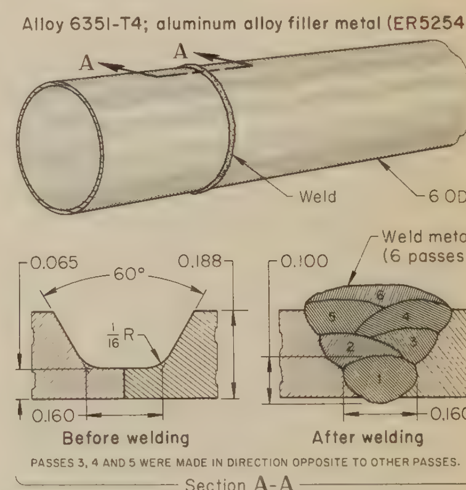
Example 299. Automatic Gas Metal-Arc Welding of Three Joints at a Time (Fig. 17)

By automatic gas metal-arc welding of three joints simultaneously, which reduced welding time to about one third of that for welding one joint at a time, aluminum alloy pressure cylinders of the type shown in Fig. 17 were made competitive with steel cylinders, despite the considerably higher cost of the aluminum alloys (5154-O, 6061-T1 and 6063-T42). Originally, a few aluminum alloy cylinders had been produced when the higher cost of aluminum was outweighed by its superior compatibility with the product being contained.

Designs for the various joints to be welded are shown in sections A-A, B-B, and C-C in Fig. 17. Before being assembled, the components were cleaned by (a) immersing them in a caustic etch-cleaner at 145 to 155 F for 4 to 6 min; (b) rinsing in warm water (100 to 120 F) for 1 min, in a bath that was overflowing and air agitated; (c) deoxidizing in an acid bath at 70 F minimum for 8 to 10 min; and (d) rinsing in warm water (125 to 145 F) for 1 min, in an overflowing bath.

The straight-side upper shell was pressed over the offset lower shell, this subassembly was placed in a welding lathe together with the collar and foot ring, and the parts were clamped by means of an air cylinder in the lathe tailstock. The assembly was rotated by means of a variable-speed drive.

Three electrode holders and wire drives were attached on side-beam carriages behind the lathe, which allowed for adjustment for cylinders of a variety of sizes. The welding controls included an adjustable weld timer to ensure correct overlap at the ends of the welds and provision for preflow and postflow of shielding gas. All of the controls were in one console.



Automatic Gas Metal-Arc Welding

Joint type	Butt
Weld type	Single-U groove
Root opening	None
Welding position	Horizontal-fixed pipe
Power supply	300-amp engine-driven generator
Fixture	Expandable mandrel
Electrode holder	Mechanized, air cooled
Electrode wire	0.035-in.-diam ER5254(a)
Shielding gas	Argon, at 60 cfh
Current	200 amp, dcrp
Voltage	20 to 24 v
Welding speed	100 ipm
Arc time per joint	80 sec
Number of passes	Six
Production rate per machine	12 welds per hour

(a) Chosen because it is compatible with all common aluminum alloys used for pipe and pipe fittings, ER5254 is a former AWS classification that has been replaced by ER5654.

Fig. 17. Pressure cylinder on which three welds were made simultaneously by automatic gas metal-arc welding (Example 299)

After alignment of electrode holders had been checked, all three welds were started simultaneously by pushing a master start button. Welding equipment and conditions are given in the table that accompanies Fig. 17. There was no postweld heat treatment, but all parts were postweld cleaned in hot dilute phosphoric acid.

All welds had to be free of undercutting on the sidewalls of the welding groove and the adjoining base metal, and it was specified that any crack, leak or other defect that appeared on the surface on a weld bead could be repaired only in accordance with a repair welding procedure for the weld in question.

Each cylinder was proof tested to 480 psig, and checked for leaks while under pressure. One cylinder from each lot of 200 cylinders or less was subjected to a series of tests. The first was a tension test across the girth weld (section A-A in Fig. 17), where minimum tensile strength required was 30,000 psi, and the minimum tensile strength calculated on the minimum wall thickness had to be at least the wall stress calculated for 960 psig. A weld-root bend test was also required. Two samples of the base metal were tension tested and both were required to meet the following requirements: tensile strength exceeding the wall stress calculated for 960 psig, yield strength not exceeding 80% of the tensile strength, and elongation in 2 in. of at least 7%. The chemical composition of the base metal was also verified.

One cylinder of each lot of 1000 cylinders was hydrostatically tested to destruction by bursting. Minimum pressure at failure was required to be 960 psig.

All pressure testing was conducted hydrostatically. Cylinders were filled with water and connected to an air-operated hydraulic pump. The low compressibility of water minimized the stored energy in the cylinder and the hazards that attended the bursting test.

Cylinders with valves, for liquefied petroleum gas service, were pressurized with 150 psig dry air after valves were attached. The entire assembly was submerged in a tank of water (with added wetting agent). Leaks showed as a stream of fine bubbles.

The production rate for automatically making three welds simultaneously was about the same as would have been expected for welding the girth joint alone, and there was no extra handling time.

In the example that follows, the reduced welding time and reduced distortion that resulted from the high welding speed obtained by automatic welding were important advantages.

Example 300. Reduction in Welding Time and Distortion by Changing From Semiautomatic to Automatic Gas Metal-Arc Welding (Fig. 18)

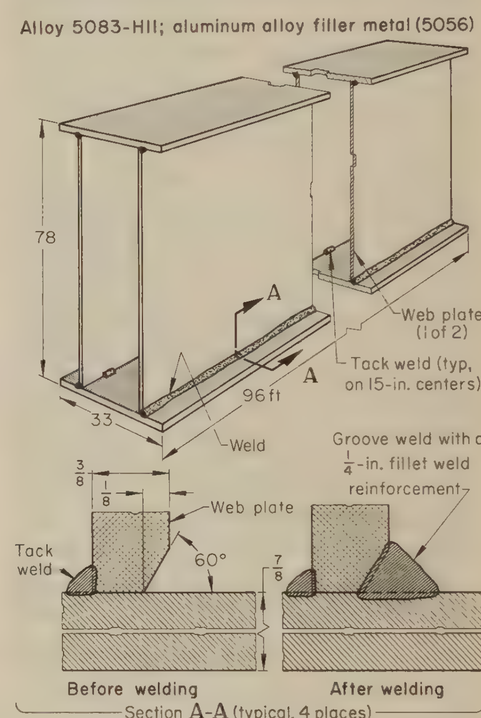
Originally, the four continuous welds along the full 96-ft length of the alloy 5083-H11 overhead-crane girder shown in Fig. 18 were made as fillet welds in square-groove joints by semiautomatic gas metal-arc welding. By changing to the single-bevel-groove weld with fillet weld reinforcement shown in section A-A in Fig. 18, and to fully automatic gas metal-arc welding, welding time was reduced by 80%. The 60° groove provided by beveling the web plates contributed to the reduction in welding time by allowing a 33% decrease in weld metal, at no sacrifice in joint strength. Welding current was increased from 260 to 375 amp.

The girders were tack welded at 15-in. centers on the inside to hold them in place for fillet welding. The continuous machine fillet welds were made in the horizontal position.

Other benefits of machine welding were a significant reduction in distortion, better joint appearance, and elimination of the defects associated with weld starts and stops. Welding conditions and a comparison of semiautomatic and automatic welding are given in the table with Fig. 18.

Production Examples of Gas Metal-Arc Welding

For the welding of aluminum, the gas metal-arc process affords welding speeds equal to or greater than those of other arc welding processes. This has led to other advantages, such as lower cost and less distortion. The previous section described some advantages of automatic gas metal-arc welding, most of which relate to the welding speed realized with this method.



Automatic Gas Metal-Arc Welding

Joint type	T
Weld type	Single-bevel-groove fillet
Root opening	None
Welding position	Horizontal
Power supply	500-amp, constant-current transformer-rectifier
Wire-feed system	Constant speed
Electrode holder	Mechanized, water cooled
Electrode wire	1/16-in.-diam alloy 5056(a)
Shielding gas	Argon, at 60 cfh
Current	See below
Voltage	26 v
Wire-feed rate	410 ipm
Welding speed	See below
Number of passes	One

Comparison of Semiautomatic and Automatic Gas Metal-Arc Welding

	Semi-automatic	Fully automatic
Current (dcrp), amp	260	375
Welding speed, ipm	12	20
Duty cycle per joint, %	33⅓	100
Welding time per joint, min	288	58
Shielding-gas consumption per joint, cu ft	64	60
Electrode consumption per joint, lb	12	8

(a) This electrode wire has been discontinued. See the footnote in the table that accompanies Fig. 22.

Fig. 18. Overhead-crane girder, the welding of which was changed from semiautomatic to automatic gas metal-arc to reduce welding time and distortion (Example 300)

Cost Savings. Higher welding speed usually results in a higher production rate per man-hour, and the lower labor cost per weld significantly affects the cost of a fabricated part. In the example that follows, a continuous-bead weld produced by gas metal-arc welding replaced a joint made by resistance spot welding and brazing, at a cost saving and with an improvement in the quality of the product.

Example 301. Gas Metal-Arc Welding of a Dust-Tight Box Cover at 60% Lower Labor Cost (Fig. 19)

When the joining process was changed from resistance spot welding plus torch brazing to continuous-bead semiautomatic gas metal-arc welding, the alloy 6061-T6 box cover shown at top left in Fig. 19 was produced not only to required dust-tightness (not attainable by spot welding plus brazing), but also at a 60% cost saving. The resistance spot welds had been placed on 1-in. centers, which permitted dust to penetrate between them during service. Torch brazing had been used at the corner gaps.

The fixture used for gas metal-arc welding was an angle-iron table with side-edge and front-edge stops, as shown in the upper right-hand corner of Fig. 19. With the parts in the position shown in the two middle views in Fig. 19, each of the ends was tacked to the cover at four places with fillet welds (lap joints), and the butt joints at the four mitered corners of the flange were tacked with square-groove welds. The square-groove tack welds, which extended to within 1⁄16 in. of the edge of the flange, were made with a minimum of weld-metal buildup. A copper bar served as a positioner and heat sink for the square-groove tack welds.

After the cover had been tack welded, it was turned over (see upper right-hand view in Fig. 19). Gaps between the ends and the cover were hammer closed and tack welded where needed. A copper backing vise gripped the back edge of the cover, a copper spatter shield was placed over the end, and the joint was welded from the apex of the cover to the back edge. The workpiece was reclamped and the joint from the apex to the front edge was welded. The second end was welded on in the same manner. A contoured arm rest assisted in electrode-holder guidance. After welding, the weld surfaces were wiped clean with a cloth and rough spots on the weld were hammered smooth. Welding conditions are given in the table with Fig. 19.

The following example describes an application in which the replacement of riveting by gas metal-arc welding resulted in a cost saving and an improvement in the product.

Example 302. Reduction in Cost and Rejection Rate by the Use of Gas Metal-Arc Welding Instead of Riveting (Fig. 20)

The truck-radiator grill frame shown in Fig. 20, an assembly of alloys 5052 and 6063 components, was originally joined by riveting with a hand-operated air gun, using rivet sets and a bucking bar. Cutouts were needed in the clamping fixture around each rivet, to allow use of the gun and bucking bar. These cutouts weakened the fixture, and the assemblies became twisted, resulting in a 12% rejection rate. Some assemblies also were out-of-square, as the joints could not be held tight and flush before riveting.

By changing from riveting to gas metal-arc welding, it was possible to use clamps that held the assemblies more securely in position during joining. Completed assemblies had more accurate dimensions and improved rigidity. Other advantages were a reduction of rejects to 1% and a 50% saving in labor time.

The assemblies were manually loaded in the welding fixture, toggle-clamped, welded in a single pass (with ER4043 filler metal, for maximum ease of welding and corrosion resistance), unclamped, and then manually unloaded. The weld passes were horizontal and vertical-up. Intermittent welding was used for all joints over 1 in. long, the procedure being to weld 1 in. and skip 4 in. Conditions for semiautomatic gas metal-arc welding are given in the table that accompanies Fig. 20.

All welds had good penetration, and weld buildup was kept to a minimum. Typical penetration was 30 to 50% of the 3⁄16-in. lower channel thickness and 40 to 60% of the 1⁄8-in. thickness of the other parts.

Minimizing Distortion. High welding speed results in less heat being absorbed by the metal being welded, which in turn results in less thermal expansion, less residual stress and less distortion. In the following example, when resistance spot welding proved unsuitable because of the inaccessibility of joints, gas metal-arc welding was selected because it caused less distortion than the other arc welding processes, although more than resistance spot welding. Close dimensional control was achieved with proper fixturing.

Example 303. Use of Gas Metal-Arc Welding in the Final Assembly of a Frame for a Truck Cab Door (Fig. 21)

Both gas metal-arc welding and resistance spot welding were used in making the alloy 6061 military-truck-cab doorframe shown in Fig. 21. The resistance spot welding is described in Example 419, in the article on Resistance Welding of Aluminum Alloys. Because some of the doorframe joints were inaccessible for resistance spot welding, or had limited accessibility (see detail A, Fig. 21), gas metal-arc welding was selected as the best alternative — its high welding speed caused less distortion than the lower welding speed of gas tungsten-arc welding. However, it was advisable to hold the gas metal-arc welds to a minimum for two reasons: (*a*) Because the heat input was greater than in resistance spot welding, the probability of distortion in the highly stressed, tempered and cold worked material was greater; and (*b*) the larger mass of the weld metal produced greater residual stress during contraction in cooling.

An important requirement of the military truck was that it be able to float

(swim) when fully loaded, the tractor portion being given buoyancy by a watertight cab. In order that the doors be watertight, the frames had to be built to close dimensional tolerances, so that they would fit snugly in their openings. Both fixturing and welding were critical in maintaining dimensions.

Gas metal-arc welding was done without removing the frame from the same rigid fixture (see Fig. 21) used for resistance spot welding. Welding conditions are given in the table that accompanies Fig. 21. After welding, the frame was allowed to cool and was removed from the fixture to check dimensions and shape. The weldment was then furnace heated at 380 F for 6 hr to T6 condition, and tested for hardness. One frame per week of production (400 doors) was strength tested to destruction.

Final checking of dimensions and shape of each frame occurred after it was incorporated in a completed door assembly, and the latter had been installed in a truck cab. The cabs were then tested for watertightness by immersing them in water to within 4 in. of the freeboard of the truck. The first cab of a production lot was permitted a door fit that leaked one quart in 6 hr. All other cabs of the lot were required to show no visible leakage after 2 min of immersion.

Often, the welding sequence may be arranged so that only a minimum amount of fixturing is needed. This is illustrated in the following example.

Example 304. Welding Alloy 5083-H11 Plate by the Semiautomatic Gas Metal-Arc Process (Fig. 22)

Transverse joints in ⅞-in.-thick alloy 5083-H11 flange plates for overhead-crane girders were welded in ten passes by the gas metal-arc process. Although welding time could have been reduced by using a fully automatic procedure, the amount of welding did not justify the cost of obtaining and setting up the necessary equipment, so semiautomatic welding was used.

The edges of the plates were prepared as shown in Fig. 22. The joints were then tack welded, starting and runoff tabs were attached, and welding was begun. After the third pass, the plates were turned over, the joint was back gouged to remove root defects, and three weld passes were made on this side of the joint. In order to check

(a) Wire was fed from a 1-lb spool that was mounted on the electrode holder.

Fig. 21. Truck-cab doorframe on which the gas metal-arc process was used to make the fillet welds shown (Example 303)

distortion, the plate was turned over three times during welding. The last two passes on each side were made with a longer arc, in order to obtain the required weld contour. About 1¾ lb of electrode wire was used for each 33-in.-long weld. Further welding details are given in the table that accompanies Fig. 22.

Gas metal-arc welding is often used for making tack welds when final welding is to be done by the gas tungsten-arc process, as in the following example.

Example 305. Use of the Semiautomatic Gas Metal-Arc Process for Tack Welding Aluminum Fuel-Tank Assemblies (Table 18)

For tack welding the 50 subassemblies and the final assembly of a fuel-storage tank for an M-60 combat tank, gas metal-arc welding was selected in preference to gas tungsten-arc welding, for these reasons: (*a*) the higher welding speed of the gas metal-arc process resulted in less distortion; (*b*) the faster welding reduced welding cost; (*c*) the electrode holder was easier to manipulate in the various welding positions; (*d*) the penetration obtained in the ⅛-in.-thick metal was excellent; (*e*) the cleaning action of the reverse-polarity direct current ensured oxide-free welds.

The parts were clamped in fixtures and tacked with 1-in.-long welds on approximately 4-in. centers, using the equipment and settings listed in Table 18. To keep distortion to a minimum, tack welding sequences for each subassembly were developed. Because of the variety of shapes, these sequences were arrived at by trial-and-error, but in general they were based on working outward from the center of joints and assemblies.

To facilitate manipulation of the electrode holder, the electrode wire was fed from a 1-lb spool mounted on the holder. Quality control of the electrode wire was necessary. In addition to the requirement that the wire meet military specification MIL-E-16053, samples of wire were tested periodically for cleanness, as described in Example 311. The wire was ordered in a very hard (H19) temper so that the small knurled drive wheels used in the wire feed would not allow the wire to slip. When softer wire was used, the knurled drive wheels would sometimes "mill" the wire, which caused it to slip and produce a burnback.

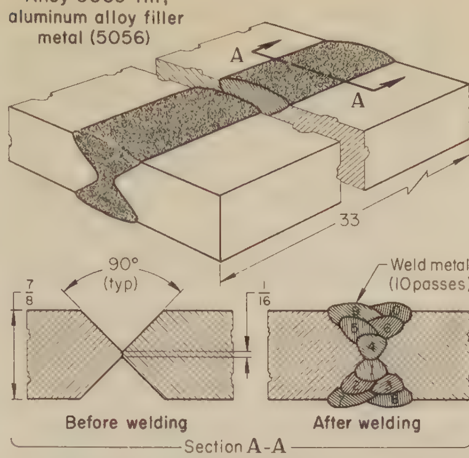
Example 293 describes preweld cleaning of the alloy 5083-H112, alloy 5086-H32, and alloy 6061-T6 components of the subassemblies, and Example 311, final seam welding.

Soundness of Welds Made by Gas Metal-Arc Welding

The five principal defects encountered in gas metal-arc welding of aluminum alloys are transverse weld-metal cracking, longitudinal weld-metal cracking, crater cracking, porosity, and inadequate penetration. In addition, inclusions and cold laps are occasionally encountered.

Transverse and longitudinal weld-metal cracking are usually associated with the higher-strength aluminum alloys of the 2*xxx* and 7*xxx* series. In particular, cracks are likely to originate at the starting and stopping points of the arc, because craters caused by normal shrinkage occur in these areas. Therefore, it is good practice to use starting and runoff tabs and not to start or break the arc on the workpiece.

In one application, consistency of weld quality in ¾-in. alloy 2219-T87 plate was improved by replacing a double-V-groove weld that required eight passes (four from each side) with a double-U-groove weld that required only three passes. First, the ⅛-in. root face of the double-U groove was welded, and then a facing pass was made on each side of the groove with the electrode holder oscillating from side to side to fill the remainder of the groove completely. (Mechanical and magnetic equipment is available to produce an oscillation in which both frequency and amplitude are adjustable.) The weld was used to join two barrel sections to form a space-launch booster tank. Welding position was vertical.



Semiautomatic Gas Metal-Arc Welding

Joint type	Butt
Weld type	Double-V groove
Welding position	Flat
Power supply	500-amp, constant-current transformer-rectifier
Wire-feed system	Constant speed
Electrode holder	Water cooled
Electrode wire	1/16-in.-diam alloy 5056(a)
Shielding gas	Argon, at 40 cfh
Current	260 to 270 amp, dcrp
Voltage	25 v
Welding speed	16 to 25 ipm
Number of passes	Ten
Total welding time per joint (33⅓% duty cycle)	45 min

(a) Alloy 5056 electrode wire has been discontinued and has been replaced by ER5356, which has the same chemical composition except for lower limits on silicon and iron and the addition of a small amount of titanium. The titanium addition refines the grains and reduces tendency for hot-short cracking. For general-purpose welding, ER5183 (which gives greater ductility) is often used. For higher-strength welds, ER5556 is used. All three electrode types can be used with the welding conditions listed above.

Wire feed	280 to 320 ipm
Number of passes	One

Weld-cracking problems can often be attributed to restrained shrinkage of the weld metal. Process variables that produce coarse-grain weld-metal deposits and large heat-affected zones are additional causes. For example, longitudinal weld-metal cracking in a square-groove butt joint in ⅛-in. alloy 5083 sheet was eliminated in one application by sufficiently relieving hold-down clamp pressure to allow slight transverse movement of the workpieces during welding. In addition, weld reinforcement was increased by reducing the welding speed, thereby creating a larger weld cross section that withstood the higher shrinkage stresses without cracking.

In another application, transverse weld-metal cracking in a square-groove butt joint in 3/16-in. alloy 5083 sheet was eliminated by increasing the solidification rate of the weld puddle. This was accomplished by reducing the arc voltage from 28 to 24 volts and the welding current from 280 to 185 amp, and increasing the welding speed from 18-to-25 to 27-to-30 in. per minute. The lower arc voltage resulted in a narrow, deeply penetrating weld and allowed the welding speed to be increased. In addition, the power supply was changed from the constant-voltage type to the conventional drooping-voltage type. The electrode diameter remained at 1/16 in. and the number of passes at two.

Sound, porosity-free welds meeting radiographic and mass-spectrometer leak-test requirements can be made in aluminum alloys by the gas metal-arc process, but careful attention must be given to the selection and use of welding equipment, materials, conditions and techniques.

Hydrogen contamination is the cause of virtually all weld porosity in aluminum alloys. Solidification shrinkage is of minor significance as a contributor to weld porosity. Hydrogen has high solubility in molten aluminum but very low solubility in solid aluminum (a small fraction of the solubility in solid

(a) Electrode wires conformed to military specification MIL-E-16053. The 5254 electrode wires (no longer an AWS classification; replaced with ER5654) were selected for strength, and the ER5356 electrode wires, for better corrosion resistance.

Fig. 24. Pressure vessel that formed part of the fuel system of a naval torpedo, showing details of two principal joints (Example 306)

steel and titanium). Hydrogen dissolved in the molten weld puddle during welding is released during solidification. The high freezing rate associated with gas metal-arc welding can prevent the evolved hydrogen from rising to the surface of the weld puddle, with the result that porosity occurs. An extremely small amount of hydrogen source can cause significant amounts of porosity.

The major sources of hydrogen are hydrated oxide, oil and other hydrocarbon contaminants on the surface of the electrode wire. Other sources are moisture, oil, grease and hydrated oxide on the work-metal surface and moisture in the shielding gas. Factors that can contribute to porosity from contamination are insufficient gas flow, excessive distance from the gas nozzle to the work metal, leakage in the shielding-gas hose or fittings, and erratic electrode-wire feed.

When weld porosity is encountered, the electrode wire should be checked, first to determine whether it is clean, and then to determine whether it is capable of depositing sound metal. In some instances, a radiograph of a weldment made in the overhead position with the wire in question can be obtained from the producer of the wire. Also, a check weld (butt or fillet) can be made, broken open and examined. If the wire will produce sound welds on one machine but not another, the source of the porosity is elsewhere than the wire. One way to make sure the wire is not a source of hydrogen is to use shaved wire.

Next, conditions for gas metal-arc welding that will bring about a slower solidification rate should be selected. Welding in the flat or vertical position also aids escape of gases.

Correct voltage and arc length can reduce porosity in a weld, such as the one in the subcooler shown in Fig. 23. This vessel was fabricated from ½-in.-thick alloy 5083 by gas metal-arc welding in the vertical-pipe position. A constant-voltage power supply and 1⁄16-in.-diam ER5183 electrode wire were used with a welding current of 280 to 290 amp, a welding speed of 18 to 20 in. per minute, and 75% argon, 25% helium shielding gas. Eight passes were required. Severe porosity was encountered. After a thorough re-evaluation of the procedure, it was concluded that welding position had little effect on the porosity but that raising the arc voltage from the 24-to-26-volt range to the 28-to-29-volt range brought about a stiffer type of spray transfer that resulted in a dense, sound weld.

Another factor that contributes to gross porosity is incorrect or erratic wire feed, which results in an unstable arc. In general, the arc should be manipulated in a reciprocating fashion to obtain the maximum amount of stirring action in the weld puddle and so to assist gases to escape. Porosity can also be reduced by using a shielding-gas mixture containing a large proportion of helium.

A small amount of porosity scattered uniformly throughout a weld has little effect on the strength of the welded joint. Clusters of porosity and gross porosity can adversely affect weld strength. Various welding codes limit the amount and distribution of acceptable porosity.

Multiple-pass welding helps prevent leakage due to porosity, as explained in the section of this article on Multiple-Pass Gas Metal-Arc Welding. In the following example, leaktight welds were obtained in joints designed so that complete penetration was obtained; four passes were used for one type of joint and about 26 passes for the other type. (Leak-free joints can also be made in one pass, as described in Example 299.)

Example 306. Producing Leaktight Welds in a Pressure Vessel (Fig. 24)

The major components of the pressure vessel shown in Fig. 24 were two closed-die-forged domes, a central partition, and an axial conduit — all made of alloy 5254. The domes were joined by a single circumferential weld that also incorporated the partition as backing (Fig. 24, detail B). The conduit was welded to the vessel at both ends. Internal baffles and fittings (not shown in Fig. 24) completed the vessel structure, which later was shrink fitted into the 4340 steel shell of a naval torpedo, the vessel forming part of the fuel system. Joint designs and welds used to join the major components of the pressure vessel are shown in Fig. 24, details A and B. The principal conditions for automatic gas metal-arc welding of both joints are given in the table that accompanies Fig. 24.

The centrally located partition and the two dome sections were welded simultaneously (Fig. 24, detail B), in four passes. To ensure weld soundness, joints between the conduit and the 1⅜-in.-thick bosses were designed for full-penetration single-J-groove welds, and were completed in about 26 passes. These joints were economical to make and had a high degree of reproducibility. The welds were of excellent quality, showing "water clear" on x-ray plates.

After edge preparation (machining) and cleaning of joint areas, internal baffles and fittings (not shown in Fig. 24) were installed in the dome sections. These sections, together with the center partition, were then assembled in an alignment fixture, clamped, mounted (axis horizontal) under a fixed electrode holder and welded. The welding area was carefully shielded from drafts. During welding, the workpiece was rotated without stopping, except to change electrode wire, and the welds were wire brushed during rotation. The conduit was then inserted and similarly welded, with the axis of the assembly vertical. After welding, the vessel and welds were machined. Welds were inspected by liquid-penetrant methods and the vessel was subjected to a mass-spectrometer leak-rate test.

Mechanical problems, such as burnback of the electrode wire into the contact tube, snagging of the electrode wire either on the wire spool or in the flexible cable joining the spool to the electrode holder, and inability of the wire to maintain a constant arc length during welding (hunting), also occur. These are almost always associated with malfunctions of equipment (especially, wire-feeding equipment), rather than with process or material limitations. All of these difficulties with gas metal-arc welding, and several others, are listed in Table 19, along with their usual causes.

Repair Welding by the Gas Metal-Arc Process

Welding is widely used for repairing defects in both cast and wrought parts. The techniques for making such repairs vary, depending on the type of defect and the properties and condition of the part to be repaired. One repair technique used on plate is described in the example that follows.

Example 307. Repair Welding Alloy 5083-O Plate (Fig. 25)

A welding technique for repairing cracks (resulting from forming) in 1⅛-in.-thick alloy 5083-O plate included trepanning a circular plug, containing the cracks, from the plate and then welding in a plug of sound metal. The plug of sound metal was machined to fit the 5-in.-diam trepanned hole with a maximum radial clearance of 0.020 in., as shown in Fig. 25. The plug was inserted in the hole and held in place by three 2-in.-long tack welds spaced 120° apart. Next, the joint region was preheated locally to 200 F with an oxyacetylene flame and the first pass was made on the side opposite the tack welds, special care being taken to avoid melt-through. Passes 2 and 3 (Fig. 25) were then made, the tack welds were ground out, and the weld was inspected radiographically. The root pass was back gouged to a depth of about 3/32 in. and the next four passes were made. The remaining passes were deposited as shown in the welding-pass sequence in Fig. 25.

Each of the 14 welding passes was made in two parts, each part through approximately 180° of the joint. Upon completion of each part of a pass, the arc was diverted to a runoff tab and broken there instead of in the repair weld to avoid the possible formation of crater cracks in the

Current	300 amp, dcrp
Voltage	32 v
Preheat	200 F
Interpass temperature	150 to 200 F
Number of passes	14
Welding time	Approx 1½ min per pass

Fig. 25. Plate in which a crack was repaired by removing the cracked area by trepanning and then welding a sound plug in the hole (Example 307)

Table 19. Common Problems With Gas Metal-Arc Welding and Their Usual Causes

Porosity

1 Gas entrapment from poor shielding, shielding gas, air
2 Hydrogen from moisture, unclean wire surface, oil on base metal
3 Excessive cooling rate of weld puddle
4 Erratic electrode-wire feed (see causes in item 2 under "Arc-Length Fluctuations")
5 Erratic arc transfer, caused by incorrect current

Transverse Weld-Metal Cracking

1 Excessive longitudinal restraint
2 Slow solidification of weld puddle
3 Absorption of halogen compound in weld puddle
4 Incorrect combination of base metal and filler metal

Longitudinal Weld-Metal Cracking

1 Excessive transverse restraint
2 Concave, instead of convex, root-pass weld bead
3 Insufficient cross section of root-pass bead
4 Excessive current for electrode-wire size

Inadequate Penetration

1 Insufficient back gouging
2 Improper edge preparation for arc characteristics (groove too narrow)
3 Insufficient current
4 Excessive voltage
5 Welding speed too high

Incomplete Fusion

1 Improper edge preparation for arc characteristics
2 Arc too long
3 Dirty workpieces or electrode wire
4 Insufficient current

Undercutting

1 Excessive current
2 Welding speed too low
3 Improper electrode-holder angle

Arc-Starting Difficulty

1 Wrong polarity (electrode should be positive)
2 Incomplete welding circuit
3 Inadequate flow of shielding gas
4 Wrong electrode-wire feed rate or welding current

Arc-Length Fluctuations

1 Poor condition of contact tube (rough inner walls, sharp shoulders, contamination by weld spatter)
2 Erratic electrode-wire feed, caused by:
   - Kinked wire (electrode wire should be evenly wound and free of kinks)
   - Excessive or erratic friction in electrode conduit or electrode holder (conduit should be in good condition and of the correct size and length)
   - Clogged contact tubes
   - Unbalance of wire spool
   - Maladjustment of wire-spool brake
   - Poor operation of wire-feed motor or wire straightener
   - Sharp bends in electrode conduit (suspend equipment overhead)
   - Fluctuations in line voltage to wire-feed unit
   - Poor ground connection or burned governor control in wire-feed motor
   - Slippage or insufficient pressure of drive rolls in wire-feed unit

Burnbacks(a)

1 Erratic electrode-wire feed (see causes in item 2 under "Arc-Length Fluctuations")
2 Poor condition of contact tube (see item 1 under "Arc-Length Fluctuations")
3 Incorrect power-supply settings
4 Poor functioning of cooling equipment
5 Poor contact between voltage pickup lead and work

Inadequate Cleaning Action by the Arc

1 Wrong polarity (electrode should be positive)
2 Inadequate gas shielding because of:
   - Insufficient gas flow
   - Spatter on inside of gas nozzle
   - Contact tube off-center in relation to gas nozzle
   - Wrong nozzle-to-work distance
   - Incorrect electrode-holder position (see item 3)
   - Drafty environment (work should be shielded)
3 Incorrect electrode-holder position (should be 7° to 15° forehand)

Dirty Weld Bead(b)

1 Dirty workpieces or electrode wire
2 Impurities in shielding gas (because of air or water leakage)
3 Wrong forehand angle
4 Damaged or dirty gas nozzle
5 Wrong gas-nozzle size (should be smallest possible)
6 Insufficient shielding-gas flow
7 Drafty environment (work should be shielded)
8 Incorrect arc length
9 Contact tube recessed too far (should not be more than ⅛ in. inside gas nozzle)

Rough Weld Bead

1 Unstable arc
2 Improper electrode-holder manipulation
3 Improper current
4 Welding speed too low

Too Narrow Weld Bead

1 Insufficient current
2 Welding speed too high

Too Wide Weld Bead

1 Excessive current
2 Welding speed too low
3 Arc too long

Poor Visibility of Arc and Weld Puddle(c)

1 Wrong position of work
2 Wrong work angle or forehand angle
3 Small, dirty or wrong lens in helmet (a No. 10 or 12 lens should be used)
4 Wrong gas-nozzle size (should be smallest size)

Overheating of Power Supply(d)

1 Excessive power demand (two similar welding machines can be used in parallel if the capacity of one is insufficient)
2 Poor functioning of cooling fan
3 Dirty rectifier stacks (regular maintenance)

Overheating of Cables

1 Loose or faulty connections
2 Cables too small

Overheating of Electrode-Wire Feed Motor

1 Excessive friction between electrode wire and conduit
2 Wrong gear ratio of wire-feed unit
3 Poorly adjusted wire-spool brake
4 Incorrect alignment of gears and rolls in wire-feed unit
5 Worn brushes on wire-feed motor
6 Inadequate capacity of wire-feed motor (high wire-feed rates and large wire sizes require motor of adequate power)
7 Worn or arced governor controls

Operator Fatigue

1 Wrong position of work (weld in flat position whenever possible)
2 Inadequate seating for welder
3 Lack of ventilation
4 Disregard of safety rules in respect to head shield, lens, gloves
5 Weight of cables (reduce by suspending cables overhead)
6 Too many auxiliary operations, such as cleaning and chipping

(a) A burnback occurs when electrode wire fuses to the copper contact tube and wire feed is stopped. It happens when the wire feed is insufficient for the current being used, which causes the arc to lengthen until it overheats the end of the contact tube. An inexperienced welder may get burnbacks while establishing the correct welding conditions.

(b) The appearance of small amounts of black smut in welding with the aluminum-magnesium alloys is not a fault.

(c) The welder must be able to see the arc and the weld puddle at all times.

(d) High demand can damage the power supply by overheating. Overheating is particularly serious with rectifiers.

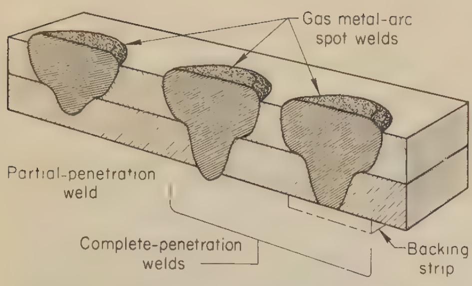

Fig. 26. Shapes of typical gas metal-arc spot welds

weld area. (Starting tabs were not used.) Between passes, the surface of the previously deposited bead was cleaned with a stainless steel wire brush. Interpass temperature was maintained between 150 and 200 F. The tensile strength of the weld repair was essentially the same as that of the original base metal.

Repair welding of castings is more common than repair welding of wrought metal. Most casting repair is done to correct foundry defects or to repair parts broken in service. For example, an alloy 355-T6 piston, 42 in. in diameter and 31 in. high with a thickness that varied from 1 to 3 in., had a large broken area on the top surface and broken areas on the skirt near the compression ring. For repair, the defective areas were chipped to sound unbroken metal, and all surfaces were washed with a solvent cleaner. The casting was then placed in an insulated box and preheated to 300 F by wrapping it with a bead-type resistance heater. For the welding operation, a constant-voltage power supply, a shielding-gas mixture of 75% argon and 25% helium, and a 1/16-in.-diam ER1100 electrode wire were used. Each area of repair was welded without interruption. Adequate weld reinforcement was provided so that the repaired area could be ground flush after cooling. The repairs, five in all, were made with no evidence of cracking, and radiographic inspection showed that they were satisfactory.

Spot Welding by the Gas Metal-Arc Process

Spot welding by the gas metal-arc process is a quick and reliable method of joining aluminum alloy sheet and extrusions. Normally, only enough force is required to hold parts in intimate contact, and only one side of the joint need be accessible. Aluminum alloys can be arc spot welded satisfactorily at high speed (12 or more spots per minute) by unskilled operators.

The cost of gas metal-arc spot welding is approximately half that of riveting, and the spots can develop shear strength and bearing strength equal to or better than those obtained with 5/32-in. 2117-T6 rivets. In addition, fatigue strength is higher than that of riveted joints and resistance spot welded joints. Weld strength and appearance can be varied to suit the job by proper selection of degree of penetration, base-metal alloy and thickness, filler-metal alloy, joint design, fit-up and shielding.

Gas metal-arc spot welding can be used to join all of the arc weldable aluminum alloys and some (for example, 7075 and 7079) whose welding by other arc processes is not recommended (Table 1). A guide to filler-metal selection is given in Table 20. The process is also useful for welding aluminum alloys to steel or copper.

For spot welding, the nozzle assembly on the conventional gas metal-arc welding electrode holder is changed and circuitry is added to provide automatic control of feed, arc, and gas time. After adjusting the current, wire feed and other operating conditions in keeping with the thickness of metal and penetration required, the nozzle is brought into contact with the first member and sufficient pressure is applied to hold the two members in contact. The welding process is started and the electrode wire feeds forward, initiating the arc, which melts through the first member into the second member and forms the spot weld. Crater filling is automatically controlled to obtain a shrink-free spot of the correct shape. The weld usually is made in one second or less.

Reverse-polarity direct current is employed, with argon, helium or argon-helium gas shielding. A pull-type wire feed with a slow run-in control is recommended, to ensure reliable arc starting. A time-lag control between wire-feed shutoff and breaking the welding current prevents the electrode wire from freezing in the weld puddle when the power is cut off.

Constant-voltage power supplies, of either the motor-generator or rectifier type, with adjustable slope control, have been found to give the best results. They are capable of delivering the high current surge required for arc initiation. Constant-current power supplies are not recommended because aluminum electrode wire is likely to ball up on the end when the arc is extinguished.

Gas metal-arc spot welding necessitates the minimum amount of preweld cleaning. Removal of normal oxides

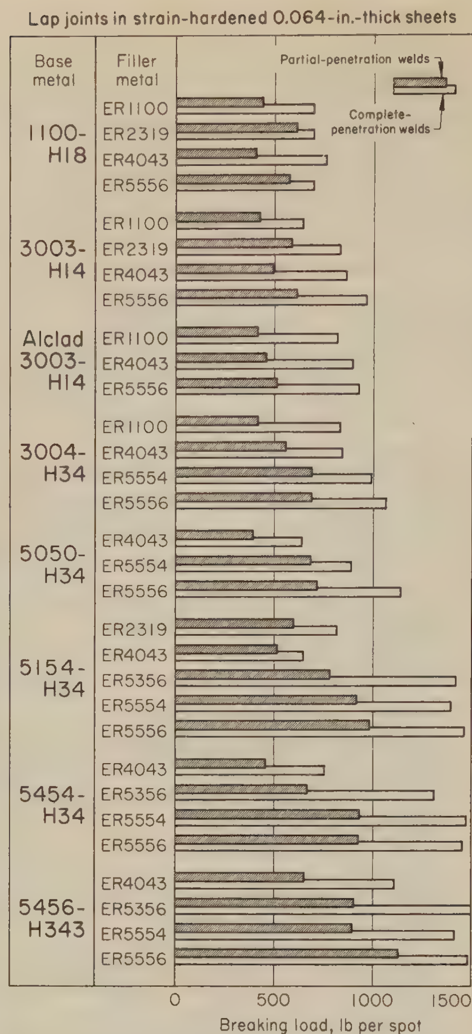

Fig. 27. Tensile-shear breaking loads for gas metal-arc spot welded 0.064-in. sheet

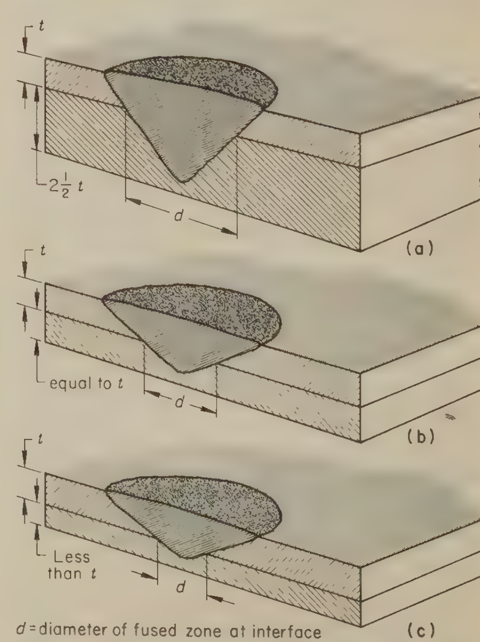

Fig. 28. Relative diameter of fused zones at sheet interface for three combinations of sheet thicknesses

and mill finishes is not necessary unless the ultimate in weld quality is demanded, but anodic and chemical-dip oxide finishes, and lacquers and other insulating coatings, must be removed. Solvent wiping is recommended for the removal of grease and die compounds. Alcohol and toluol are the preferred cleaning agents. Chlorinated solvents such as carbon tetrachloride and trichlorethylene should be used only with thorough ventilation and in an area far remote from the welding area, because they decompose and yield toxic fumes when in the vicinity of an electric arc.

Helium shielding is preferred when welding thin sheet (less than 0.040 in. thick) because its use results in a less sharply pointed weld cone than the use of argon shielding, thus permitting a larger fused area to be made at the faying surfaces. Drawbacks to the use of helium are: it is less readily available than argon, it is more costly, it has a higher level of spatter, and it results in a rougher weld surface. Low gas-flow rates — approximately 20 cu ft per hour — are possible because the spot welding nozzle provides an almost complete enclosure. Gas hoses should be purged with shielding gas before making the first weld in a series. A 5-sec purge is usually sufficient, but a longer purge may be needed at the beginning of the day's work. Once the gas nozzle is purged, successive welds can be made as quickly as the electrode holder can be repositioned.

Aluminum in thicknesses from 0.020 to ¼ in. can be joined by gas metal-arc spot welding. When the first member (usually, the top member) is ⅛ in. thick or less, no special preparation is needed, but if the first member is ⅛ to ¼ in. thick a pilot hole is required. The second member should preferably be at least as thick as the first member, and ideally two to three times as thick. Minimum thickness for the second member is generally 0.030 in. using solid backing; otherwise, it is 0.050 in. Use of chilled or massive backing allows complete penetration through the second member, to achieve maximum nugget diameter and strength.

Spot welds look like slightly crowned buttons on the surface closest to the electrode holder. In cross section, they should be cone-shape and penetrate through, or almost through, the second member. Figure 26 shows the shapes of diametral sections through typical spot welds. For sheets of nearly equal thickness, weld strength is highest when the weld penetrates through the second member. When made against a flat, clean metal backing plate, the spots are flush and uniform, leaving a mark resembling a resistance spot weld. For consistent results, clamping may be necessary to ensure uniform contact at the faying surfaces and between the work and backing. Partial-penetration spot welds show no mark at all on the back surface, and stiffeners and brackets can be welded to the back of architectural panels and other products where appearance is of prime importance, without any marring of the opposite surface.

Gas metal-arc spot welding of aluminum alloys is covered in Table 21.

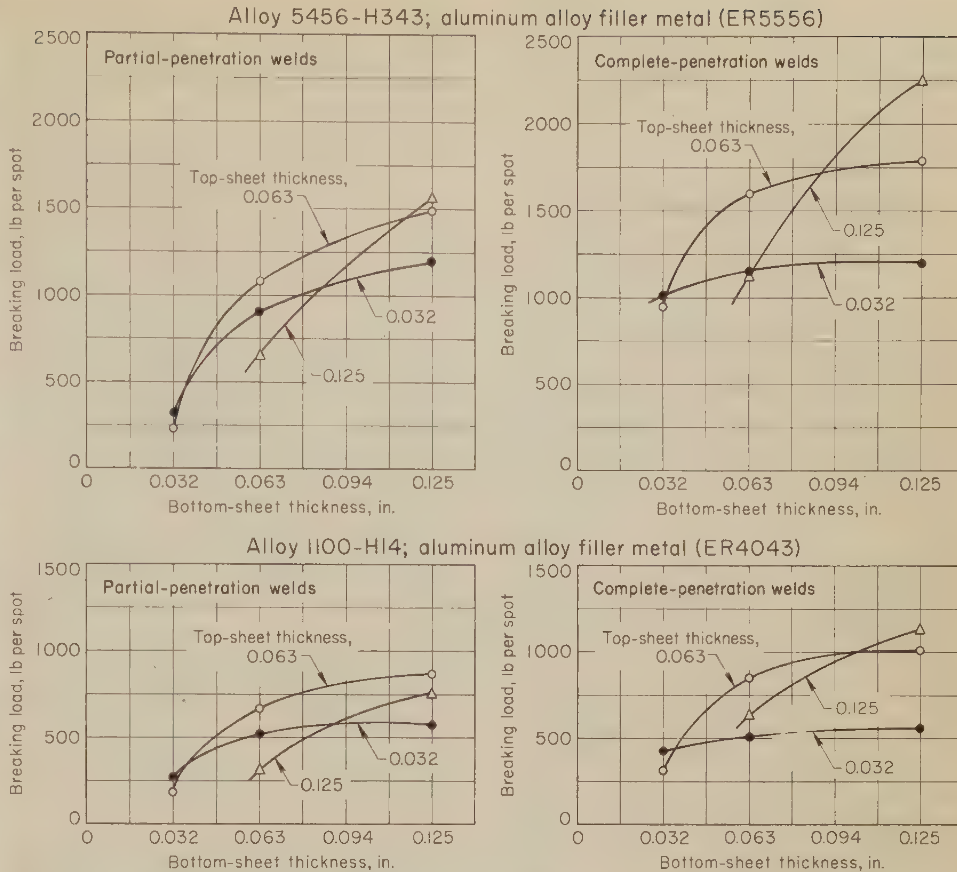

Fig. 29. Effect of sheet thicknesses on tensile-shear breaking load for partial-penetration and complete-penetration gas metal-arc spot welds

The strength of a spot weld is a function of the alloy and the area of the nugget at the interface. Figure 27 shows tensile-shear breaking loads for 0.064-in. sheet of various aluminum alloys with partial-penetration and complete-penetration spot welds. Welds in alloys of the 5*xxx* series have the highest strength. The higher base-metal strength of the heat treatable alloys of series 2*xxx*, 6*xxx* and 7*xxx* is not reflected in the as-spot-welded strength. The combination of alloy 5456 sheet and ER5556 filler metal produces the highest tensile-shear strength per spot weld at a given thickness.

Table 20. Guide to the Choice of Filler-Metal Alloys for Gas Metal-Arc Spot Welding (a)

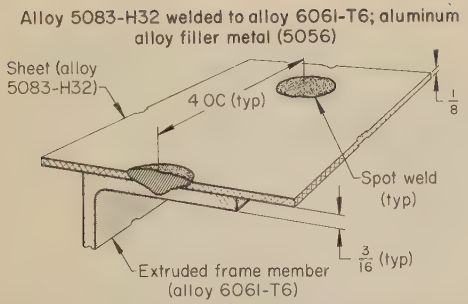
(a) Overlap joints; electrode, 0.047-in.-diam ER5554. (b) Welding current (dcrp), in amperes, is approximately equal to one-half wire feed, in inches per minute, of 0.047-in.-diam electrode wire.



Semiautomatic Gas Metal-Arc Spot Welding

Joint type	Lap
Welding position	Flat
Power supply	500-amp, constant-voltage transformer-rectifier
Fixtures	Clamping (when needed)
Electrode holder	500 amp, water cooled
Gas nozzle	¾-in. diam, copper
Electrode wire	1/16-in.-diam alloy 5056(a)
Shielding gas	Argon, at 60 cfh
Electrode stickout	½ in.
Current	610 amp, dcrp
Voltage	32 v
Arc time	58 cycles per spot
Shielding-gas consumption	7 to 10 cu ft/100 spots
Electrode consumption	0.3 to 0.4 lb/100 spots
Production rate	7 to 10 min/100 spots

(a) This electrode wire has been discontinued. See footnote in table with Fig. 22 for information on alternative wires.

Fig. 30. Roof sheet and frame members that were joined by semiautomatic gas metal-arc spot welding (Example 308)

Maximum strength is obtained when the bottom sheet is at least twice the thickness of the top sheet, as the interface will be nearer to the face of the weld nugget and therefore larger (Fig. 28a). When the bottom sheet is about 2½ times thicker than the top sheet, the area of the weld nugget does not vary greatly with small variations in penetration. If the two sheets are of equal thickness (Fig. 28b) or if the top sheet is thicker (Fig. 28c) and if complete penetration cannot be tolerated, the same percentage variation in depth of penetration produces much greater variation in the weld-nugget interface area. If the surface of the bottom sheet is completely penetrated, less variation results in the interface area.

Figure 29 shows the effect of various combinations of top and bottom sheet thicknesses on tensile-shear breaking load per spot, for partial-penetration and complete-penetration spot welds made in alloy 5456-H343 with ER5556 electrode wire and in alloy 1100-H14 with ER4043 electrode wire.

Thicknesses being joined, and strength and appearance requirements, should be considered in determining whether control should be set to produce welds with partial or complete penetration. Welding conditions are easier to establish for complete-penetration welds, and the welds produced will have more uniform strength and appearance. Variability in partial-penetration welds will be reduced if the weld area of the second member is rigidly supported to ensure that the pressure on the first member by the electrode holder will hold the two members in contact.

The two examples that follow describe the use of gas metal-arc spot welding. In the first example, welding was semiautomatic and partial-penetration welds were made through thinner metal into thicker metal. In the second example, welding was automatic and complete-penetration welds were made through thicker metal into backed-up thinner metal.

Example 308. Use of Semiautomatic Gas Metal-Arc Spot Welding for Joining Flat Roofs to Extruded Frame Members (Fig. 30)

In the manufacture of covered railway hopper cars, ⅛-in.-thick 5083-H32 flat roof sheet was laid over 3/16-in.-thick 6061-T6 extruded frame members and welded. Originally, fillet welds were deposited either intermittently or continuously from below, by semiautomatic gas metal-arc welding, but this method was costly and difficult to use on thin material in this position.

Gas metal-arc spot welding was tried. The surfaces to be welded were precleaned by degreasing, and spot welding was done in the flat position through the ⅛-in. roof sheet into the frame member. The pressure of the nozzle of the hand-held electrode holder was usually enough to ensure no gap between the surfaces, but clamping was used when needed to ensure closure.

After spot welding was completed, the perimeter of the roof sheet was manually fillet welded to the car frame to seal against moisture. In addition to their structural functions, the spot welds held the roof sheet firmly in place for the fillet welding. Welding conditions for gas metal-arc spot welding are given in the table that accompanies Fig. 30.

Example 309. Use of Automatic Equipment for Making 700 Spot Welds per Hour by Gas Metal-Arc Welding (Fig. 31)

Gas metal-arc spot welding was used to attach stiffeners to sidewalls and roofs in the welding of 30-ft-long cargo containers for shipboard transportation. Other subsequent welding operations were required to join the wall and roof panels to floor assemblies, siderails, and corner posts to make a leakproof container.

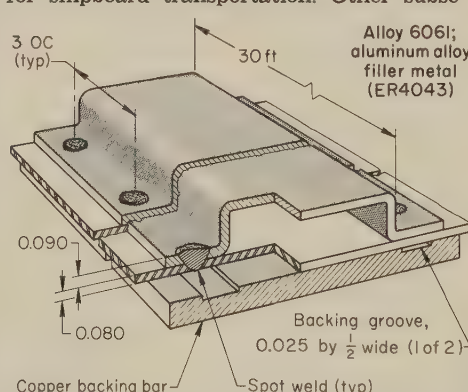
Joining the stiffeners (extrusions) to the roof (sheet) by resistance spot welding was impractical, because the large size of the roof panels would have necessitated the provision of a welding machine with an excessively deep throat. Joining by riveting would have been expensive and would have required the sealing of each rivet hole. The cost of gas metal-arc spot welding, including labor, consumable supplies, and amortization of equipment, was estimated to be about half the cost of joining by riveting.

Wall and roof panels were made of 0.060 to 0.080-in.-thick 6061-T6 sheet; the stiffeners were hat-shape extruded sections, 0.080 to 0.090 in. thick, of 6061-T6. Because more than 4200 spot welds were to be made on each container and many containers were to be made, special mechanized welding equipment and controls were constructed. A gantry-type assembly that housed 14 spot welding electrode holders rode over the work on two siderails. An operator indexed it over a stiffener and then the control unit automatically actuated groups of four electrode holders in a predetermined sequence designed to minimize distortion of the panel. The electrode holders applied 40 psi pressure to the work to clamp the extrusions and sheet together. After a stiffener was welded in place, the gantry assembly was indexed about 18 in. to the next stiffener and the operation was repeated.

A 75% helium, 25% argon shielding-gas mixture and 1/16-in.-diam ER4043 electrode wire were selected to prevent weld crater cracking. No precleaning was required.

Copper backing bars with a relief groove under the welds were used to ensure good metal-to-metal contact during welding and to allow controlled full penetration for maximum strength. The backing bar was also essential because the thicknesses of the two pieces of metal being welded were unequal and because welding was being done through the thicker piece into the thinner piece, which is more difficult than the opposite arrangement.

All penetration nuggets were ground off to meet interior-smoothness requirements (no retention of any particle larger than 300 mesh). Shear strength in excess of 700 lb per spot was consistently obtained. Other processing data are given in the table that accompanies Fig. 31.



Automatic Gas Metal-Arc Spot Welding

Joint type	Lap
Welding position	Flat
Power supply	500-amp, constant-voltage transformer-rectifier, with variable slope and inductance
Fixtures	Pneumatic clamping; copper backing bar
Electrode-holder clamping pressure	400 psi
Electrode holder	500 amp, water cooled
Gas nozzle	1-in. diam, copper
Electrode wire	1/16-in.-diam ER4043
Shielding gas	75% helium, 25% argon, at 50 cfh
Electrode stickout	⅝ in.
Current	325 amp, dcrp
Voltage	28 v
Arc time	About 30 cycles(a)
Shielding-gas consumption	About 1 cu ft/100 spots
Electrode consumption	About 0.0743 lb/100 spots
Production rate	About 700 spots/hour(b)

(a) Depending on the metal thickness being joined. (b) Includes indexing of gantry and loading and unloading of work.

Gas Metal-Arc Spot Welding Aluminum to Other Metals. In gas metal-arc spot welding of aluminum alloys to other metals, the brittle intermetallic compounds formed at the periphery of the welds have little effect on strength and ductility in shear loading, which permits fusion spot welding of metal combinations that cannot be welded along seam joints without the use of special techniques.

When the other metal is thin, the weld can be made by melting through it with the arc. The in-rushing aluminum alloy filler metal and the force of the arc push the other metal away from the center of the weld so that the core and crown are composed of relatively ductile aluminum. The maximum thickness of the other metal that can be handled in this way is about 0.030 in. A pilot hole (about ¼ in. in diameter) through the nonaluminum member improves performance by providing a path for the filler metal, so that it remains undiluted and ductile. Pilot holes are essential when the other metal is more than 0.030 in. thick.

With a filler metal suitable for fusion welding the other metal, joints

can be made in which the bottom member is the other metal. These filler metals usually have higher melting points than aluminum, though, and a superior joint is obtained if the aluminum is sandwiched between two pieces of the other metal. Three-layer joints of this type, with copper outer members and aluminum in the middle (see Fig. 32), are useful in making permanent connections in electrical applications.

Two or more pieces of aluminized steel can be joined by gas metal-arc spot welding, using an aluminum alloy filler metal and a backing strip of aluminum beneath the bottom steel sheet. In this joint, only the aluminum is exposed to the environment.

Gas Tungsten-Arc Welding

The advantages of welding aluminum alloys by the gas tungsten-arc process are the same as for other metals, as discussed in the article on Gas Tungsten-Arc Welding, which begins on page 113 of this volume.

Welding can be done with or without filler metal, but because filler metal is often used, there must be access at the joint for both torch and filler metal.

Thicknesses of aluminum alloys commonly welded by the gas tungsten-arc process range from 0.040 to ⅜ in. for manual welding and from 0.010 to 1 in. for automatic welding. Gas tungsten-arc welding is especially suitable for the automatic welding of thin workpieces that require the utmost in quality or finish, because of the precise heat control possible and the ability to weld with or without filler metal. Metal thicker than ⅜ in. can be manually welded; however either gas metal-arc or automatic tungsten-arc welding is preferred.

Power Supply and Equipment. For joining aluminum alloys, gas tungsten-arc welding utilizes either alternating or direct current. Both straight and reverse polarity are used with direct-current welding. The same power supplies, arc-stabilization accessories, torches, and control systems as are used for gas tungsten-arc welding of other metals are used for aluminum (see the article on Gas Tungsten-Arc Welding, page 113). Single-phase alternating-current welding transformers should have an open-circuit voltage of 80 to 100 volts.

The oxide layer on the surface of aluminum alloys gives rise to some arc rectification during the reverse-polarity half of the alternating-current cycle. This arc rectification, either partial or complete, is undesirable, because it results in poor arc stability and possible overheating of the transformer; it can be overcome by the use of condensers in the welding circuit or preferably by placing a battery bias in series with the welding circuit. Battery power of 6 to 8 volts is usually sufficient to balance the current. The positive terminal should be in the direction of the electrode. About 100 amp-hr of storage-battery capacity should be used with every 100 amp of welding current. If two or more batteries are needed to obtain the required ampere-hour electrical capacity, they should be connected in parallel.

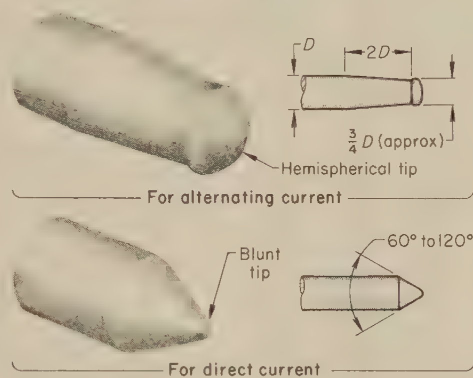

Fig. 33. Electrode tips used for gas tungsten-arc welding of aluminum alloys

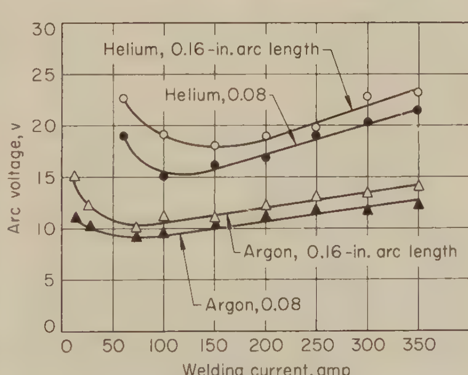

Fig. 34. Arc-voltage characteristics of argon and helium shielding gas in gas tungsten-arc welding of aluminum alloys

Electrodes for Gas Tungsten-Arc Welding

For alternating-current gas tungsten-arc welding, unalloyed tungsten and tungsten-zirconium electrodes are recommended. Zirconiated electrodes are less likely to be contaminated by aluminum and have a slightly higher current rating. Unalloyed tungsten electrodes minimize inclusions in the weld bead and current unbalance.

Electrodes of 1% thoriated tungsten, which have higher current capacity than unalloyed tungsten and cost less than zirconiated electrodes, are also used; their main disadvantage for alternating-current welding is a slight tendency to drip. This drip will result in some tungsten inclusions in the weld metal. With a skilled operator and good equipment, the inclusions are small and well dispersed. For best results with 1% thoriated electrodes, the electrode should have a ground surface. Electrodes of 2% thoriated tungsten are not generally used for alternating-current welding of aluminum alloys.

When gas tungsten-arc welding aluminum with alternating current, the tip of the electrode should be hemispherical, as shown in Fig. 33. The tip is prepared by using an electrode one size larger than required for the welding current, taper grinding the tip and forming the hemispherical end by welding for a few seconds with a current 20 amp higher than needed, holding the electrode vertically up.

Thoriated tungsten electrodes are normally used for direct-current gas tungsten-arc welding of aluminum. The tip of the electrode should be ground to a blunt conical point, having an included angle between 60° and 120° as shown in Fig. 33, to attain maximum penetration.

When an electrode becomes contaminated with aluminum, it must be replaced or cleaned. Minor contamination can be burned off by increasing the current while holding the arc on a piece of scrap metal. Severe contamination can be removed by grinding or by breaking off the contaminated portion of the electrode and re-forming the correct electrode contour on a piece of scrap aluminum.

Shielding Gases for Gas Tungsten-Arc Welding

Argon, helium, and mixtures of argon and helium are used as shielding gases in the gas tungsten-arc welding of aluminum alloys. The selection is somewhat dependent on the type of current used.

Welds made with alternating current show little difference in soundness or strength whether made with argon or helium shielding. With helium shielding, penetration is deeper; hence helium is sometimes employed with higher speeds and for thicker sections. Also, the welds develop slightly higher mechanical properties. However, argon is used more, for the following reasons:

1 It is more readily available and costs less than helium.
2 It affords better control of the weld puddle.
3 It gives a smoother, quieter arc, greater arc cleaning action, and easier arc starting.
4 Less gas is required for a specific application.
5 It has better cross-draft resistance than helium.
6 There is less clouding, and the metal stays brighter. The operator can see the weld puddle more easily.

With argon shielding, the arc voltage is lower for a given current value and arc length, as shown in Fig. 34. The lower arc-voltage characteristic of argon is essential to the successful manual alternating-current welding of

Table 22. Typical Conditions for Manual Gas Tungsten-Arc Welding of Butt Joints, Using Alternating Current(a)

	H	O	1/4	3/16	55	5/8	40	280	4

(a) Welding speed is 8 in. per minute for all metal thicknesses except 1/8 and 3/16 in., for which it is 10 in. per minute. Preheat is not required for metal through 3/16 in. thick; it is optional for 1/4-in.-thick metal; for welding 3/8-in.-thick metal in the flat position, it is up to 400 F; for welding 3/8-in.-thick metal in the other positions and for welding 1/2-in.-thick metal in all positions, it is up to 600 F. (b) F = flat; H = horizontal; V = vertical; O = overhead.

extremely thin material, because it decreases the probability of burn-through. This same characteristic is advantageous in vertical and overhead welding, because the molten metal is less likely to sag or run.

In special applications, where a balance of characteristics is desired, a mixture of argon and helium is used with alternating-current welding.

Argon is preferred for reverse-polarity direct-current welding because it establishes an arc more easily and provides better arc control.

Helium or an argon-helium mixture is always used with straight-polarity direct-current welding of aluminum. It assists in providing the deep, narrow penetration essential for the best properties and a minimum heat-affected zone. Helium shielding also prevents development of the rippled surface typical of argon shielding and straight-polarity direct-current welding.

When aluminum is welded with alternating current or reverse-polarity direct current, a white band of varying width appears alongside the weld bead. This white band, disclosed by one analysis to be aluminum oxide, never occurs when welding is done with straight-polarity direct current, and it is believed to be caused by the emission of electrons from the surface of the aluminum when it is on the cathode side of the arc (dcrp). The electrons leave the aluminum through the aluminum oxide, thus serving to detach the oxide from the surface.

When the white band alongside the weld is of hairline width immediately adjacent to the weld bead itself, the flow of shielding gas is adequate for proper shielding of the tungsten arc. Any increase in gas flow will cause widening of the band, indicating that gas is being wasted.

Filler Metals for Gas Tungsten-Arc Welding

Gas tungsten-arc welding can be done with or without filler metal. Sometimes the joint design permits the base metal to provide the weld metal. In some square-groove butt joints, the weld metal comes from the straight sides of the groove, or extra metal may be provided on a corner or flange that is melted to form the weld. If restraint is likely to cause cracking, best results are achieved by the addition of separate filler metal.

Usually, filler metal is added in the form of a bare rod for manual welding or as a coil of wire for automatic feeding. The filler-metal alloys used for gas-shielded arc welding of aluminum are discussed earlier in this article (see page 296) and are listed in Table 3. Suitability of the various filler metals for use with different aluminum alloys, and for different properties, is given in Tables 4, 5 and 6.

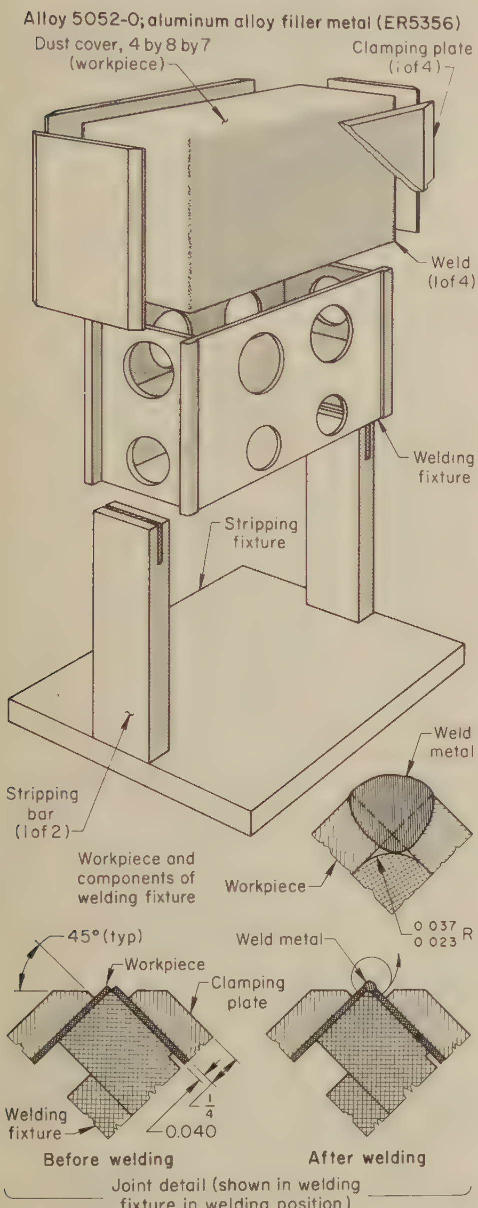
Filler-metal rod and wire comes in a wide range of sizes. Straight lengths of rod (36 in. long), packaged in tubes containing 5 lb of filler metal, are available in diameters of 1/16, 3/32, 1/8, 5/32, 3/16 and 1/4 in. from regular stock, and rod in diameters of 0.030, 0.035, 0.040, and 3/64 is available on special order. Wire is available in 1-lb and 10-lb spools in sizes from 0.030 to 0.040 in. in diameter and in 1-lb and 15-lb spools in sizes from 3/64 to 1/8 in. in diameter.

Weld Backing in Gas Tungsten-Arc Welding

Backing bars are commonly used when butt welds are made from one side only, but they are usually not necessary in automatic straight-polarity

direct-current welding of square-groove butt joints from one side only.

Temporary backing bars are shown with the butt welds in Table 22. Permanent backing bars like those shown in Table 17 and described in Example 297 (for gas metal-arc welding) are also applicable to gas tungsten-arc welding. For additional discussion of backing bars, see the section on Weld Backing for Gas Metal-Arc Welding.



Manual AC Gas Tungsten-Arc Welding

Joint type	Corner
Weld type	Fillet
Welding position	Flat

Alternating-Current Gas Tungsten-Arc Welding

Almost all manual and automatic gas tungsten-arc welding of aluminum alloys 0.040 through 3/8 in. thick is done with balanced-wave alternating-current high-frequency-stabilized power supplies, argon shielding gas, and unalloyed tungsten electrodes. Zirconiated tungsten electrodes and helium and argon-helium shielding-gas mixtures are also used with alternating-current welding for reasons discussed earlier, in the sections on Electrodes for Gas Tungsten-Arc Welding and on Shielding Gases for Gas Tungsten-Arc Welding. Adequate gas shielding is indicated by the bright silvery band bordering each side of the weld bead (also discussed earlier) and a shiny bead.

Usually, alternating-current welding provides the optimum combination of current-carrying capacity, arc controllability, and arc cleaning action for the welding of aluminum alloys. A short arc length must be maintained in order to obtain sufficient penetration and to prevent undercutting, excessive width of weld bead, and consequent loss of control of penetration and weld contour. Arc length should be about equal to the diameter of the tungsten electrode. On fillet welds, a short arc and adequate current are needed to prevent bridging the root. A short arc also ensures that the inert gas completely surrounds the weld as it forms.

Manual Welding. Typical conditions for manual alternating-current gas tungsten-arc welding are given in Tables 22 to 25. Metal that is more than 1/8 in. thick is grooved to ensure complete penetration. A single-V groove with an included angle of 60° to 90° is the most often used. Under certain conditions, a double-V groove may be advantageous for metal more than 1/4 in. thick. If the operator has difficulty in maintaining a very short arc, a larger included angle or joint spacing may be required in order to allow a longer arc to be used.

The arc should not be started by touching the tungsten electrode to the aluminum workpiece, because this may mark the work or result in aluminum being picked up on the electrode, which is likely to cause a wild, uncontrollable arc and a dirty weld. The initial arc should be struck on a starting block to heat the electrode to its operating temperature. (The arc should never be struck on a piece of carbon, as this will contaminate the electrode.) The arc is then broken and reignited at the joint. This technique reduces the likelihood of forming tungsten inclusions at the start of the weld, which can happen when a cold electrode is used to start the weld.

The arc is struck like striking a match — by swinging the electrode holder in a pendulum-like motion toward the starting place. With superimposed high-frequency current for arc stabilization, there is no need to touch the work with the electrode as the arc will start when the electrode tip is brought close to the work surface. Some machines apply the high frequency only when starting; others have it on continuously, or have a switch that permits the operator to cut it on or off at will. The arc is held at the starting point until the metal liquefies and a weld puddle is established. Establishment and maintenance of a suitable weld puddle is important and welding must not proceed ahead of the puddle. A separate foot-operated heat control, available with certain power supplies, is highly advantageous in preventing uneven penetration by permitting the current to be adjusted as the work becomes hotter. Breaking the arc also requires special care, to prevent the formation of shrinkage cracks in the weld crater. Several techniques are used. The arc can be gradually lengthened while filler metal is added to the crater; the arc can be quickly broken and restruck several times while adding filler metal to the crater; or a foot control can be used to reduce current at the end of the weld. Crater-filling devices may be used if properly adjusted and timed.

By using these techniques, and adequate fixturing, weld joints can be made manually in aluminum alloys down to 0.040 in. thick, without excessive distortion. This is shown in the following example.

Example 310. Maintaining Close Dimensional Tolerances During Manual Gas Tungsten-Arc Welding of Thin Aluminum Sheet (Fig. 35)

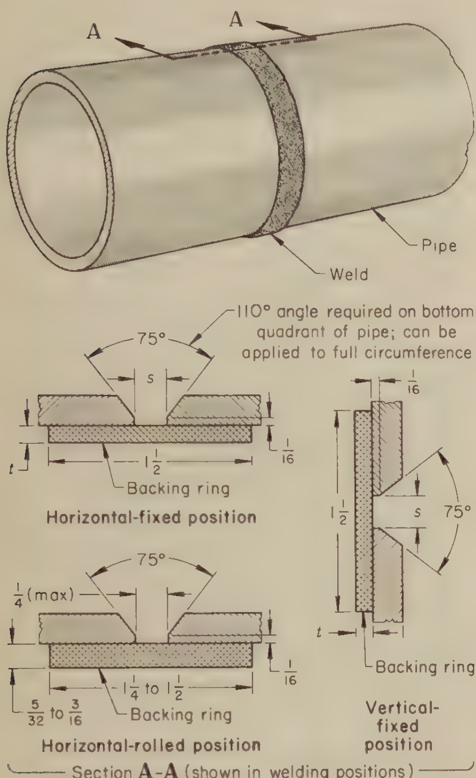
The open-end module can shown in Fig. 35, which served as a dust cover and a heat sink for electronic gear, was made from a single sheet of 0.040-in. aluminum alloy 5052-O by brake bending the bottom corners and manually welding the four vertical corner joints. Tolerances of ±0.01 to ±0.02 in. were necessary to ensure close fit over components for heat-sink efficiency.

To meet the tolerances, alternating-current gas tungsten-arc welding and ER5356 filler metal were selected, and a box-shape fixture was constructed that consisted of four 1/2-in.-thick steel plates joined so as to match the internal dimensions of the can. The fixture was tapered so that the can was slightly under dimension at the

closed end, and slightly over dimension at the open end.

The sequence of operations for welding was as follows:

1 After the can was formed and chemically cleaned, the fixture was inserted.
2 Four ¼-in.-thick plates of a size to leave access for welding the four vertical corners of the can were placed against the outer surfaces of the four sides of the can and clamped to the fixture through the end.
3 The corner joints were welded in the flat position (slightly downhill) on a welding table by the manual gas tungsten-arc process. (Welding conditions are given in the table that accompanies Fig. 35.)
4 The clamping plates were removed, leaving the can held on the fixture by shrinkage.
5 The can and fixture were placed on raised supports, the can was heated with an oxyacetylene torch, the can expanded, and the fixture dropped free.



Root opening, *s*, is zero with no backing ring or with a removable backing ring, and ¼ in. max with an integral backing ring. For thickness of backing ring (*t*) for fixed-position welding, see Table 26.

Manual AC Gas Tungsten-Arc Welding

Joint type	Butt
Weld type	Single-U groove
Joint spacing	None
Welding position	Horizontal-fixed pipe
Power supply	400-amp engine-driven generator
Fixtures	External alignment clamp
Torch	Water cooled
Electrode	3/16-in.-diam EWZr, taper ground
Filler-metal wire	1/8-in.-diam alloy ER5254(a)
Shielding gas	Argon, at 25 cfh
Current	190 amp, ac
Arc time per joint	7 min
Number of passes	Three
Hourly production per welder(b)	5 joints

(a) Chosen because it is compatible with all common aluminum alloys used for pipe and pipe fittings, ER5254 is a former AWS classification that has been replaced by ER5654. (b) Includes allowance for downtime.

Fig. 39. Welding large-diameter aluminum pipe for a pipeline (Example 312)

The can, welding fixture, clamping plates, stripping fixture, and joints are shown in Fig. 35. The inside radii of the welded corners were established by the corner radii of the fixture. The outside radii were dressed as needed to maintain a 0.04-in. maximum radius.

Tack welding before final welding is helpful in controlling distortion. Tack welds should be of ample size and strength, and preferably should be chipped out or tapered at the ends before welding over them. Alternating-current gas tungsten-arc welding is less suitable for tack welding than straight-polarity direct-current gas tungsten-arc welding, or than gas metal-arc welding (in which reverse-polarity direct current is used). Gas metal-arc welding (with dcrp) was used for tack welding during assembly of fuel tanks as described in Example 305; for final welding of the joints in these tanks, as described in the example that follows, manual alternating-current gas tungsten-arc welding was selected, because of the high weld quality that could be obtained with this process.

Example 311. Manual AC Gas Tungsten-Arc Welding of Fuel Tanks (Fig. 36)

Manual gas tungsten-arc welding, with alternating current, was used for making the 200 ft of groove welds and fillet welds required in the fabrication of the aluminum alloy fuel-storage tank shown in Fig. 36. The various butt, T and corner joints involved in welding the final assembly are also shown in Fig. 36. It was essential that the fuel tanks be leaktight, so the gas tungsten-arc process was selected for making these final welds because the ease with which the weld puddle could be controlled helped to ensure high weld quality.

The special preweld cleaning required for the components of this tank is described in Example 293. Tack welding of the components into 50 subassemblies, and tack welding of the subassemblies for final welding, were done by gas metal-arc welding, as described in Example 305, because the faster welding speed of that process reduced distortion and cost.

Before gas tungsten-arc welding, the tack welds and joints were mechanically cleaned with a stainless steel wire power brush. To avoid accumulation of dirt on the cleaned surfaces, final welding was done within 24 hr of the wire brushing.

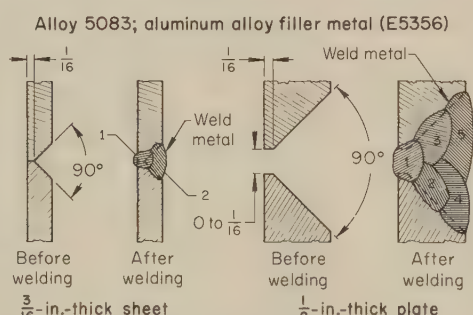
Alloy 5086-H32 sheet, 1/8 in. thick, was welded to itself and to 5083-H112 extrusions, which served as stiffeners and attachment flanges, and also formed an integral part of the fuel-tank wall. Bosses and fittings were of alloy 6061-T6. The parts were assembled and welded in a fixture.

As shown in the table that accompanies Fig. 36, many of the welding conditions were the same for all joints. Current varied according to joint design and welding position. Complete-penetration welds were deposited in single continuous passes. Tack welds were not removed. When the operator encountered a tack weld, he proceeded at about the same speed but added only enough filler metal to maintain proper weld contour. This procedure completely re-fused the tack welds.

After welding, the fixtured assembly was stress relieved in a furnace at 450 F for 2 hr, furnace cooled to 200 F, and then cooled in air to room temperature while still in the fixture.

Testing Procedures. Weld quality was checked by visual inspection based on workmanship samples, and the fuel tanks were tested for leaktightness by two different tests. In one test, the openings were plugged, the tanks were internally pressurized to 3 psi, and a liquid soap solution was flowed over all the welds. Leaks showed as a stream of fine bubbles. In the second test, the tanks were filled to 75% of capacity with a 0.25-to-0.50% aqueous solution of a detergent and a water-soluble dye, the remaining air space was pressurized to 3 psi, and the tanks were placed in a fixture and spun at 3 rpm for 3 min and 10 rpm for 7 min. The tanks were required to pass both tests with no leaks. If a leak occurred, which was unusual, repair was made by gas tungsten-arc welding.

Cleanness of Filler-Metal Wire. Because cleanness of the materials used to make the fuel tanks was of utmost importance (see Example 293), quality control of the filler-metal wire was necessary. In addition to the requirement that the wire meet Federal Specification QQ-R-566, samples of wire were tested periodically for cleanness by the following procedure. Using gas tungsten-arc equipment and settings (see the table that accompanies Fig. 36), an arc was struck near one edge of a clean coupon of alloy 5086 (1/8 in. thick by 4 in. wide by 6 in. long). Without adding filler metal, the arc was moved across the coupon, fusing well into it. If all conditions were correct, the weld puddle was clean and quiet. Next, some suspect filler metal was added to the puddle. Clean filler metal caused only a slight agitation of the puddle when added, and no dirt was seen floating on the molten puddle or on the weld bead afterward. Dirty filler metal caused violent action of the puddle and resulted in dirt floating on the surface. This was seen during the test through the proper shade of filter lens. After the test was completed, dirt could be seen on the surface of the weld bead.



Manual AC Gas Tungsten-Arc Welding

Joint type	Butt
Weld type	Single-V groove
Welding position	Horizontal
Power supply	Stabilized
Weld backing	None
Torch	Manual, water cooled
Electrode:	
3/16-in. sheet	1/8-in.-diam EWZr
1/2-in. plate	1/4-in.-diam EWZr
Filler metal:	
3/16-in. sheet	5/32-in.-diam ER5356
1/2-in. plate	3/16-in.-diam ER5356
Shielding gas	Argon, at 35 cfh
Current:	
3/16-in. sheet	160 amp, ac
1/2-in. plate	300 amp, ac
Preheat:	
3/16-in. sheet	None
1/2-in. plate	200 F
Interpass temperature	200 to 400 F
Number of passes:	
3/16-in. sheet	Two
1/2-in. plate	Five

Results of Qualification Tests

Tensile strength	26,805; 27,400 psi(a)
Failure	Ductile failure, in weld metal
Guided bend tests (4)	Results acceptable

(a) Results of two tests in reduced-section tensile specimens 0.750 by 0.487 in. and 0.751 by 0.474 in.

Fig. 40. Welds in 3/16-in. sheet and 1/2-in. plate, made in the horizontal position by the gas tungsten-arc process (Example 313)

Because gas tungsten-arc welding with alternating current affords close control of the weld puddle in all positions, it is often used for the welding of pipe joints. Typical welding conditions are given in Tables 26 and 27, and joint edge preparations are shown in Fig. 37 and 38.

Manual alternating-current gas tungsten-arc welding is an economical process for joining pipe up to fairly long lengths. The equipment required is less expensive than that for gas metal-arc welding and it needs less maintenance, a desirable feature when field welding. The suitability of this process for welding aluminum pipe is described in the following example, in which the importance of joint design is also discussed.

Example 312. Welding Pipe in the Horizontal-Fixed Position by the Gas Tungsten-Arc Process (Fig. 39)

The 6-in.-OD, 0.188-in.-wall alloy 6351-T4 pipe shown in Fig. 39 was welded economically in lengths up to five miles (for use in a pipeline) by the manual gas tungsten-arc process. Because the pipe was fixed in the horizontal position, it was necessary to be able to control the weld puddle in all positions. The gas tungsten-arc process was therefore chosen. The joint was a single-U-groove butt with no root opening, as shown in Fig. 39. Joint surfaces were precleaned by wiping with solvent, an external clamp was used to align the joint, and the joint was tack welded. After tack welding, the clamp was removed and the joint was welded in three passes, each consisting of three segments. By remelting starts and stops of each segment when restriking the arc, potential defects were avoid-

ed. The weld passes are shown in section A-A in Fig. 39, and the sequence and direction of the segments of each weld pass are shown at lower left in Fig. 39. Segments 1, 4 and 5 were made in the overhead position, with the welder lying under the pipe, and the remainder of the segments were made in the vertical-up position, with the welder kneeling. Welding conditions are given in the table that accompanies Fig. 39.

Preheating parts thicker than about 3⁄16 in. may be advantageous when gas tungsten-arc welding with alternating current. The preheating temperature depends on the thickness of the base metal and the particular problems associated with the job. Often 200 F is a sufficient preheat temperature for material up to ½ in. thick, as in the following example, in which the use of preheat and careful selection of electrode material helped in obtaining the necessary mechanical properties.

Example 313. Use of Preheat in Welding ½-In.-Thick Alloy 5083 Plate (Fig. 40)

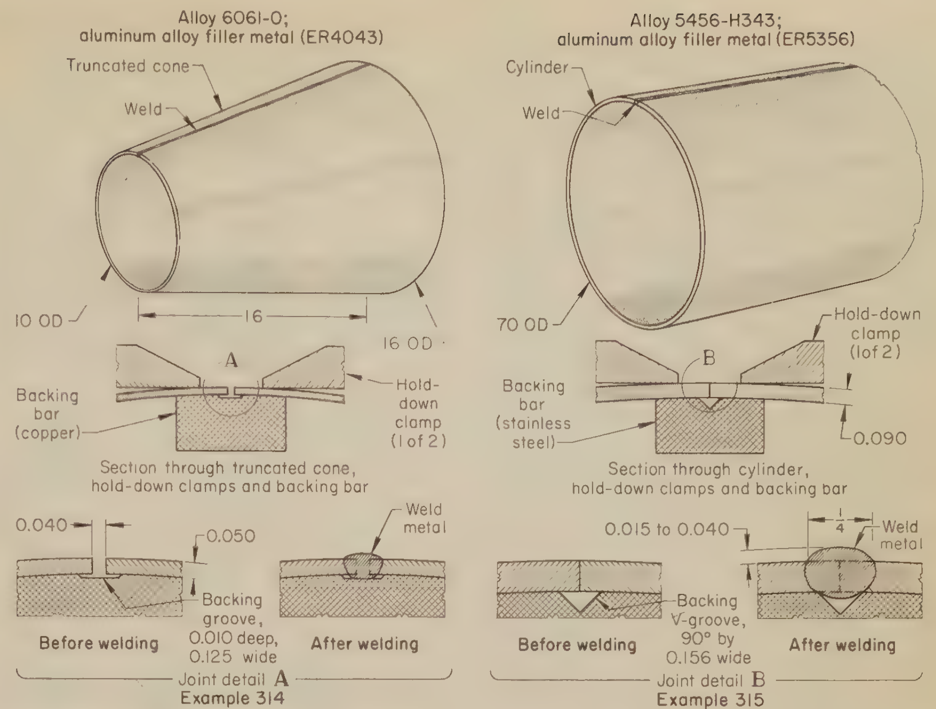
Figure 40 shows the joint designs and the buildup sequences used in manual gas tungsten-arc welding of 3⁄16-in.-thick sheet and ½-in.-thick plate, both of alloy 5083. In welding the ½-in. plate, preheating to 200 F was found helpful in producing a weld puddle fluid enough for welding in the horizontal position; the 3⁄16-in. sheet could be welded without preheat. Both the sheet and the plate were welded with EWZr electrodes, which resulted in clean weld metal, with minimum tungsten contamination.

The edges to be welded were grooved by machining or grinding, or both. All grease, oil, and oxide were removed by solvent cleaning and brushing with a stainless steel wire brush before welding. It was essential that the welding current and method of depositing the weld metal be such that there was no undercutting. All cracks and blowholes that appeared on the surface of a bead were removed by chipping or grinding before depositing the next bead. Production data and results of welding-procedure qualification tests are summarized in the table that accompanies Fig. 40.

Automatic Welding. The gas tungsten-arc process can be mechanized either with or without the addition of filler metal. If filler metal is used, it is normally added mechanically by cold-wire feed units. Automatic gas tungsten-arc welding usually employs a shorter arc length, and higher welding current and welding speed, and results in deeper penetration than manual welding. Typical conditions for the automatic alternating-current gas tungsten-arc process, for butt joints and metal thicknesses from 1⁄16 to ½ in., are given in Table 28.

Joint fit-up, joint cleanness and filler-metal cleanness are especially important with automatic welding. Joint-edge cleaning must be thorough and should immediately precede welding. Additional torches can be installed ahead of the main welding torch for cleaning and preheating.

Automatic alternating-current gas tungsten-arc welding has been used in the aerospace industry for joining relatively thin aluminum. High-strength high-quality welds can be made without excessive distortion, and the quantities are usually large enough to warrant mechanization. Two such applications of the automatic gas tungsten-arc process are described in Examples 314 and 315, which follow.



Item	Example 314 (Truncated cone)	Example 315 (Cylinder)
Conditions for Automatic AC Gas Tungsten-Arc Welding		
Base metal	6061-O	5456-H343
Base-metal thickness, in.	0.050	0.090
Joint type	Butt	Butt
Weld type	Square groove	Square groove
Root opening, in.	0.040	None
Welding position	Flat	Flat
Power supply	300 amp with high-frequency stabilization	300 amp with balanced wave

Fig. 41. A truncated cone and a cylinder that were automatic gas tungsten-arc welded, and hold-down devices, backing-groove designs, and joint details (Examples 314 and 315)

Examples 314 and 315. Welding Aerospace Parts by the Automatic Alternating-Current Gas Tungsten-Arc Process (Fig. 41)

Example 314 — Truncated Cone (Fig. 41). Because the welded truncated cone (alloy 6061-O) shown at the left in Fig. 41 served as a blank to be explosively formed into a streamlined (ballistic ogive) shape, the welded joint had to be ductile enough to undergo considerable distortion without rupturing. The 0.010-in. by 0.125-in. groove in the backing bar provided for complete joint penetration, but with limited reinforcement to help ensure ductility of the weld. After welding, but before forming, the weld bead was roll planished. After forming, welds were checked for cracks by liquid-penetrant inspection. The joints made using the conditions listed in the table that accompanies Fig. 41 consistently had acceptable ductility, and they were crack-free after forming.

Example 315 — Cylinder (Fig. 41). The alloy 5456-H343 cylinder shown at the right in Fig. 41 was part of a missile fuel tank. The 0.156-in.-wide 90° V-groove in the backing bar was used to provide the maximum root reinforcement allowed. The weld bead face was ¼ in. wide and had a reinforcement of about 30%. Welding was done under the conditions given in the table that accompanies Fig. 41. The square-groove butt joint had zero root opening. The edges were drawfiled and scraped to remove surface oxides prior to welding.

Welds had acceptable radiographic quality and tensile properties — 31,820 psi yield strength, 50,620 psi tensile strength, and 5.5% elongation. Gas metal-arc welding was also tried for this part, and although welding speed was about twice that for gas tungsten-arc welding, rejections because of cracks and porosity were numerous.

Another application in which automatic alternating-current gas tungsten-arc welding was used to join rela-

Table 28. Typical Conditions for Automatic Gas Tungsten-Arc Welding of Butt Joints, Using Alternating Current (a)

Metal thickness, in.	Electrode diameter, in.(b)	Argon flow, cfh	Welding current (ac), amp(c)	Number of passes
1⁄16	1⁄16	15	60 to 80	1
⅛	3⁄32	20	125 to 145	1
3⁄16	⅛	20	190 to 220	1
¼	3⁄16	25	260 to 300	2
⅜	¼	30	330 to 380	2
½	¼	30	400 to 450	4

(a) Power supply: alternating current with superimposed high-frequency current, balanced wave. (b) Unalloyed tungsten electrodes are recommended. (c) Current ranges are averages for butt welds with square edges. For metal ¼ in. thick or more, edges are usually beveled.

tively thin aluminum was the fillet welding of an 0.087-in.-thick alloy 5456-H343 extruded T-ring stiffener to the inside surface of a 0.071-in.-thick alloy 5456-H343 sheet cylinder, as shown in Fig. 42. The fillet welds were made using an oscillating torch, which was mounted on a boom that reached inside the cylinder. Welding was done in the horizontal-rolled position, with the cylinder being rotated by a precision positioner. The torch had arc-voltage control. A 300-amp balanced-wave power supply and 0.030-in.-diam ER5556 filler-metal wire were used.

The assembly was part of a fuel tank. Manual welding of the stiffeners had been tried, but it resulted in excessive distortion, defects requiring repair, and excessive production time. Automatic welding reduced the number of out-of-tolerance parts by 90%, weld defects by 30%, and welding time per tank by 200 man-hours.

As the thickness of the metal to be welded increases, power requirements increase. When the power requirement exceeds the capacity of the power supply, maximum welding speed cannot be attained and one of the advantages of mechanization is not realized. For single-pass square-groove butt welding, the advantage of higher welding speed is lost when the thickness of the material reaches 3/16 to 1/4 in. For example, when welding the circumferential seam of a manifold sump in 0.190-in.-thick alloy 5052-H32, the current was raised from 210 amp, which is normally used for automatic gas tungsten-arc welding of this thickness of aluminum, to 310 amp (the upper limit of the power supply) and the welding speed was raised to only 8 in. per minute, about the same as for manual welding. The weld joint and the conditions for welding are shown in Fig. 43. The filler metal was smaller in diameter than often used, to improve control of the weld puddle. Although the welding speed was slow, the welds did meet requirements — namely, uniform bead width, very smooth bead surface, radiographic quality to class II (MIL-R-45774), and weld-metal yield strength of 14,150 psi, tensile strength of 29,300 psi, and elongation of 14%.

For butt welds in material thicker than 3/16 to 1/4 in., the edges of the joint are usually beveled to a single or double V-groove for multiple-pass welding. An alternative process would be gas tungsten-arc welding with straight-polarity direct current, which can make square-groove welds in material up to 3/4 in. thick without difficulty.

Repair welding can be done by the alternating-current gas tungsten-arc process. In the following example, filler metal was not added until a clean weld puddle was well established, which was helpful in obtaining clean weld metal on a resin-impregnated casting.

Example 316. Repair of Spotfacing Error in Resin-Impregnated Aluminum Alloy Casting (Fig. 44)

A spotfacing error in an attachment boss (Fig. 44) used for bolting together the two halves of an aircraft-engine crankcase casting made of alloy 355-T7 reduced the height of a boss below tolerance. The casting was salvaged by weld repair, which was permitted because the service load in the boss area was relatively low. The equipment and welding conditions, as listed in the table that accompanies Fig. 44, were conventional for gas tungsten-arc welding. However, deposition of the weld bead required careful manipulation to avoid development of porosity and to obtain complete fusion, because the casting had been impregnated with a polyester resin.

The casting had been cleaned by blasting at the foundry, but required vapor degreasing and stainless steel wire brushing of the boss and surrounding area. Preheat and postheat were considered unnecessary because the service load was not a critical factor in this portion of the casting.

To remove the impregnated resin, an arc was struck and manipulated over a small area until a puddle of clean metal was obtained. This puddle was then extended to cover the entire area to be welded; no filler metal was used at this stage. After the puddle solidified, the area was wire brushed. The arc was restruck and a thin layer of filler metal was deposited in crescent-shape beads to cover the area. This layer was wire brushed, and a second bead was similarly deposited, bringing the buildup to a height sufficient for re-spotfacing to correct size.

After visual inspection and machining, the welded area was radiographed to check for cracks and porosity. The repair operation proved satisfactory.

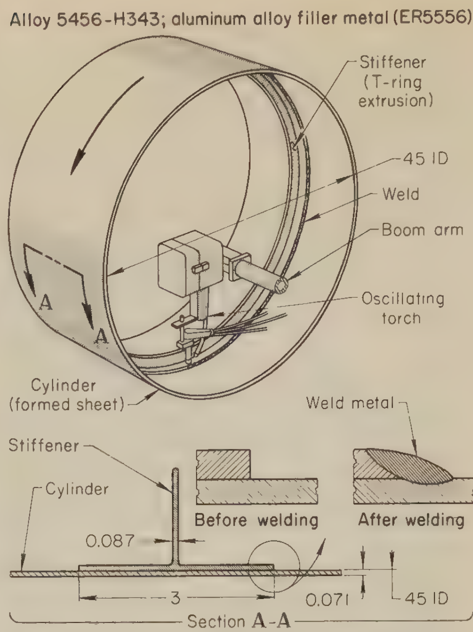

Fig. 42. Automatic ac gas tungsten-arc welding, with an oscillating torch, of an extruded stiffener to a fuel-tank cylinder, which was rotated in a precision positioner during welding

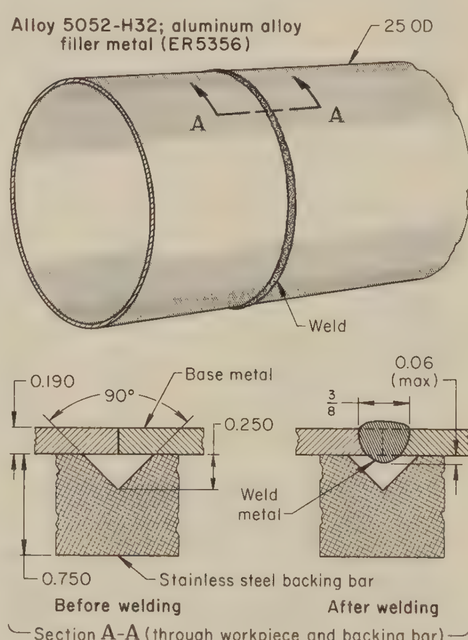

Automatic AC Gas Tungsten-Arc Welding

Joint type	Butt

Reverse-Polarity Direct-Current Gas Tungsten-Arc Welding

Although gas tungsten-arc welding of aluminum with reverse-polarity direct current (electrode positive) is seldom used, this process offers certain advantages in the joining or repairing of thin-wall heat exchangers, tubing and similar assemblies with sections up to about 3/32 in. thick.

The process is characterized by shallow penetration, ease of arc control and good arc cleaning action. However, reverse-polarity direct current causes most of the heat of the arc to be generated at the electrode, which necessitates the use of large-diameter electrodes and decreases arc efficiency. If practical electrode sizes are to be used, work must be thin. For example, a 1/4-in.-diam electrode is needed in order to carry a 125-amp current. This would weld aluminum up to about 1/8 in. thick.

Reverse-polarity direct-current welding is useful for small shops because it can be used with almost any general-purpose power supply. Thoriated tungsten electrodes are normally used, and argon shielding is preferred, because it facilitates arc starting and arc control. Table 29 gives typical conditions for welding butt joints in metal up to 0.050 in. thick with reverse-polarity direct current.

Reverse-polarity direct-current welding was used in constructing from 0.020-in.-thick alloy 1100 sheet reflectors that required a high-quality mirror finish after buffing. Riveting could not be used as it resulted in distortion and polishing difficulties. Spot and seam resistance welding were ruled out by the shape of the parts, and the material was too thin to be joined by gas metal-arc welding. Therefore, gas tungsten-arc welding had to be used, and reverse-polarity direct current was selected because its shallow penetration reduced the risk of burn-through.

The reflectors weighed about 1 lb each and required butt, corner and lap

joints. The joint areas were precleaned by sandblasting, and the parts were lightly clamped and tack welded.

Direct current was supplied by a rectifier of 200-amp capacity, adjustable to as low as 10 amp. A standard water-cooled torch was used, with a ceramic gas nozzle, argon shielding gas, a 3/16-in.-diam thoriated tungsten electrode, and ER1100 filler metal. Reflectors of satisfactory quality were made without difficulty.

Reverse-polarity direct current was also used in welding an open box to be used as a housing. The housing was required to be both rigid and lightweight. Sand casting could not be used because the walls were too thin, and the design and the low total production ruled out die casting. Therefore, the housing was designed as a weldment in 0.050-in.-thick alloy 6061-T6 sheet, with stiffeners and numerous bosses, up to 1/4 in. thick, welded on. The housing weighed about 3 lb.

Resistance spot welding of the housing joints was unsuitable because of the shape of the components and the combination of thin and thick sections. Gas metal-arc welding was ruled out because of the short joint lengths, the need for frequent repositioning of the assembly, and the thinness of the metal. Therefore, gas tungsten-arc welding was used and reverse-polarity direct current was selected because of its shallow penetration.

The parts were vapor degreased, and tack welded in standard clamps. They were then removed from the clamps and were welded without preheating. The current was supplied by a 200-amp rectifier. A special foot switch was used to break the arc at the end of the seam, to prevent the formation of craters. A standard water-cooled torch was used, with a ceramic gas nozzle, argon shielding, a 3/32-in.-diam thoriated tungsten electrode, and ER4043 filler metal. After welding, the housing was re-aged, which gave it sufficient rigidity and dimensional stability, and critical dimensions were machined.

Straight-Polarity Direct-Current Gas Tungsten-Arc Welding

With straight-polarity direct current (electrode negative), the heat is generated at the workpiece surface, producing deep penetration and permitting higher welding currents for a given electrode size than can be used with reverse polarity. As a result, smaller electrodes can be employed with a given welding current, which helps to keep the weld bead narrow. Because of the narrow and deep penetration obtained, less edge preparation and less filler metal are needed, and welding is faster than when using reverse polarity. Because of the high heat generated on the workpiece surface, melting is rapid, no preheat is required, even of thick sections, and there is little distortion of the base metal.

The process has been used for years on as-received material to make irrigation tubing in high-speed tube mills, at speeds up to 50 ft per minute. It is the process employed in almost all of the highly automatic coil-joining welders used on continuous process lines in the aluminum industry. Perhaps more lineal feet of welds in aluminum alloys have been made by this process than by any other process.

Table 29. Typical Conditions for Manual Gas Tungsten-Arc Welding of Square-Groove Butt Joints, Using Reverse-Polarity Direct Current (a)

Metal thickness, in.	Electrode diameter, in. (b)	Filler-metal diameter, in.	Argon flow rate, cfh	Current (dcrp), amp (c)
0.020	1/8 to 5/32	0.020	15-20	40-55
0.030	3/16	0.020 or 3/64	15-20	50-65
0.040	3/16	3/64	25-30	60-80
0.050	3/16	3/64 or 1/16	25-30	70-90

(a) Single-pass welds made in the flat position. Use of a backing bar having a generous groove is recommended. (b) Thoriated tungsten electrodes. (c) Higher currents with larger electrodes may be used for automatic welding.

Straight-polarity direct-current gas tungsten-arc welding is also especially suitable for joining thick sections and has been used on aluminum up to 1 in. thick. It is well suited for tack welding and produces welds of good contour and high quality. Butt joints are characteristically narrow and flat, and buildup can be controlled by varying the size and amount of filler wire. Fillet welds characteristically have a concave or flat face. Fillet size can be regulated easily by varying the size of the filler wire. The shape of the weld is generally uniform, and the concentrated heat of the arc gives good fusion at the root of the joint.

The mechanical properties of welds made by this method are equal to or better than those made with alternating current. The welding heat is more

concentrated, the heat-affected zone is smaller and, because preheating is not needed and only a few weld passes are customary, residual tensile stress is low. Also, cold worked alloys retain their temper. These are important advantages when joining heavy sections of alloys such as the 5*xxx* series.

As surface oxides on aluminum are not removed during straight-polarity direct-current welding, thorough preweld cleaning is necessary to ensure that oxide will not be trapped in the molten weld puddle. Normal practice in the aerospace industry is to clean chemically and to scrape or file the joint area. However, many commercially acceptable welds have been made with no preweld cleaning.

The surfaces of the welds are not as bright as those made with alternating current because they are coated with an oxide film. The film does not indicate any lack of fusion or the presence of porosity or inclusions and is easily removed by a light wire brushing.

Because of the highly penetrating nature of the straight-polarity direct-current arc, melting occurs the instant the arc is struck. Care should be taken to strike the arc within the weld area to prevent undesirable marking of the workpiece. Although a high-frequency sparking current is not required to stabilize the arc during direct-current welding, it is useful for starting the arc without marking the workpiece or causing tungsten inclusions. A starting tab of scrap aluminum can be used for touch starting if a high-frequency circuit is not available.

Because continuous high-frequency and wave-balancing circuits are not used in direct-current welding, performance can be duplicated easily by using standardized arc voltages and amperages, even on different machines. Normally, thoriated tungsten electrodes are employed, with helium shielding.

Manual Welding. Typical conditions for welding by the manual straight-polarity direct-current gas tungsten-arc process are given in Tables 30 and 31. Metal thicker than 1/4 in. is grooved (single-V or single-U) to ensure complete joint penetration. A double-V or double-U groove may be advantageous for metal more than 1/2 in. thick.

Table 32. Typical Conditions for Automatic Gas Tungsten-Arc Welding of Square-Groove Butt Joints, Using Straight-Polarity Direct Current (a)

Metal thickness, in.	Electrode diameter, in. (b)	Filler metal: Diameter, in.	Filler metal: Feed, ipm	Helium flow rate, cfh	Arc: Current (dcsp), amp	Arc: Voltage, v	Welding speed, ipm

Semiautomatic Gas Tungsten-Arc Welding (dcsp)

Joint type	Circumferential T
Weld type	Fillet
Power supply	500 amp, with constant voltage and high-frequency start
Mechanization	Automatic torch rotation, automatic workpiece rotation
Fixtures	Expanding backing mandrel, copper hold-down bars, holding fixture
Torch	Mechanically held, pencil type, water cooled
Electrode	3/32-in.-diam EWTh-2
Filler metal	1/16-in.-diam ER4043
Shielding gas	Helium, at 75 cfh
Current	160 amp, dcsp
Voltage	15 v
Filler-wire feed	110 ipm
Welding speed	12 ipm

Fig. 46. Welding a tubular fitting into the wall of a tank (Example 318)

The welder must use care in maintaining a suitable short arc length. In addition to the standard techniques (runoff tabs and striking plates) for preventing and filling craters, foot-operated heat controls are used. These controls are also advantageous for adjusting the current as the workpiece heats up and as section thickness changes. The arc is moved steadily forward and filler metal is fed into the leading edge of the weld puddle or laid on the joint and melted by the arc. Bead size can be controlled by varying filler-metal size.

Automatic Welding. Straight-polarity gas tungsten-arc welding is readily adaptable to mechanization, which is desirable in order to maintain the required short arc lengths. The result is improved weld quality, as discussed in the following example, which describes the automatic butt welding of relatively thin alloy 6061 sheet.

Example 317. Welding 0.091-In.-Thick Sheet by the Automatic Straight-Polarity Direct-Current Gas Tungsten-Arc Process (Fig. 45)

A 20-in.-long butt weld (see Fig. 45) used to complete a cylinder formed from 0.091-in.-thick alloy 6061 sheet was required to be defect-free under radiographic inspection. Automatic gas tungsten-arc welding was chosen, a clamping fixture and a grooved copper backing bar were used, and the process variables were closely controlled (see the table that accompanies Fig. 45).

The joint was cleaned chemically and by draw filing. To facilitate arc initiation and adjustment, starting and runoff tabs were attached at the joint. The welding torch was adjusted to give a very short arc — from below the original workpiece surface to about 0.015 in. above, and on the verge of short circuiting. To ensure accurate weld placement, the carriage with the welding torch mounted on it was aligned with the joint to within ±0.005 in. for the entire 20-in. length of the weld. Helium with a small amount of argon added was the shielding gas.

Sound, defect-free welds were produced. Production rate varied from 20 to 40 pieces per shift (including cleaning and setup time), depending on operator skill.

Mechanization is useful in preventing crater cracking by eliminating all but one start and stop. This is illustrated in the following example, which describes the fillet welding of alloy 6061 tubing to alloy 2014 sheet.

Example 318. Semiautomatic Welding of 0.125-In.-Wall Tubular Fittings in a 0.190-In.-Thick Tank Wall (Fig. 46)

When manual gas tungsten-arc and gas metal-arc welding the alloy 6061 tubular fittings shown in Fig. 46 to alloy 2014 tank walls, several repositionings of the workpieces were required, necessitating several starts and stops. Weld crater cracking became a problem, and so it was decided to change to semiautomatic gas tungsten-arc welding, which could be done continuously and with close control. Straight-polarity direct current was selected because of the deep penetration that could be obtained by using it.

During welding, either the workpieces were rotated and the torch was stationary, or the torch was rotated and the workpieces were stationary — depending on workpiece size and the tooling available. Auxiliary wire feed was used to obtain the required fillet size. Some designs required fillet welds on both sides of the joint. Precise tooling was needed to align the electrode and the filler wire with the joint. Copper backing mandrels and copper hold-down bars promoted rapid cooling and faster welding. As a result, the size of the heat-affected zones was restricted and good weld strength was obtained.

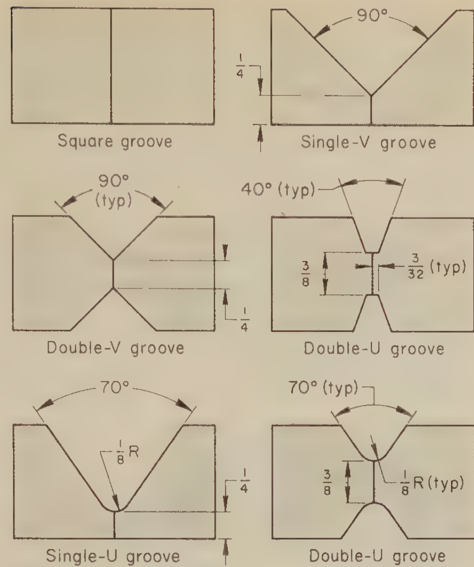

Fig. 47. Typical joint designs for making butt welds by the automatic straight-polarity direct-current gas tungsten-arc process

Various methods were used to minimize crater cracking, the preferred method being automatic sequencing of welding variables so as to add filler-metal wire after travel had stopped, while gradually increasing arc voltage and decreasing current.

Preweld cleaning consisted of manual brushing, wiping with commercial cleaners, and wiping dry with clean cloths. Welding conditions and equipment data are shown in the table that accompanies Fig. 46.

For best results, a fully mechanized automatic setup should be employed. With a fully automatic setup, welds are made in aluminum alloys from 0.010 in. thick to more than 1 in. thick. Because this process allows precise control of weld penetration, it is often selected for joining aluminum in the thickness range from 0.010 to ⅛ in.

Typical conditions for making square-groove butt welds with automatic straight-polarity direct-current gas tungsten-arc welding in aluminum up to ⅜ in. thick are given in Table 32. Automatic welding has also been used to weld square-groove butt joints in aluminum up to 1¼ in. thick, but V-groove and U-groove edge preparations are often used on thick sections. Mechanical and magnetic oscillation can be used to spread the filler metal and to aid fusion when groove welding with this process. Typical edge preparations are shown in Fig. 47.

Because square-groove butt welding using the automatic straight-polarity direct-current gas tungsten-arc process results in narrow weld beads, low dilution with filler metal, and excellent weld strength, this process is used for joining rather thick sections of high-strength aluminum alloys. Conditions for welding three such alloys (5083, 2219 and 7039) are given in Table 33.

Two examples of this type of weld in 0.406-in.-thick and 1.000-in.-thick alloy 2219 plate follow.

Example 319. Making Aerospace-Quality Arc Welds in Alloy 2219 Plate (Fig. 48)

In producing the large cylindrical shell shown in Fig. 48 for part of a rocket-propellant tank, it was necessary to weld four segments together. Alloy 2219-T87 was cho-

Table 35. Common Problems With Gas Tungsten-Arc Welding and Their Usual Causes

Arc-Starting Difficulty

1 Incorrect adjustment of high-frequency spark gap
2 Incomplete welding circuit

Inadequate Cleaning Action by the Arc

1 Incorrect adjustment of high-frequency unit or battery bias
2 Open-circuit voltage too low
3 Inadequate gas shielding, caused by:
  Insufficient gas flow
  Spatter on inside of gas nozzle
  Contact tube off-center in relation to gas nozzle
  Wrong nozzle-to-work distance
  Incorrect position of welding torch
  Drafty environment

Dirty Weld Bead

1 Insufficient shielding-gas coverage, caused by:
  Insufficient gas flow
  Damaged or dirty gas nozzle
  Wrong nozzle-to-work distance
  Incorrect position of welding torch
  Contact tube off-center in relation to gas nozzle
  Wrong nozzle size (use smallest possible)
  Drafty environment
  Impurities in shielding gas, due to air or water leakage
2 Poor cleaning action by the arc (see causes listed under the heading "Inadequate Cleaning Action by the Arc", above)
3 Unstable arc (use battery bias)
4 Electrode contamination
5 Dirty workpieces or filler metal

Electrode Contamination by Aluminum

1 Improper manipulation of torch
2 Excessive electrode extension
3 Wrong electrode material (use zirconiated electrode with alternating current)

Incorrect Electrode Contour

1 Incorrect electrode size for current
2 Incorrect contouring of electrode end before welding
3 Wrong electrode material (use zirconiated electrode with alternating current)

Weld-Bead Contamination by Electrode

1 Electrode size too small for current
2 Improper manipulation of torch
3 Wrong electrode material (use zirconiated electrode with alternating current)

Rough Weld Bead

1 Unstable arc
2 Improper manipulation of torch
3 Incorrect current

Weld Bead Too Wide

1 Excessive current
2 Welding speed too low
3 Arc too long
4 Electrode stickout too short
5 Incorrect position of welding torch

Inadequate Penetration

1 Wrong edge preparation for the arc characteristics (groove too narrow)
2 Excessive filler metal in weld puddle
3 Insufficient current
4 Arc too long
5 Welding speed too high

Difficulty in Adding Filler Metal

1 Improper manipulation of welding torch or filler metal, or both
2 Incorrect current, welding speed or filler-metal size
3 Incorrect adjustment of high-frequency unit
4 Poor insulation on high-frequency unit or leads
5 Incorrect operation of battery bias (connections may be reversed)

Poor Visibility of Arc and Weld Puddle

1 Wrong position of work
2 Incorrect position of welding torch
3 Small or dirty lens helmet
4 Wrong size of gas nozzle (use smallest possible)

Overheating of Power Supply

1 Excessive power demand (two similar welding machines can be operated in parallel if the capacity of one is insufficient)
2 Poor functioning of cooling fan
3 Poor grounding of high-frequency unit
4 Poor functioning of bypass capacitor
5 Poor functioning of battery bias
6 Dirty rectifier stacks (regular maintenance required)

Overheating of Welding Torch, Leads and Cables

1 Loose or faulty connections
2 Welding torch, leads or cables too small
3 Inadequate cooling-water flow

Welder Fatigue

1 Wrong position of work (weld in flat position whenever possible)
2 Inadequate seating arrangement for welder
3 Lack of ventilation
4 Disregard of safety rules regarding head shield, lens, gloves
5 Weight of cables (reduce by suspending cables overhead)
6 Too many auxiliary operations, such as cleaning and chipping (provide additional help)

sen for this application because of its combination of good base-metal strength at elevated temperature, good weld strength, and good weldability compared to other high-strength, heat treatable aluminum alloys. High-quality welds were required.

The four segments were produced from plates 120 in. wide by 311 in. long and 2 in. thick by curving them in the long direction to a 16½-ft radius and mechanically milling the concave side to various final thicknesses. Vertical stiffening ribs 2 in. thick, top and bottom rims, and 2-in.-wide lands 0.406 in. thick (and thus with root faces 0.406 in. wide) were left on the plates. Other areas of the plates were machined to various thicknesses up to 0.25 in., which was the thickness that adjoined the weld lands. The extra thickness of the weld lands was designed to compensate for the lower unit strength of the weld area compared with that of the base metal.

The procedure for making the welds was as follows:

1 Clean the areas to be welded, both chemically and mechanically.
2 Place shell segments on leveling fixtures and against chucks to form the cylinder. Position clamping straps inside the top rim and clamp in place. Clamp welding fixture in place with two vacuum chucks, one on either side of the joint.
3 Check joint alignment and spacing.
4 Manually weld aluminum runoff tabs, 6 in. square, top and bottom of each joint.
5 Make 1-in. tack welds manually on 6-in. centers.
6 Check equipment.
7 Automatically weld four 10-ft-long joints in one pass each, on inside of cylinder.
8 Inspect visually and radiographically.
9 Remove runoff tabs.

With the machine settings used, it was not necessary to use a backing bar, but the back of the weld was cooled with excess helium gas from the welding operation. The weld was made in one pass, with only minor distortion. If the weld lands had been thicker, thus providing wider root faces, or if less distortion than the minor amount obtained had been required, a double-welded joint with one pass from each side would have been used, as discussed in the following example. Welding conditions are shown in the table that accompanies Fig. 48.

Example 320. Automatic Straight-Polarity Direct-Current Gas Tungsten-Arc Welding of 1-In.-Thick Alloy 2219 (Fig. 49)

A Y-shape ring machined from a rectangular forging was used as a transition fitting between the large-diameter cylindrical

shell and the bulkhead of a rocket-propellant tank, as shown in Fig. 49. Welding of the alloy 2219-T87 cylinder is described in Example 319. In welding the Y-ring to the cylinder, the 1.000-in. wall thickness required two weld passes, one from each side.

The workpieces were alkaline cleaned and deoxidized, and the joint edges were mechanically scraped to bare metal before welding. They were then mounted on a rotating table powered by a 3-hp-drive motor with proportional and integral servo-amplifier speed control. Two welding units were used: one outside and one inside the cylinder. The unit inside the cylinder was placed so that its weld puddle lagged approximately 4 ft behind the weld puddle of the outside unit. Both welding units were equipped with sequence control for programing starts and stops and were also equipped with a cold filler-wire feed driven by a closed-loop velocity servo system.

Tack welds 2 in. long were made on 6-in. centers around the full circumference of the cylinder. Penetration was established before rotation of the workpiece started. Welding was done simultaneously from both sides using the "buried-arc" technique in which fairly low arc voltage and a high current were used, the electrode following the concave molten weld puddle below the original workpiece surface. With this technique, deep penetration and narrow welds were obtained at fairly high welding speed. Weld-quality requirements were severe; virtually no porosity or defect was allowed.

Setup time was about 8 hr, and welding time was 5 hr per joint.

Although the welding of some of the high-strength heat treatable alloys, such as 7075 and 7079, is not recommended, they can be gas tungsten-arc welded with straight-polarity direct current by skilled welders using special techniques. A welding technique that will ensure retention of the high strength of the base metal, and that will prevent cracking of the weld metal and allow development of maximum weld-metal strength is imperative. Full postweld heat treatment (solution heat treatment, quenching, and aging) results in the highest strength, but solution heat treatment and quenching often causes excessive warping of the part, and thick sections are difficult to quench effectively. A combination of welding conditions and postweld aging that produced good results in one application is noted in the next example:

Example 321. Welding Plate of High-Strength Alloys 7075 and 7079 (Table 34)

Butt welds between two plates of alloy 7075-T6, ⅝ in. thick, and two plates of alloy 7079-T6, ¼ in. thick, were made by the gas tungsten-arc process. The joint design for the 7075 plates was a double-V groove with a 5⁄16-in. root face, and for the thinner 7079 plates, a single-U groove with a 3⁄16-in. root face. The large root faces and small grooves for both welds favored substantial alloying of the base metal in the weld metal, as shown in the table below:

Element	Base metal	Filler metal(a)	Weld metal
Welding Alloy 7075 Plate			
Zinc, %	5.1-6.1	0.25 max	4.10
Magnesium, %	2.1-2.9	4.3-5.2	2.50
Copper, %	1.2-2.0	0.10 max	1.20
Welding Alloy 7079 Plate			
Zinc, %	3.8-4.8	4.4	4.75
Magnesium, %	2.9-3.7	2.8	2.50
Copper, %	0.4-0.8	1.0	1.10

(a) Filler metal ER5183 was used in welding the alloy 7075 plate, and a special high-zinc alloy of the composition shown was used in welding the alloy 7079 plate.

The weld metal in both joints had about the same zinc and magnesium contents as alloy 7039 (3.5 to 4.5% Zn, 2.3 to 3.3% Mg), which is readily arc weldable and is strengthened by natural aging.

The postweld aging treatments and the properties obtained in the weld metal for both alloys are shown in Table 34, along with the welding conditions.

Problems in Gas Tungsten-Arc Welding of Aluminum Alloys

Many of the problems that are encountered in gas metal-arc welding of aluminum alloys are also present in gas tungsten-arc welding. Common problems and their causes are summarized in Table 35.

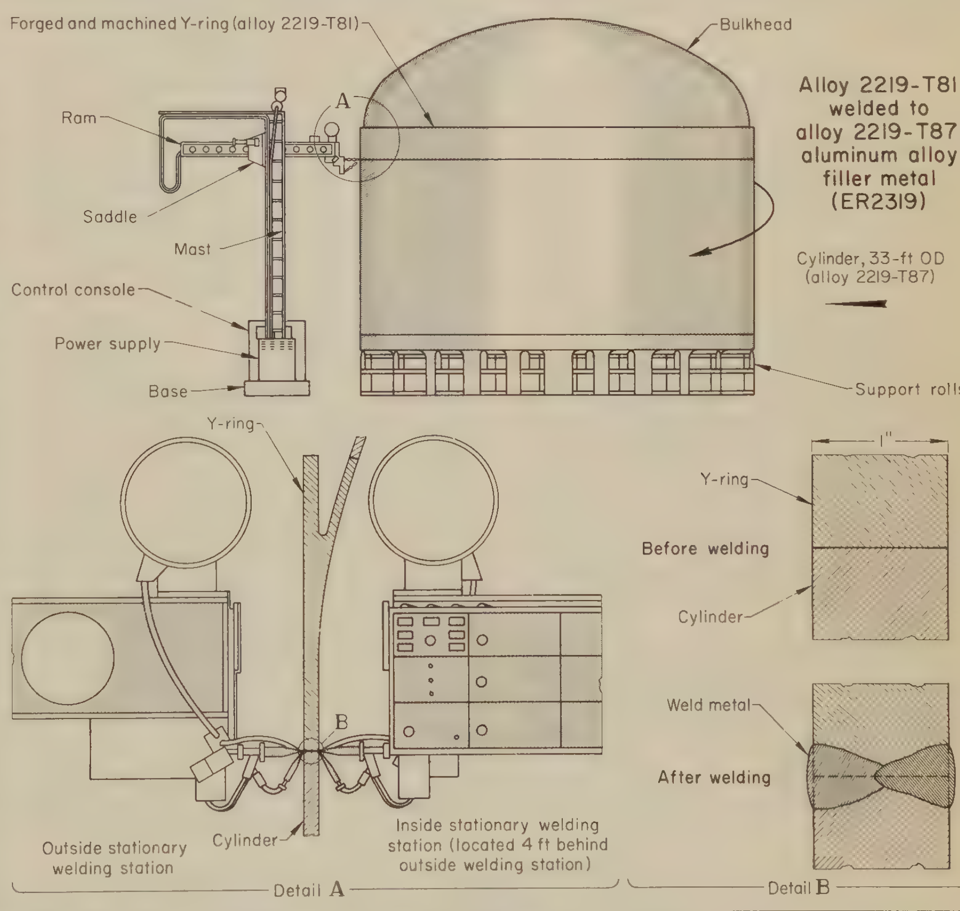
Dirty workpieces and filler metal can result in a dirty weld bead and an unsound weld. Preweld cleaning of workpieces is described in the section on page 297 of this article. An effective test for cleanness of filler metal is described in Example 311 on page 326.

Improper fixturing can also result in weld defects. For instance, when a rough and uneven weld bead with excessive porosity and areas of incomplete fusion was encountered on a corner weld in alloy 6061, investigation showed that the magnetic field surrounding the arc had been deflected by the nearby carbon steel fixturing, which had caused arc instability. Changing to a nonmagnetic fixturing material ended the trouble. Aluminum fixturing was tried, but it became loose on heating. Austenitic stainless steel proved satisfactory.

In other applications, excessive spatter of tungsten was ended by changing from an unalloyed tungsten electrode to a thoriated tungsten electrode; complete penetration was obtained when the ⅛-in.-diam filler-metal wire was replaced with a 1⁄16-in.-diam wire.

Gas Metal-Arc Welding vs Gas Tungsten-Arc Welding

The uses of gas metal-arc and gas tungsten-arc welding overlap to some extent. The general merits of the two



Conditions for Automatic Gas Tungsten-Arc Welding (dcsp)

Joint type	Butt	Torch	Water cooled
Weld type	Square groove	Gas nozzle	⅝-in. diam
Welding position	Horizontal	Electrode	5⁄32-in.-diam EWTh-2
Power supply	600 amp, constant current, controlled to 1% variation; 100% duty cycle	Filler metal	1⁄16-in.-diam ER2319(a)
Mechanization	Automatic arc-voltage control to 0.1% variation; wire-feed system; 360° rotation of work on motor-drive table	Shielding gas	Helium, at 120 cfh
Wire-feed system	1 to 100 ipm, controlled to 1% variation	Voltage	11.5 to 12.5 v
		Filler-metal feed	1 in. of wire per inch of travel
		Welding speed	2 to 5 ipm
		Number of passes	Two

(a) Wire was stored in a hermetically sealed container before use, and was fed from dustproof containers during welding.

Repair welding	B	A
Fabrication with castings	A	B

(a) An A rating is better than a B rating. NA indicates process is not applicable.

processes are compared in Table 36. Individual applications should be considered in detail, with reference to Table 36 and the following factors.

Advantages of Gas Metal-Arc Welding. Most of the advantages of gas metal-arc welding over gas tungsten-arc welding stem from the fact that in gas metal-arc welding reverse-polarity direct current is used at a high current density. This is possible because the electrode is consumable and is melted during the welding, whereas in gas tungsten-arc welding the current is limited by the melting temperature of the electrode. Heat transfer by the arc is very efficient.

High Welding Rate. Welding speeds two to three times those obtainable by manual gas tungsten-arc welding are possible, particularly when welding metal more than ⅜ in. thick. When machine welding thinner metal, the welding speed is about the same for the two processes.

In manual gas tungsten-arc welding, the length of welding is somewhat limited by the length of filler-metal rod that the welder can conveniently handle; he usually cannot make a weld longer than 12 in. without breaking the arc.

The gas metal-arc process and the automatic gas tungsten-arc process share the feature that the filler metal is added mechanically, and the operator is usually able to weld at least 24 in. without having to break the arc and change position. Therefore, with these latter processes less time is lost in starting and stopping, which results in fewer weld craters and more feet of weld per hour. They are also less fatiguing than the manual gas tungsten-arc process because the operator does not have to coordinate the movement of both hands, and he can continue welding for a greater length of time, a factor that contributes to higher welding rates.

Lower Welding Cost on Metal More Than ¼ In. Thick. The equipment used for gas metal-arc welding is more expensive than that used for gas tungsten-arc welding, but on thick sections requiring multiple-pass welding (generally more than ¼ in. thick), the higher welding rates of the gas metal-arc process generally result in lower welding cost.

Low Distortion. Because of the high welding speed, which results in rapid chilling of the weld area, distortion is generally low. The distortion produced on aluminum with the gas metal-arc process is no more, and is usually less, than that produced on steel of the same thickness when it is welded with flux-cored electrodes. As soon as the arc is established, filler metal is added to the joint, which aids in preventing distortion when sheet is being welded to thicker framing members.

Good Weld Quality. The quality of welds produced by the gas metal-arc process using spray transfer is of a very high order.

Good Out-of-Position Welding. Because the appreciable arc force projects the weld metal across the arc at a high velocity, not affected by gravity, welding can be done in any position.

High Deposition Rate. Where a high rate of filler-metal deposition is required, as in welding heavy sections or in building up a surface, the gas metal-arc process has a considerable advantage. High rates of metal deposition are easy to obtain with the large-diameter filler wires (up to ⅜2 in. in diameter) when they are used with high welding currents.

Readily Adapted to Machine Welding. Because of its semiautomatic nature, the gas metal-arc process can be readily adapted to automatic welding for metal from 0.030 in. thick to the thickest commercially available. Automatic gas tungsten-arc welding requires good control of joint fit-up, usually within 0.003 to 0.010 in., depending on material thickness, but gas metal-arc welding is less sensitive to variations in fit-up.

Freedom From Radio Interference. Gas metal-arc welding employs direct current, and so it is not necessary to use high-frequency current for arc stabilization, which means that there is no radio interference as there may be when using high-frequency current with gas tungsten-arc welding.

Table 37. Approximate Costs of Gas Metal-Arc and Gas Tungsten-Arc Welding Equipment

Electrode-wire diameter, in.	Cost: Welding unit(a)	Cost: Power supply	Cost: Total	Thicknesses to be welded, in.
Gas Metal-Arc Welding Equipment				
0.030 to ³⁄₃₂	$2200	$900 to $1350	$3100 to $3550	0.040 to over 3

Machine capacity, amp	Cost: Alternating-current unit(b)	Cost: Welding torch	Cost: Total	Thicknesses to be welded, in.
Gas Tungsten-Arc Welding Equipment				
200	$ 800 to $ 900	$200	$1000 to $1100	0.020 to ³⁄₁₆
300	950 to 1050	200	1150 to 1250	0.020 to ⁵⁄₁₆(c)
400	1000 to 1100	200	1200 to 1300	0.020 to ⅜(c)
500	1100 to 1200	200	1300 to 1400	0.020 to ½(c)

(a) Including wire feeder, control panel, welding torch, and secondary contactor. (b) Including high-frequency unit and water and gas controls. (c) Being able to weld 0.020-in.-thick metal depends on ability to reduce current output of machine below normal rated output.

Table 38. Pounds per Foot, and Feet per Pound, of Various Diameters of Aluminum Alloy Filler-Metal Wire (a)

Wire diam, in.	Pounds per foot	Feet per pound
0.030	0.000848	1180
0.035	0.001153	867
0.040	0.001508	664
³⁄₆₄	0.00207	484
¹⁄₁₆	0.00368	272
³⁄₃₂	0.00828	121
⅛	0.01473	68

¼	0.0589	17

(a) Based on a density of 0.100 lb per cubic inch. For correction factors for alloys of other densities, see Table 39.

Advantages of Gas Tungsten-Arc Welding. Most of the advantages of gas tungsten-arc welding stem from the fact that the filler metal is introduced separately into the arc, which allows the welding current and wire speed to be independently adjusted.

Lower Welding Costs on Metal Less Than ⅛ In. Thick. In automatic welding, where attainable welding speed is nearly equal to that used in gas metal-arc welding, greater economy is usually realized with the gas tungsten-arc process, because welding current and wire speed can be independently adjusted to reduce the consumption of filler metal to the minimum. However, in semiautomatic welding, greater economy is generally realized with the gas metal-arc process because welding speed is two to three times faster than that obtainable with the gas tungsten-arc process.

The equipment used for gas tungsten-arc welding is less expensive than that used for gas metal-arc welding, and needs less maintenance.

Very Thin Material Can Be Welded. Using a pulsed arc, the gas metal-arc process can be used to weld metal as thin as 0.040 in., but metal as thin as 0.010 in. can be welded by the gas tungsten-arc process, provided the workpieces are correctly aligned and held.

Butt Welds Can Be Made in Small Shapes. Because filler metal is added manually to the weld in manual gas tungsten-arc welding, the welder has complete control of the weld puddle at all times. This is a definite advantage in butt welding small and medium angles and other shapes in which heat requirement at the toe of the angle is less than at the heel.

Welds Can Be Made Without Filler Metal. This is important in fusing together the edges of a butt joint or the edge of a lap joint, to make smooth welds that require little grinding or cleaning.

Excellent Weld Quality. The quality of welds made by the gas tungsten-arc process is of a very high order, and the process offers excellent reliability. When welding thick material by the gas tungsten-arc process, the filler metal need not be added to the weld until the base metal has been well penetrated; with the gas metal-arc process, filler metal is added as soon as the arc is struck, which sometimes prevents penetration and causes cold starts. Preheating thick material to 200 to 250 F ensures satisfactory starts when gas metal-arc welding; otherwise, cold starts must be chipped out and rewelded.

Cost of Welding. The over-all cost of welding comprises capital expenditure for equipment, the actual welding expenses, and the cost of material preparation and finishing (edge preparation, cleaning, fitting, assembling, handling, and surface finishing). The actual welding expenses are the cost of filler-metal wire, gas, overhead, labor, and maintenance of welding equipment. Ordinarily, the process that enables a

(a) Multiply value in Table 38 by this factor.

weldment to be made in the minimum time is the most economical.

The amount of welding, and whether or not it is repetitive, influence the selection of a welding process and auxiliary equipment. Large amounts of welding will usually justify a considerable investment in welding equipment, jigs and fixtures.

In computing welding costs, it is usually assumed that the arc is maintained for only 33% of the time — that is, the operator welds for only 20 min of each hour. On certain production jobs where fast-operating jigs are employed, the operating factor may exceed 33%, and on those where a large amount of time for fit-up is required, or where only one assembly is being made, the operating factor may be much less than 33%.

In selecting a welding process, cost of equipment should be weighed against its advantages, because often the cost of an expensive piece of equipment can be offset by increased production and a higher-quality product. For a small production lot, high equipment cost can be justified only if the equipment is required for special reasons of quality or accessibility, or if future high-production use is anticipated. Table 37 gives the approximate costs of equipment for gas tungsten-arc welding and gas metal-arc welding. The gas tungsten-arc units described are standard alternating-current arc welding machines having a built-in high-frequency unit and gas and water controls. The machines can be converted for the welding of steel by operating a switch to bypass the high-frequency unit and gas and water controls.

Weights of aluminum welding wire of various diameters and correction factors for alloys are given in Tables 38 and 39, respectively.

Selection of Process. Availability of equipment may determine the process to be used for a given application, but generally selection is based on the capability of a process to meet joint requirements, and on cost. When the thickness of aluminum sheet reaches about 3⁄16 in., the use of the automatic gas tungsten-arc process with alternating current for single-pass butt welding becomes prohibitively slow, although joint quality is excellent. The same joints in this thickness and above can be single-pass welded at a much higher speed using gas tungsten-arc welding with straight-polarity direct current, because of the narrower and deeper penetration obtained, but more careful edge cleaning is needed to ensure high joint quality. Both processes are capable of producing welds to high quality standards, and joint thickness becomes a consideration when deciding which to use.

Aluminum sheet 3⁄16 in. or more in thickness can also be welded by the gas metal-arc process using spray transfer and at much higher speeds. Because reverse-polarity direct current is used, edge cleaning is less critical than for gas tungsten-arc welding with straight-polarity direct current. Joint quality is good and easily meets commercial requirements.

In Table 40, these three processes are roughly compared for mechanized welding of butt joints in ¼-in.-thick aluminum alloy plate, using hold-down clamps and a grooved backing bar. The illustration in Table 40 shows the two most commonly used types of edge preparation for these joints — square grooves and single-V grooves.

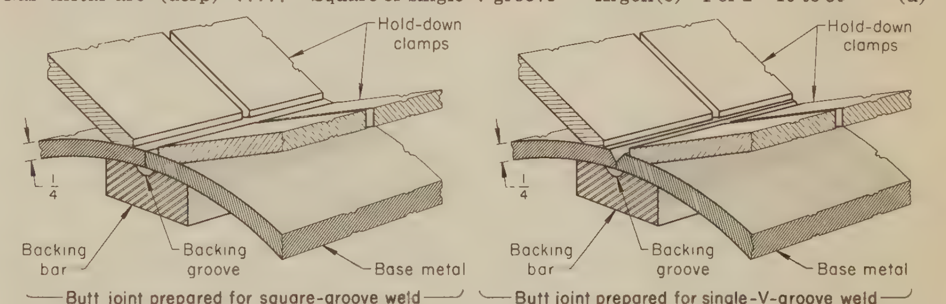
The use of gas tungsten-arc welding with alternating current, as indicated in Table 40, would necessitate edge preparation in the form of a single-V groove to obtain complete penetration. The welding speed of this process is relatively low, and the effective welding speed for the joint is only half the actual welding speed, because two passes are needed to fill the joint. Sound weld metal is produced.

Gas tungsten-arc welding with straight-polarity direct current can be done at a relatively high welding speed, and deep penetration is obtained. Although the square-groove edge preparation shown in Table 40 to be applicable for this process does not entail beveling, to obtain optimum weld-metal soundness joint edges must be cleaned chemically and mechanically (by filing or scraping) before welding. Starts and stops must be regulated by current-control devices, or must be eliminated completely by means of starting and runoff tabs.

Gas metal-arc welding of the joints shown in Table 40 can be accomplished at high welding speed, depending on the quality and reliability demanded of the weld, but it is more difficult to establish and maintain precise control

Table 40. Comparison of Three Arc Welding Processes for Welding Butt Joints in ¼-In.-Thick Aluminum Alloy Plate

Welding process	Edge preparation (weld type)	Shielding gas	No. of passes	Typical welding speed, ipm	Suitability of process
Gas tungsten-arc (ac)	Single-V groove	Argon	2	4 to 8	(a)
Gas tungsten-arc (dcsp)	Square groove	Helium	1	12 to 20	(b)
Gas metal-arc (dcrp)	Square or single-V groove	Argon(c)	1 or 2	10 to 50	(d)



(a) Suitable for nuclear and aerospace applications, but too slow. (b) Suitable for nuclear and aerospace applications. (c) Helium additions up to 80% improve radiographic quality. (d) Suitable for commercial applications — both code (pressure vessel, piping) and noncode applications.

Table 41. Comparison of the Gas Tungsten-Arc and the Gas Metal-Arc Processes for Welding of Butt Joints in 0.160-In.-Thick Alloy 5456 Sheet(a)

Item	Automatic gas metal-arc welding	Automatic gas tungsten-arc welding
Welding Conditions		
Current, amp	160, dcrp	260, ac
Voltage, v	24	12
Shielding gas	Argon-helium, at 60 cfh(b)	Argon, at 25 cfh
Welding speed, ipm	22	15
Costs per Lineal Foot of Weld		
Labor and burden(c)	$0.237	$0.280
Gas	0.087	0.054
Cleaning(d)	0.022	...
Total	$0.346	$0.334
Weld Quality		
X-ray standard(e)	Class II	Class I
Appearance	Uniform bead width and contour, rough penetration, excessive spatter on weld-face side	Very uniform bead width, excellent surface appearance, smooth penetration, well-fused edges
Mechanical properties:		
Yield strength, psi	23,300	24,450
Tensile strength, psi	47,700	49,800
Elongation, %	6	9.5

(a) Single-pass welds in square-groove butt joints. (b) 30 cfh of argon and 30 cfh of helium. (c) Includes wages of operator, based on 50% welding time, and administrative, general overhead, and amortization costs. (d) Includes removal of spatter and discoloration, and dressing of rough starts. (e) Class standards as defined by MIL-R-45774.

over welding variables in gas metal-arc welding than in gas tungsten-arc welding. For example, arc length, burnoff rate, wire-feed speed, and current and voltage are directly related in gas metal-arc welding. The butt joints in Table 40 could be welded in a single pass with high reinforcement if square-groove edge preparation were used, or in two passes with limited reinforcement if single-V-groove edge preparation were used. Although argon is normally used in gas metal-arc welding of metal up to ¾ in. thick, radiographic quality of the weld metal can be improved by the addition of up to 80% helium.

For welding the joints shown in Table 40, the first process, gas tungsten-arc welding with alternating current, is too costly; it would be used only if no other process were available. As between gas tungsten-arc welding with straight-polarity direct current and gas metal-arc welding, weld-quality requirements would be the deciding factor. Gas tungsten-arc welding is capable of meeting the highest standards of nuclear and aerospace applications; gas metal-arc welding is capable of meeting the requirements of pressure-vessel and piping codes, as well as other commercial standards, where high deposition rates are more important than in nuclear and aerospace applications.

When the aluminum sheet thickness is less than 3/16 in., the gas tungsten-arc process becomes competitive with gas metal-arc welding. The costs for making a single-pass square-groove butt weld in 0.160-in.-thick alloy 5456 sheet by the gas tungsten-arc and gas metal-arc processes are compared in Table 41. Although the power supply and tooling costs are roughly the same for both processes, the other equipment costs for gas metal-arc welding can be $2000 more. This adds to the amortization costs and lessens the advantage of the lower labor and burden costs. In Table 41, the higher costs for shielding gas and postweld cleaning more than offset the lower labor and burden costs of making the weld by the gas metal-arc process, so that the over-all cost of producing the welded joint was less for the gas tungsten-arc process. In addition, gas tungsten-arc welding produced a weld that had better quality, needed less repair welding and developed higher mechanical properties.

In the following example, both the automatic gas tungsten-arc and the automatic gas metal-arc processes were found acceptable for making fillet welds between ¼ and ½-in. stock. The welding speeds were similar enough so that the welding cost differences became less important than the availability of equipment.

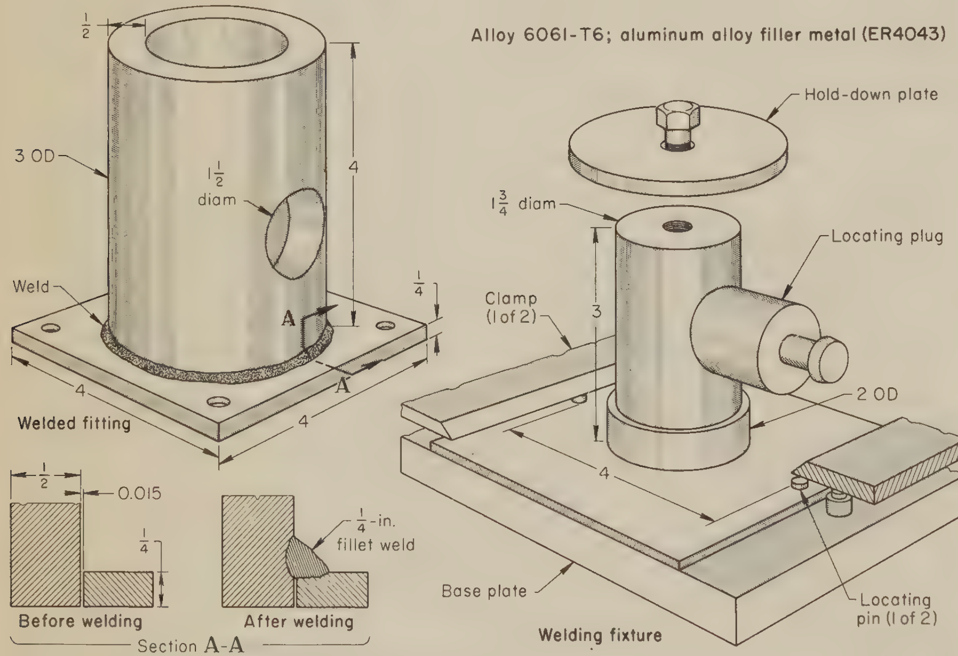
Example 322. Approval of Both Automatic Gas Tungsten-Arc and Automatic Gas Metal-Arc Processes for Welding Alloy 6061 (Fig. 50)

For joining the alloy 6061-T6 aircraft bypass fitting shown in Fig. 50, several processes were considered. Oxyacetylene welding was tried, but without success. The heat was dissipated too rapidly, and the resulting weld was not up to the standard required. The assembly could have been furnace brazed, but this method was unacceptable because: (*a*) in order to make the part to close tolerances to provide close fits, the tooling would have had to be changed; and (*b*) there was no brazing furnace available in the plant and so brazing would have had to be subcontracted, which would have added to the cost.

The part was successfully welded by the gas tungsten-arc process. Manual welding, using alternating current, was tried first. This met all aircraft standards and engineering requirements, but it was very slow, even though small turntables were used to rotate the part. Automatic gas tungsten-arc welding made fully satisfactory welds. A voltage-controlled contour welding machine with automatic wire feed was combined with an adjustable torch-holding carriage and a turntable that were already available. A welding fixture (see Fig. 50) was designed to fit on the turntable. The use of automatic welding resulted in the required increase in welding speed.

Although gas metal-arc welding was not extensively used in the plant, because most aluminum alloy parts welded were too thin for the process, it was tried for the bypass fitting, in which sections were fairly thick (¼ and ½ in.). The same fixture, turntable and carriage as those used for automatic gas tungsten-arc welding were used for automatic gas metal-arc welding. The results were good. Etching and face-bending tests met the requirements for the assembly.

Welding time was slightly less for gas metal-arc welding than for gas tungsten-arc welding, but both automatic processes were approved and used. This was one of the few assemblies for which both processes were permitted.



Item	Automatic gas tungsten-arc welding	Automatic gas metal-arc welding
Joint type	Corner	Corner
Weld type	Fillet	Fillet
Root opening, in.	0.015	0.015
Welding position	Flat	Flat
Power supply	300-amp transformer-rectifier	300-amp transformer-rectifier
Mechanization	Turntable	Turntable
Filler-wire feed system	Automatic, push	Automatic, push
Fixtures	Assembly, clamping	Assembly, clamping
Edge preparation	Deburring	Deburring
Torch or electrode holder	Water cooled, held at 40° angle	Air and gas cooled
Filler metal	3/64-in.-diam ER4043-H18	3/64-in.-diam ER4043-H18
Shielding gas	Helium, at 20 cfh	Argon, at 20 cfh
Electrode stickout, in.	½	⅜

Number of passes	One	One

Fig. 50. An aircraft bypass-fitting assembly that could be welded by either the automatic gas tungsten-arc or the automatic gas metal-arc process in approximately the same welding time, both producing welds that met quality standards, and the fixture used for welding by both processes (Example 322)

Other Arc Welding Processes

In addition to being welded by the gas metal-arc and gas tungsten-arc processes, aluminum alloys are sometimes joined by shielded metal-arc, stud, and percussion welding.

Shielded metal-arc welding is used primarily in small shops for miscellaneous repair work in noncritical applications. A flux-covered aluminum alloy electrode is used. The flux combines with aluminum oxide to form a slag. The slag must be removed after each weld pass. Weld soundness and surface smoothness are poor. The process is limited to butt welds in ⅛-in. and thicker aluminum. AWS A5.3-69 includes two covered electrodes: one with core wire corresponding to ER1100 and one to ER4043.

Stud welding of aluminum alloys is generally accomplished by the capacitor-discharge method, rather than the arc method. Examples 169, 172 and 174 in the article on Stud Welding (page 167) are illustrations of the stud welding of aluminum alloys.

Percussion welding of aluminum alloys is used principally for joining wire to wire. Numerous dissimilar metal joints, including aluminum to copper and to steel are made.

Arc Welding of Copper and Copper Alloys

*By the ASM Committee on Welding and Brazing of Copper and Copper Alloys**

COPPERS AND COPPER ALLOYS that are most frequently arc welded are listed in Table 1, which gives nominal compositions, melting points (liquidus temperatures) and relative thermal conductivities, and rates the materials as to weldability by the gas tungsten-arc, gas metal-arc, and shielded metal-arc welding processes. Leaded and other free-machining copper alloys are not ordinarily arc welded.

Gas tungsten-arc welding is the arc welding process most widely used for joining coppers and copper alloys. Desirable features of the process — particularly on the more heat-conductive copper alloys — are its intense localized heat input, good control, and suitability for use with or without filler metal. Gas tungsten-arc welding is used mainly for sections up to ⅛ in. thick, but good results can be obtained on sections up to ½ in. thick.

For sections more than ½ in. thick, gas metal-arc welding is preferred (when applicable), because of its high deposition rate and high heat input.

Shielded metal-arc welding is used in low-volume production to join copper and copper alloys because of its simplicity, low cost, versatility and the mobility of the equipment. Sometimes this process is used because of its suitability for welding odd-shape parts and where access to the work is difficult. Uniformity and quality of welds are generally lower than for the gas-shielded processes, especially for the more conductive copper alloys, and labor and material costs are higher.

Because of the reduction in strength, formation of oxides, or volatilization of elements that often accompany arc welding, brazing is frequently selected for joining copper alloys (see the article that begins on page 685).

Effects of Alloying Elements on Welding

Several alloying elements have pronounced effects on the welding behavior of copper and copper alloys. At least small amounts of volatile, toxic alloying elements are present in copper and its alloys, and, as a result, the use of an effective ventilation system to protect the welder or welding-machine operator and to recover dusts, fumes and mists is more critical than for ferrous metals (see section on Safety at the end of this article).

Free-Machining Additives (Pb, Te, S). Low-melting elements such as lead, tellurium and sulfur, which are sometimes added to copper alloys to improve machinability, make them susceptible to hot cracking in welding. The adverse effect on weldability begins to be evident at about 0.05% of the additive and is more severe with larger additions. Free-machining copper alloys (which usually contain from 0.5 to 3 or 4% Pb) are not ordinarily welded, and are not listed in Table 1.

Zinc reduces the weldability of all the brasses and nickel silvers shown in Table 1, approximately in proportion to the amount present.

In addition to reducing weldability, zinc also gives off toxic vapors, so that when the copper-zinc alloys are welded, efficient forced ventilation is mandatory and a recovery system should be used to condense the fumes (see section on Safety in this article).

Tin, in amounts of about 1 to 10%, as in the phosphor bronzes and tin brasses, does not interfere with arc welding. Compared with zinc, tin is less volatile and much less toxic, and usually is present in lower amounts.

Beryllium, aluminum and nickel form tightly adherent oxides that must be removed by cleaning before welding. Formation of these oxides on the heated copper alloy must be prevented by gas shielding or by fluxes, in conjunction with selection of the appropriate type of current.

Nickel oxides interfere with arc welding less than oxides of beryllium or aluminum. Thus, the nickel silvers and copper nickels are less sensitive to type of current.

Oxygen as gas or in cuprous oxide causes porosity and reduces the strength of welds made in alloys that do not contain enough phosphorus or other deoxidizer. Most copper alloys that are welded contain deoxidizing elements (usually phosphorus, silicon, aluminum, iron or manganese) that combine with oxygen. The same deoxidizers are included also in filler metals.

The soundness and strength of arc welds made in commercial coppers depend on the cuprous oxide content. Soundness increases as oxide content decreases. Best results are obtained for deoxidized coppers, because they are free from cuprous oxide and contain residual phosphorus. (See "Effect of Cuprous Oxide", on page 340, in this article.)

Silicon has a beneficial effect on the weldability of copper-silicon alloys, because of its deoxidizing and fluxing action. This effect, combined with low thermal conductivity, makes the silicon bronzes the most weldable of the copper alloys by arc processes.

Iron and Manganese. Iron, which is present in some special brasses, aluminum bronzes and copper nickels, in amounts of 1.4 to 3.5%, does not significantly affect the weldability of these alloys. Manganese, which is present in some of these alloys in lower concentrations than iron, has no measurable effect on welding.

Factors That Affect Weldability

Other than the elements that comprise a specific alloy, the principal factors that influence weldability are: thermal conductivity of the alloy being welded, shielding gas, type of current, joint design, welding position, and surface condition (cleanness). Effect of type of current is discussed under the individual processes and alloys.

Effect of Thermal Conductivity. The welding behavior of copper and copper alloys is strongly influenced by thermal conductivity, which varies greatly among these alloys.

Table 1 shows relative thermal conductivities that are based on the conductivity of alloy 102 (oxygen-free copper), which is 226 Btu/sq ft/ft/hr/°F at 68 F, as 100. The range shown in Table 1 is from 100, for alloys 102 and 110, to lows of 8 to 12 for nickel silvers and copper nickels, and 9 for alloy 655 (high-silicon bronze A). For comparison, the thermal conductivity of carbon steel — 30 Btu/sq ft/ft/hr/°F at 68 F — is 13 on this scale.

(a) Based on the thermal conductivity of alloy 102 (226 Btu/sq ft/ft/hr/°F at 68 F) as 100. For comparison, carbon steel has a thermal conductivity of 30 Btu/sq ft/ft/hr/°F, which is 13 on this scale. (b) E = excellent, G = good, F = fair, NR = not recommended; for gas tungsten-arc welding (GTAW), gas metal-arc welding (GMAW), or shielded metal-arc welding (SMAW). (c) In the precipitation-hardened condition. (d) Alloys 443 and 465 contain a nominal 0.06% As; alloys 444 and 466, a nominal 0.06% Sb; alloys 445 and 467, a nominal 0.06% P.

In the welding of commercial coppers and lightly alloyed copper materials having high thermal conductivity, the type of current and shielding gas must be selected for maximum heat input, because heat is rapidly dissipated from the weld region.

Even the less-conductive copper alloys may require preheating (depending on section thickness), in spite of the concentrated heat input of arc welding processes. The interpass temperature should be the same as that for preheating. Copper alloys are not postweld heat treated as frequently as alloy steels are, but they may require controlled cooling, to minimize residual stress and hot shortness.

Shielding gas for the gas-shielded arc welding processes is usually argon, or argon plus 25 to 75% helium. Because helium costs from two to ten times as much per cubic foot as argon, it is advantageous to develop welding procedures compatible with the use of argon or high-argon mixtures whenever possible.

Argon or argon-helium mixtures produce more uniform welds than helium on copper alloys, give a more stable arc, and cause less weld spatter.

Helium alone or in mixtures with argon is preferred where high heat input is needed, as in welding of the highly conductive coppers or copper alloys. Helium gives about one-third greater heat input than does argon at equal welding current.

Joint design for arc welding of copper and copper alloys does not differ greatly from that used in the arc welding of steel. Sections up to ⅛ in. thick can be joined by use of square-groove welds without root openings. Thicker sections ordinarily are joined using either single-V-groove or double-V-groove welds with root faces not more than ⅛ in. wide.

Joint design and fixturing should be such as to minimize constraint and contraction stresses, and to make allowance for the high coefficient of expansion of copper and copper alloys, in order to prevent cracking, which may result from hot shortness of the base metal at temperatures close to and above the solidus.

Backing strips or rings are used more extensively than on steel, to avoid loss of molten metal, particularly on the highly fluid coppers and high-copper alloys. Backing strips and rings are usually made either of the alloy that is being welded, or of copper, carbon or graphite.

Joint and weld types used for arc welding of copper and copper alloys are illustrated in Table 5. Typical dimensions, root openings and groove angles for welding the various types of alloys are given in the tables of nominal welding conditions in this article.

Welding Position. The flat position is used whenever possible, because of the high fluidity of copper and most cop-

per alloys. The horizontal position is used in some fillet welding of corner joints and T-joints.

Vertical and overhead positions, and the horizontal position in welding butt joints, are infrequently used. They are ordinarily restricted to the gas tungsten-arc welding and gas metal-arc welding of aluminum bronzes, silicon bronzes and copper nickels. Small electrodes and filler-metal wire and low welding currents are used for out-of-position welding.

When using the shielded metal-arc process, out-of-position welding is usually limited to the joining of aluminum bronzes and copper nickels, but can also be done on phosphor bronzes and silicon bronzes.

Surface Condition. Grease and oxide on work surfaces should be removed before welding. Wire brushing or bright dipping can be used (see the article on Cleaning and Finishing of Copper and Copper Alloys, which begins on page 635 in Volume 2 of this Handbook).

Mill scale on the surfaces of aluminum bronzes and silicon bronzes is removed for a distance from the weld region of at least ½ in., usually by mechanical means.

Grease, paint, crayon marks, shop dirt and similar contaminants on copper nickels may cause embrittlement, and should be removed before welding. Mill scale on copper nickels must be removed by grinding or pickling; wire brushing is not effective.

Table 2. Filler Metals Most Frequently Used in Gas Tungsten-Arc Welding of Copper and Copper Alloys(a)

Filler metal	AWS classification	Principal constituents(b)
Copper	RCu	98.0 min Cu+Ag, 1.0 Sn, 0.5 Mn, 0.50 Si, 0.15 P
Phosphor bronze	RCuSn-A	93.5 min Cu + Ag, 4.0-6.0 Sn, 0.10-0.35 P
Phosphor bronze	ECuSn-C(c)	7.0-9.0 Sn, 0.05-0.35 P, rem Cu+Ag
Aluminum bronze	RCuAl-A2	1.5 Fe, 9.0-11.0 Al, rem Cu+Ag
Aluminum bronze	RCuAl-B	3.0-4.25 Fe, 11.0-12.0 Al, rem Cu+Ag
Silicon bronze	RCuSi-A	94.0 min Cu + Ag, 2.8-4.0 Si, 1.5 Zn, 1.5 Sn, 1.5 Mn, 0.5 Fe
Copper nickel	RCuNi	1.00 Mn, 0.40-0.70 Fe, 29.0-32.0 Ni+Co, 0.20-0.50 Ti, rem Cu+Ag

(a) Based on AWS A5.7 and A5.6; see current editions of those specifications for complete compositions and qualifications. (b) Single percentages are maximums unless otherwise stated. Optional elements and impurities have been omitted. (c) ECuSn-C is classified by AWS as electrode wire for gas metal-arc welding, but is used also as filler wire in gas tungsten-arc welding.

Gas Tungsten-Arc Welding

Gas tungsten-arc welding is well suited for copper and copper alloys because of the intense arc, which produces an extremely high temperature at the joint, and a narrow heat-affected zone. In welding copper and the more heat-conductive copper alloys, the intensity of the arc is important in completing fusion with minimum heating of the surrounding, highly conductive base metal. In welding copper alloys that have been precipitation hardened, a narrow heat-affected zone is particularly desirable.

Gas tungsten-arc welding of copper and copper alloys is most frequently used for sections up to about ⅛ in. thick that have been prepared with a square edge. Often, no filler metal is used in joining these thicknesses. When sections over ⅛ in. thick are gas tungsten-arc welded, filler metal is almost always used (an exception is described in Example 326, in which ¼-in.-thick sections were gas tungsten-arc welded without the use of filler metal). Sections more than ½ in. thick are gas tungsten-arc welded only if gas metal-arc welding equipment is not available or if special conditions such as hot shortness of the base metal or adjacent heat-sensitive features make it necessary to limit the heat input.

Type of Current. Gas tungsten-arc welding is done on most copper and copper alloys with direct current, straight polarity (dcsp), to permit use of an electrode of minimum size for a given welding current and to provide maximum penetration.

Alternating current stabilized by high frequency is used on beryllium coppers and aluminum bronzes, to prevent the buildup of tenacious oxide films on these base metals.

Electrodes. Any of the standard tungsten or alloyed tungsten electrodes described on page 118 in the article on Gas Tungsten-Arc Welding can be used in gas tungsten-arc welding of copper and copper alloys, and the selection factors discussed in that article apply in general to these metals. Except as noted for specific classes of copper alloys, thoriated tungsten (usually EWTh-2) is preferred for its better performance, longer life and greater resistance to contamination.

Filler metals most frequently used in gas tungsten-arc welding of copper and copper alloys are listed in Table 2. Frequently, the filler-metal composition is matched closely to the base-metal composition, but a filler metal of composition different from that of the base metal may be selected. The reasons are dealt with in the discussions on gas tungsten-arc welding of the various copper alloys, throughout this article.

Mechanized Applications. One application of gas tungsten-arc welding of copper and copper alloys that is frequently mechanized to some degree is welding the ends of tubes into tube sheets. In the following example, a change from manual gas tungsten-arc welding to automatic welding, with mechanized equipment, increased production rate two to six times and improved quality for such welds.

Example 323. Change From Manual to Automatic Gas Tungsten-Arc Welding of Tubes to Tube Sheet (Table 3)

In the fabrication of heat exchangers and condensers, 0.048-in.-wall tubes ¾ in. in outside diameter of various copper alloys were automatically gas tungsten-arc welded to typically 1-in.-thick tube sheet of various other copper alloys (see Table 3).

Originally, the welds were made manually, but the operation was difficult and resulted in low productivity and questionable weld quality.

When processing was changed to automatic welding, joint strength equal to the minimum tensile strength of the base metals was usually attained, and production rates were two to six times as fast as in manual welding. Welding conditions, production rates and weld tensile strengths for automatic welding are shown in Table 3.

The joint was similar to that shown in Fig. 3 (for Example 330), consisting of a hole through the sheet, for insertion of the tube, with an 82° (included angle) countersink 0.040 in. deep on the face of the sheet, and with the tube end swaged outward into the countersink to lock it in place.

Equipment used in welding included a mandrel, which was inserted into the end of the tube, a welding torch, and rotary equipment that caused the electrode to trace a circle around the mandrel, and thus around the tube, when the control circuit was closed. The diameter of the welded circle could be adjusted to suit the workpiece.

In welding, controlled circuitry initiated a timed gas prepurge, and arc starting was by means of a high-frequency pulse. Welding was at full current around the 360° joint and an additional 20° overlap. A current decay was used to avoid crater cracks or pipes when the arc was broken.

Another application of mechanized gas tungsten-arc welding is butt joining the ends of small coils of metal strip, to make larger coils. The welding head traverses the length of the joint automatically. The use of this procedure for six alloys is described in the following example.

Example 324. Semiautomatic Gas Tungsten-Arc Welding To Join Strips of Alloy 110, 122, 210, 220, 230 or 260 (Table 4)

Strips 0.030 to 0.190 in. thick and up to 25 in. wide of alloy 110, 122, 210, 220, 230 or 260 were butt welded by the semiautomatic gas tungsten-arc process, under the conditions shown in Table 4, to make longer strips for cold reduction by rolling. Alloys 110, 122, 210, 220 and 230 were hard when welded; alloy 260 was soft.

The setup was similar to those shown in Fig. 4 (for Example 331), except that no shielding gas was fed through a backing groove. Filler metal was used only in welding the 0.190-in. strips of alloy 110 or 122.

The ends to be joined were cleaned of oxides and lubricants, sheared square simultaneously, butted together, and held flat with clamps. Tabs of the composition

Table 3. Welding Conditions, Production Rate and Tensile Strength for Automatic Gas Tungsten-Arc Welds Between Five Combinations of Copper Alloy Tube Sheet and Tube (Example 323)

(Welding with straight-polarity direct current, argon shielding gas at 15 cfh, and no filler metal)

Alloy numbers (and common names): Tube sheet(a)	Tube(b)	Current, amp	Welding time, sec	Production rate, welds/hr	Average tensile strength, psi
614 (aluminum bronze D)	687 (aluminum brass, arsenical)	160-170	16	80-85	50,800
655 (high-silicon bronze A)	122 (phosphorus-deoxidized, DHP)	170-180	12	90-100	34,300
655 (high-silicon bronze A)	442 (admiralty, not inhibited)	160-170	12	90-110	46,900
655 (high-silicon bronze A)	687 (aluminum brass, arsenical)	160-170	16	80-85	51,500
715 (copper nickel, 30%)	715 (copper nickel, 30%)	120-130	24	90-110	47,800

(a) Typically 1 in. thick, with holes (for the tubes) having 82° countersinks 0.040 in. deep. (b) ¾-in. outside diameter by 0.048-in. wall.

of the metal to be welded were placed under each end of the joint to control burn-through at the ends of the weld, and to be used for the arc to start and stop on. All joints were backed with a carbon block that had a groove ¼ in. wide by 1/64 in. deep cut into it directly beneath the joint. The electrode was ⅛-in.-diam EWTh-2. The torch nozzle was ½ in. in diameter. Helium shielding gas was used.

After welding, all of the alloys except alloy 260 were cold rolled to 25% reduction in cross section, annealed, and cold rolled again. Alloy 260 was cold rolled to 70 to 80% reduction before annealing.

None of the welds broke in rolling, although all of the brasses (alloys 210, 220, 230 and 260) fumed during welding and, as determined by examination of samples taken through the weld area, had some weld porosity.

Other uses of automation in gas tungsten-arc welding of copper and copper alloys are described in Examples 325, 326, 330 and 331.

Gas Tungsten-Arc Welding of Coppers

Although the weld quality of the commercial coppers joined by gas tungsten-arc welding differs depending on the cuprous oxide content of the copper, the nominal welding conditions for coppers of a given thickness and joint design are approximately the same (see Table 5).

Effect of Cuprous Oxide. Cuprous oxide present in the base metal or introduced through oxidation of the molten metal during the arc welding process migrates to the grain boundaries, thereby lowering the strength and ductility of the weld.

Best results in the arc welding of copper are obtained on deoxidized coppers, because (*a*) they are free from cuprous oxide, and (*b*) they contain residual phosphorus, which combines with oxygen absorbed during heating or welding, and thus prevents the formation of cuprous oxide. Strength, ductility and porosity of welds in alloy 102 (oxygen-free copper) are intermediate between the corresponding properties for welds in deoxidized coppers (alloys 120 and 122) and in alloy 110 (electrolytic tough pitch copper), which contains 0.02 to 0.05% oxygen.

The decrease in properties obtained by arc welding copper containing cuprous oxide is less than the decrease caused by gassing and embrittlement experienced in oxyacetylene welding of oxygen-bearing copper.

Shielding Gas. Argon is used typically in welding thicknesses of 1/16 or ⅛ in. In Example 325, an argon atmosphere was used in a closed chamber in welding a 1/16-in.-thick copper joint.

Helium or argon-helium mixtures are used in welding thicker workpieces, for which more heat input is needed. Helium and helium-rich mixtures with argon are used more often for copper than for most copper alloys because of the high thermal conductivity of copper and the consequent need for a high heat input. In Examples 324 and 326, helium shielding was used for welding 0.030 to ¼-in.-thick copper.

Gas-flow rate usually ranges from 15 to 40 cfh, being higher for the higher currents used in welding thicker sections (Table 5).

Table 4. Conditions for Semiautomatic Gas Tungsten-Arc Butt Welding Strips of Copper Alloys 110, 122, 210, 220, 230 and 260 (Example 324) (a)

Strip thickness, in.	Current (dcsp), amp	Voltage, v	Travel speed, ipm
Alloy 110 or 122			
0.030 to 0.035	80 to 95	20	50
0.080	230	21	40
0.190(b)	420 to 490	13 to 14	2
Alloy 210, 220 or 230			
0.030 to 0.035	80 to 95	20	50
Alloy 260			
0.090	180	17	35

(a) Strips of each alloy up to 25 in. wide, with ends cut with a shear set at 7° from the normal to the longitudinal direction, were welded with a square-edge butt joint, using an ⅛-in.-diam EWTh-2 electrode, a ½-in.-diam torch nozzle, helium shielding gas, and no filler metal (except for 0.190-in.-thick strips of alloy 110 or 122).

(b) A preheating pass with the torch was made at 4 in. per minute, by use of 200 amp and 18 to 20 v; a lithium-deoxidized copper filler wire was used in making the welding pass.

Type of Current. As indicated in Table 5, straight-polarity direct current is preferred for gas tungsten-arc welding of commercial coppers.

Electrodes. A thoriated tungsten electrode containing 2% thoria (EWTh-2) has the best electrode life and requires minimum tip maintenance in welding copper with straight-polarity direct current; EWTh-2 electrodes were used in Examples 324, 325 and 326, which deal with welding of copper alloys 110, 120 and 122.

Electrodes for use on copper are usually pointed, with a cone angle of 60°. The point on the tip is usually broken to a 0.005 to 0.020-in. flat.

Welding Without Filler Metal. Square-groove butt joints in copper up to ⅛ in. thick usually can be gas tungsten-arc welded without the use of filler metal, although filler metal is sometimes used in welding thicknesses close to ⅛ in. In Example 324, tough pitch and deoxidized coppers in thicknesses of 0.030 and 0.080 in. were welded without using filler metal; and in Example 325, no filler metal was used in making a shallow weld on an edge joint between two 1/32-in.-thick projections of deoxidized copper.

Copper in sections thicker than ⅛ in. can be gas tungsten-arc welded without the use of filler metal by making two passes, one from each side (as was done in joining ¼-in.-thick tough pitch copper in Example 326).

Filler metal is generally used in gas tungsten-arc welding of copper thicker than about ⅛ in. (Table 5). In Example 324, although no filler metal was used in butt welding copper 0.080 in. or less in thickness, a lithium-deoxidized copper filler wire was used on a thickness of 0.190 in.

The selection of a filler metal containing residual deoxidizer is important because of the adverse effects of oxygen on the dutility, strength and soundness of the weld metal (see discussion under "Effect of Cuprous Oxide", above). The adverse effects of oxygen are even more severe on the filler metal than on the base metal, because filler metal has greater exposure to welding heat.

Generally, copper filler metal that contains 0.15% max P and 0.50% max Si as deoxidizers (AWS RCu; see Table 2) is selected. Deoxidized coppers (alloys 120 and 122) as filler metal do not contain enough residual phosphorus to ensure sound welds. Other advantages of RCu filler metal are relatively high electrical conductivity (30 to 40% IACS) and good color match with the copper base metal.

Any of the other filler metals listed in Table 2 can be used in gas tungsten-arc welding of commercial coppers (because they contain adequate amounts of deoxidizing elements such as phosphorus, silicon, iron, aluminum or titanium), but electrical conductivity is limited and color match is poor. However, these filler metals provide greater joint strength.

Joint designs used in gas tungsten-arc welding of pure coppers as well as copper alloys are shown in Table 5. A root opening is required for welding butt joints in thicker sections with filler metal (see Table 5) because of the high thermal conductivity of copper. The clearance is needed to prevent the base metal from conducting heat away so rapidly that molten filler metal solidifies too quickly and chokes the joint before it is filled.

Backing strips or rings (usually made of copper, carbon or graphite) are ordinarily used in gas tungsten-arc welding of butt joints in copper, because of its high fluidity. Backing is needed for both tightly fitted butt joints in thin metal and loosely fitted butt joints in thick metal, to prevent loss of molten metal, and may also be used where needed for this purpose in making other types of joints.

Preheating. In gas tungsten-arc welding of sections thicker than ⅛ in., preheating is usually required, to maintain the base metal at welding temperature without excessive loss of heat to the surrounding area. The small arc used in gas tungsten-arc welding cannot maintain welding heat in thick sections of copper even under the most favorable conditions. Preheat temperatures are given in Table 5.

Deoxidized Coppers. Welded copper pressure vessels and other weldments that require the strength of the base metal are usually made from deoxidized copper.

Even with the localized heat input of gas tungsten-arc welding, special fixturing and other welding conditions may be needed to minimize distortion, as in the following example.

Example 325. Redesign of Joint and Fixture To Minimize Distortion in Gas Tungsten-Arc Welding of Alloy 120 (Fig. 1)

A wafer of nuclear fuel was encapsulated in an alloy 120 can-and-cover assembly by automatic gas tungsten-arc welding. The completed weldment is shown in Fig. 1(a). As shown in detail A in Fig. 1, the can had a machined recess for the wafer and a 0.005-in.-thick bottom. The can-to-cover joint had raised lips, which eliminated the need for filler metal.

The weld had to provide hermetic sealing without distorting the assembly, including the thin can bottom, which was only 3/16 in. from the welded area. Leak testing by a mass spectrometer was specified.

The welds were made in a controlled-atmosphere chamber, with the can mounted

(a) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions, for welding of parts on which previous experience is lacking; they are subject to adjustments as necessary to meet the special requirements of individual applications. (b) Copper, carbon or graphite backing strips or rings may be used (see text). (c) Mixtures of argon and helium are also used (see text). (d) Depth of back V is 3/8 of stock thickness. (e) Use of filler metal optional for thicknesses of 1/4 in. or less.

in a rotating copper chill-block clamping fixture under a stationary electrode. Welding conditions are given in the table accompanying Fig. 1.

Originally, the fixture and joint shown in Fig. 1(b) and detail A (for original method) were used, but at currents high enough for fusion, the welds were porous, the welded joint leaked, and the can warped unacceptably.

The porosity that caused leaking resulted because, in machining of the can, lubricant was wiped into the surface of the metal by the cutting tool and subsequent cleaning failed to remove it. Machining without a lubricant eliminated the difficulty.

To minimize distortion, the joint and fixture were improved as follows:

1. The square lips of the joint were chamfered (40°) to a sharp edge, as shown in detail B (Improved method) in Fig. 1, to reduce the heat input necessary to make the weld. With the chamfered lips, the welding current could be lower because a smaller mass of metal was being melted at any instant.
2. The mass of the fixture was increased, as shown in Fig. 1(b), for improved method, to increase heat withdrawal. (The redesigned fixture also provided complete support for the thin can bottom against pressure during leak testing.)

Before welding, the assembly was retained in the fixture, which was held by a small chuck with all of the 0.005-in.-thick can bottom resting on the thick copper backing, as shown in the "improved method" view in Fig. 1(b) and in detail B. The fixtured assembly was welded in a chamber that was first vacuum-purged and then filled with 100% argon under slightly positive pressure.

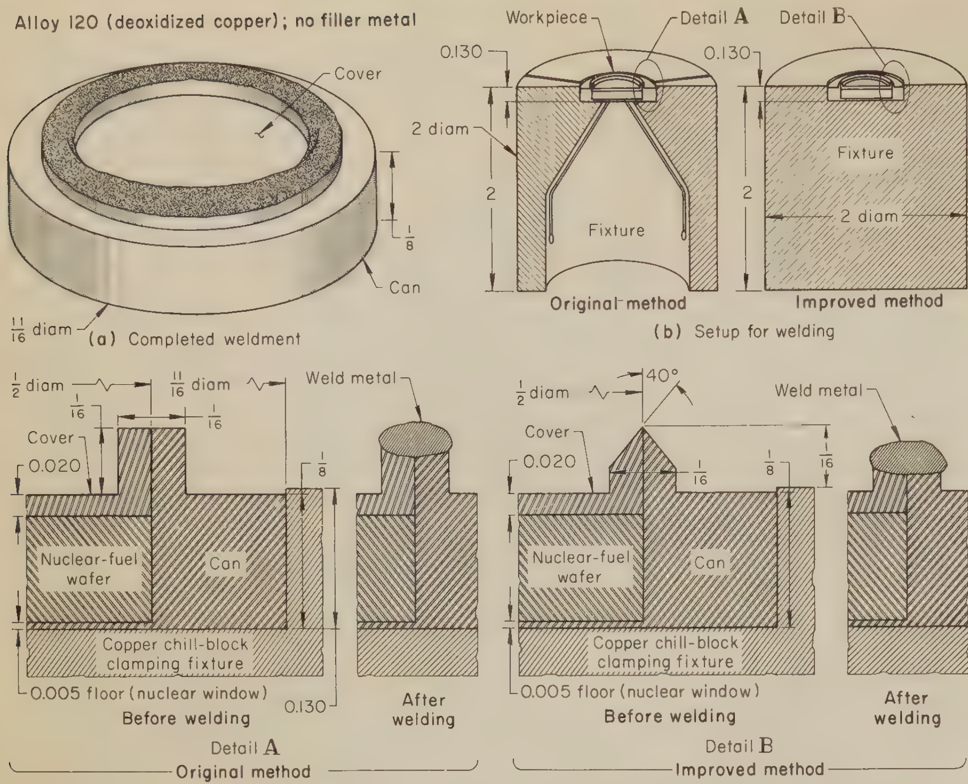
The torch was rigidly mounted on a sliding base with locating stops by which the electrode tip was positioned over the seam, and clamped in position. In the argon atmosphere it was not necessary to provide a shielding gas to the electrode tip or to use an electrode cup. The electrode was ground to a sharp point, to reduce currrent flow and to pinpoint the arc.

During welding, the chuck holding the fixture was rotated by a variable-speed drive. The arc was started, and arc stability was maintained, by a superimposed high-frequency current that was continuous. Current upslope was not controlled. Two revolutions, at 3½ rpm, were used, because slight variations in pressure between the cover and the can caused variations in the thickness of the weld bead after the first revolution. The second revolution smoothed out these irregularities, and ensured adequate penetration of the base metal along the circumference of the joint. After the second revolution, the current was tapered to zero in 5 sec.

Distortion was minimized because of the low welding current, the high heat-sink efficiency, and rigid support by the fixture. Control of heat input was also helpful in preventing excessive internal gas expansion after the joint was closed.

After welding, the welding chamber was evacuated to 10^{-6} torr. The interior of the can remained at approximately 15 psi. Under this pressure differential, the can, still in the fixture, was inspected for leaks by use of a mass spectrometer. The fixture supported the thin can bottom against internal pressure.

Oxygen-Free and Tough Pitch Coppers. Gas tungsten-arc welding is preferred to gas metal-arc welding, or



Automatic Gas Tungsten-Arc Welding

Joint type	Circumferential edge
Weld type	Edge flange
Power supply	250-amp rectifier
Electrode	0.040-in.-diam EWTh-2
Torch	110-amp, air cooled(a)
Filler metal	None
Fixture	(b)
Current	16 amp, dcsp(c)
Arc starting	(d)
Arc length	0.015 in.
Shielding gas	Argon(e)
Welding position	Flat
Travel speed	5.5 ipm

(a) Modified by elimination of ceramic cup, and by use of bare connecting cable to avoid the presence of organic material in the chamber.
(b) Copper chill-block clamping fixture held by a small chuck that was rotated by a variable-speed drive.
(c) With continuous superimposed high-frequency current, for arc stability. (d) Superimposed high-frequency current, which was continuous, as described in footnote (c). (e) In a vacuum-purged welding chamber; under slight positive pressure.

Fig. 1. Nuclear-fuel container for which distortion in welding was minimized by increasing mass of the fixture to increase heat withdrawal and by chamfering of joint edges to permit reduction of welding current (Example 325)

other processes generating less localized heat input, for joining either oxygen-free copper (alloy 102) or electrolytic tough pitch copper (alloy 110) in thicknesses up to about ½ in.

In Example 604, in the article on Resistance Brazing, automatic gas tungsten-arc welding was used in continuously welding the longitudinal seam in an ocean-cable inner conductor tube made of oxygen-free copper 0.023 in. thick. The close control of welding conditions obtainable with the process, and the use of a mixture of argon and helium as the shielding gas, provided electrode life of more than 100 hr before regrinding was required.

Gas tungsten-arc welds in alloy 102 (oxygen-free copper), because of the absence of a deoxidizer, have slightly lower strength and ductility, and are slightly more porous, than those in deoxidized coppers, unless all traces of oxygen are excluded.

Gas tungsten-arc welds in alloy 110 (electrolytic tough pitch copper) have somewhat lower tensile strength than that of welds in deoxidized coppers, and are more porous (see "Effect of Cuprous Oxide", page 340). However, the properties of gas tungsten-arc welds in electrolytic tough pitch copper (alloy 110) are acceptable in many applications involving welded electrical conductors — particularly when tensile strength is relatively unimportant, as for the induction-coil weldment described in the following example.

Example 326. Automatic Gas Tungsten-Arc Welding of 30-Ft Joints Between Alloy 110 Bar and Tubing (Fig. 2)

Alloy 110 solid bar 30 ft long was gas tungsten-arc welded automatically to a 30-ft length of alloy 110 tubing. The weldment was used in making water-cooled induction coils for low-frequency (60 to 180 Hz) induction heating that required more cross-sectional area for electrical conduction than was provided by the tubular section alone. Figure 2 shows a weldment with a cross section of typical size. The 30-ft length was standard for inductor stock. The weldment was bent into 4-in.-ID coils with the bar on the inside. The joint had to maintain good electrical conductivity.

Originally, the bar and tubing were torch brazed along the full length with a silver alloy filler metal. Not only was the filler metal expensive, but brazing was slow, needing two men to handle the 30-ft lengths of tubing and bar.

To increase production rate, a faster and less costly method was developed by mechanizing a gas tungsten-arc welding procedure in which no filler metal was used.

Welding conditions are given in the table accompanying Fig. 2. The fixture, which could accommodate the sizes of inductor bar and tubing regularly used, consisted of six guide rolls, as shown in Fig. 2, that properly aligned the assembly during welding. A chain and variable-speed drive were used to pull the assembly through the rolls during welding. The torch was on an adjustable mount that permitted it to be positioned over the joint to suit the size of components being welded.

Before welding, the leading end of the joint was brazed for about 1 in., to prepare the assembly for feeding through the guide rolls. The position of the assembly, guide rolls and electrode holder during welding is shown in Fig. 2. To make the weld, the assembly was pulled through the rolls at 13 in. per minute, as shown. One pass was used, without coolant, for each side, and the ends were trimmed after welding.

The high thermal conductivity of alloy 110 caused rapid dissipation of the heat energy. However, this difficulty was overcome without preheating by the use of helium as the shielding gas. Helium provided a hotter arc than could be obtained with argon. Thus, it was possible to produce relatively deep narrow welds at 13 in. per minute. Oxygen from the oxide in alloy 110 caused some porosity, but this was minimized by the fast freezing promoted by the fast travel speed. Thus required joint properties were obtained.

Gas Tungsten-Arc Welding of High-Conductivity Beryllium Copper

Gas tungsten-arc welding is preferred to other arc welding processes for joining precipitation-hardened alloy 175 (high-conductivity beryllium copper, 0.6% Be; composition as shown in Table 1) in thicknesses up to about ¼ in., because of the narrow heat-affected zone. The maximum thickness that can be gas tungsten-arc welded without substantial decrease in strength is about ½ in.; thicker workpieces are gas metal-arc welded (see Example 334). When heat treatment is required after welding, gas tungsten-arc welding generally is used only for thicknesses up to 0.090 in., and gas metal-arc welding for thicker sections.

Alloy 175 is more difficult to weld than alloys 170 and 172 (high-strength beryllium coppers), because of its higher thermal conductivity — which, for alloy 175 in the precipitation-hardened condition, is 53 to 66% that of tough pitch copper, or about twice that of high-strength beryllium coppers. A difficulty common to both high-conductivity and high-strength beryllium coppers is that of keeping the work surfaces free from beryllium oxide and cuprous oxide during welding.

Nominal conditions for gas tungsten-arc welding of alloy 175 are given in Table 6. The shielding gas is usually a mixture of argon and helium, to obtain a hot arc, smooth and spatter-free welds, and maximum electrode life.

Type of Current. Variation in arc length or welding speed during gas tungsten-arc welding can produce tenacious oxide films on beryllium copper. For this reason, high-frequency-stabilized alternating current, which continually breaks up the oxide coating, is preferred (see Table 6) in automatic welding, and must be used in manual welding. In automatic welding, advantage can sometimes be taken of the high heat input to the work and the deep penetration of straight-polarity

direct current, if close control is maintained over arc length and welding speed to minimize oxide formation.

Susceptibility to porosity and cracking is greater for welds made in high-conductivity than in high-strength beryllium copper, especially in multiple-pass welding. However, successfully welded joints show less effect on mechanical properties in the heat-affected zone than similar joints in high-strength beryllium copper.

Electrodes. The preferred electrode metal when using alternating current is zirconiated tungsten (EWZr); for economy, unalloyed tungsten (EWP) can be used in noncritical applications. Thoriated tungsten (such as EWTh-2) is preferred when straight-polarity direct current is used.

Filler metal of the same composition as the base metal (alloy 175) is generally used, because high electrical conductivity is usually desired in the welds. If maximum electrical conductivity across the joint is not a requirement, silicon bronze filler metal is satisfactory; aluminum bronze filler metals are usable, but less satisfactory.

Joint Design. As Table 6 indicates, the usual joint designs for gas tungsten-arc welding of high-conductivity beryllium copper are square-groove or 90° single-V-groove butt joints with 1/16-in. maximum root face, and no root opening. (See illustrations of joints in Table 5.) All joints should be backed with grooved copper or graphite backing strips or rings.

Preheating is not ordinarily needed for welding alloy 175 up to about 1/8 in. thick, but thicker stock (on which multiple-pass welds are used) is usually preheated to 800 F.

Gas Tungsten-Arc Welding of High-Strength Beryllium Coppers

High-strength beryllium coppers, alloys 170 (1.7% Be) and 172 (1.9% Be), are more easily welded than the higher-melting and less fluid high-conductivity beryllium copper.

Factors governing the suitability of gas tungsten-arc welding for high-strength beryllium copper are as described for high-conductivity beryllium copper. However, contrary to practice with the high-conductivity alloys, the gas tungsten-arc process can be used on thicknesses greater than 1/2 in. when it is not practical to weld by the preferred gas metal-arc process.

Nominal conditions, or suggested starting points, for gas tungsten-arc welding of high-strength beryllium coppers are given in Table 6. Shielding gas, type of current, and electrode type are the same as for alloy 175.

Filler metal is almost always used to fill the joint or to provide joint reinforcement in V-groove welds, because joint strength is of primary concern in welding these alloys. Rods or strips of the same composition as the base metal are generally used as filler metal; the standard filler metals of other copper alloys are weaker and offer no advantages.

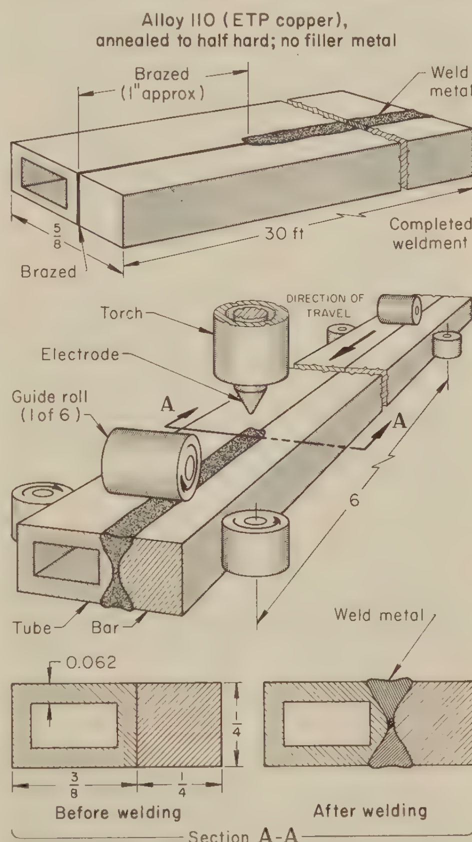
Joint design, which is indicated in Table 6, is the same as for high-conductivity beryllium copper. The 90° single-V-groove butt welds can be used for thicknesses greater than 1/2 in.

Table 6. Nominal Conditions for Gas Tungsten-Arc Welding of Beryllium Coppers(a)

(For butt joints having zero root opening; welding with a zirconiated tungsten electrode, filler metal of the same composition as the base metal, argon-helium shielding gas at 25 cfh)

Work-metal thickness, in.	Butt-joint groove(b)	Electrode diameter, in.	Current, amp(c)	Travel speed, ipm	Number of passes	Preheat temperature, F
Alloy 175 (High-Conductivity Beryllium Copper)(d)						
0 to 0.090	Square	3/32	150	5 to 10	1	None
0.090 to 1/8	90° single-V(e)	3/16	250	5 to 10	1 to 2	None
1/4	90° single-V(e)	3/16	250	5 to 10	4 to 5	800
Alloys 170 and 172 (High-Strength Beryllium Coppers)(d)						
0 to 0.090	Square	3/32	150	5 to 10	1	None
0.090 to 1/8	90° single-V(e)	3/32	180	5 to 10	1	None
1/4 to 1/2(f)	90° single-V(e)	3/16	250	5 to 10	3 to 4	300
Over 1/2(f)	90° single-V(e)	3/16	250	5 to 10	5 to 8	400

(a) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts for which previous experience is lacking; they are subject to adjustment as necessary to meet the special requirements of individual applications. (b) See Table 5 for illustrations of joints. (c) High-frequency-stabilized alternating current is preferred; straight-polarity direct current, with a thoriated tungsten electrode, is suitable under some conditions (see text). (d) For composition, see Table 1. (e) Maximum root face is 1/16 in. (f) Gas tungsten-arc welding is used on these thicknesses only when gas metal-arc welding cannot be used.



Automatic Gas Tungsten-Arc Welding

Joint type	Butt
Weld type	Square groove, zero root opening
Power supply	500-amp rectifier(a)
Electrode	1/8-in.-diam EWTh-2(b)
Torch	350-amp, water cooled(c)
Filler metal	None
Shielding gas	Helium, at 20 cfh
Fixture	Six guide rolls(d)
Current	220 amp, dcsp
Arc starting	Torch start
Arc length	1/8 in.
Cup-to-work distance	5/16 in.
Welding position	Flat
Number of passes	Two (one per side)
Welding speed	13 ipm
Preheat and postheat	None

(a) Constant-voltage. (b) Taper ground. (c) Fixed, on an adjustable mount. (d) Variable-speed drive and chain used to pull assembly through rolls.

Fig. 2. Alloy 110 tubing and bar, for inductor coils, that were automatic gas tungsten-arc welded, and position of assembly, guide rolls and torch during welding (Example 326)

Preheating and Postweld Heat Treatment. Preheating to 300 to 400 F is recommended for welding of metal thicker than 1/8 in. Maximum weld strength is obtained by solution annealing and aging after welding. Aging treatments are 3 hr at 600 F for alloy 170, and 3 hr at 650 F for alloy 172. However, even for welds made under optimum conditions, this postweld treatment does not consistently provide the full strength of solution annealed and aged base metal. Higher strength can be obtained by cold working the annealed metal to a higher temper and modifying the aging treatment.

For some applications, the intermediate weld-metal strength obtained by aging after welding, without solution annealing, is adequate; omission of solution annealing avoids the expense and distortion associated with that high-temperature operation.

Examples of Applications. Three applications of gas tungsten-arc welding of high-strength beryllium coppers are summarized in the grouped examples that follow.

Examples 327, 328 and 329. Gas Tungsten-Arc Welding of High-Strength Beryllium Coppers (Table 7)

Table 7 gives operating conditions for gas tungsten-arc welding of an alloy 170 pressure vessel (Example 327); a cylindrical generator liner for which alloy 170 was welded to alloy 172 (Example 328); and a cover, cast from a BeCu (1.7% Be) alloy, that was welded to an alloy 170 housing (Example 329).

The pressure vessel (Example 327) was used to scavenge propane from a Freon bubble chamber. Gas tungsten-arc welding was used because the vessel could not be solution annealed after welding, because of danger of warping. The service conditions for this vessel included pressure of 600 psi and rapid thermal cycling.

The cylindrical generator liner (Example 328) was back-extruded from a cast billet, and longitudinal ribs about 1/4 by 1/4 in. were machined on the outer surface. Nine reinforcing rings, 1 1/2 by 1 1/4 in., rolled from extruded alloy 170, were equally spaced along the ribs and welded to them. The liner, used in a magneto-hydrodynamic electrical power generator, contained plasma at 3000 to 3500 F.

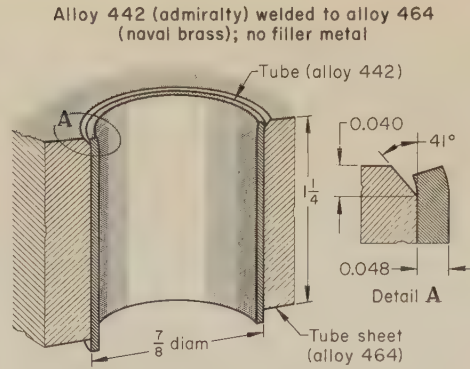
The cover-to-housing weldment (Example 329) was for ocean-cable use. The cast cover was welded to an extruded housing to provide a joint that was watertight at 12,000 psi.

Gas Tungsten-Arc Welding of Copper-Zinc Alloys

Of the copper-zinc alloys rated as to weldability in Table 1, the low-zinc brasses are shown to have good weldability by the gas tungsten-arc process. High-zinc brasses, tin brasses, special brasses and nickel silvers are shown to have only fair weldability, either because of high zinc content or because of moderate zinc content in combination with other elements, such as oxide-forming aluminum or nickel.

Gas tungsten-arc welding, because of its ability to weld rapidly with a highly localized heat input, is sometimes used for welding copper-zinc alloys (20% zinc or less) that contain up to 1% lead, even though leaded copper alloys are generally not recommended for arc welding.

Maximum thickness of copper-zinc alloys ordinarily gas tungsten-arc welded is about ⅜ in., although thick sections of cast alloys such as manganese bronze are sometimes repair welded in small local areas. Preheat is not ordinarily used in joining applications with these alloys.



Semiautomatic Gas Tungsten-Arc Welding

Joint type	Cylindrical edge
Weld type	Bevel
Electrode	⅛-in.-diam EWTh-2
Filler metal	None
Current	185 amp, dcsp
Voltage	(a)
Arc time	6 sec
Shielding gas	Argon, at 15 cfh
Welding speed	27.5 ipm

(a) Controlled by fixed arc length of 0.040 in.; no readings were taken.

Fig. 3. Joint preparation for welding a tube into a tube sheet by semiautomatic gas tungsten-arc welding (Example 330)

Shielding-gas selection is influenced by the heat requirements, which are related to the thermal conductivity of the base metal. Argon is commonly used for welding those alloys that are least conductive, whereas helium or helium mixtures are preferred for the alloys having greater conductivity. However, helium and helium-rich mixtures with argon are sometimes used on even the less conductive alloys (high-zinc brasses, tin brasses, special brasses and nickel silvers), to reduce zinc fumes.

Filler metals used in arc welding copper-zinc alloys should not contain zinc. The arc is struck and held on the filler metal rather than on the base metal, to help reduce zinc loss and fuming. RCuSn-A is recommended for the low-zinc brasses, and RCuSi-A for the high-zinc alloys.

The silicon in RCuSi-A helps to decrease zinc fumes. For this reason, and to provide joint reinforcement, RCuSi-A is sometimes used, with alternating current, on copper-zinc alloys 0.050 in. thick or less. RCuAl-A2 is sometimes used in welding the high-zinc alloys. It makes sound welds, but does not decrease zinc vaporization.

Welding Without Filler Metal. If filler metal is not used, high electrode travel speed will help to limit the amount of fuming by shortening total arc time. Tube-sheet joints similar to those described in Example 323 can be made with brass members using the same kind of joint preparation, if high electrode travel speed is maintained, as in the following example.

Example 330. Welding of Copper-Zinc Alloy Tube-Sheet Assemblies (Fig. 3)

Semiautomatic gas tungsten-arc welding was used to weld alloy 442 (admiralty) tubes to alloy 464 (naval brass) tube sheets as shown in Fig. 3. The tubes were ⅞ in. in outside diameter with 0.048-in. walls.

Linear speed of the welding electrode tip was 27.5 in. per minute, and each weld was completed in 6 sec.

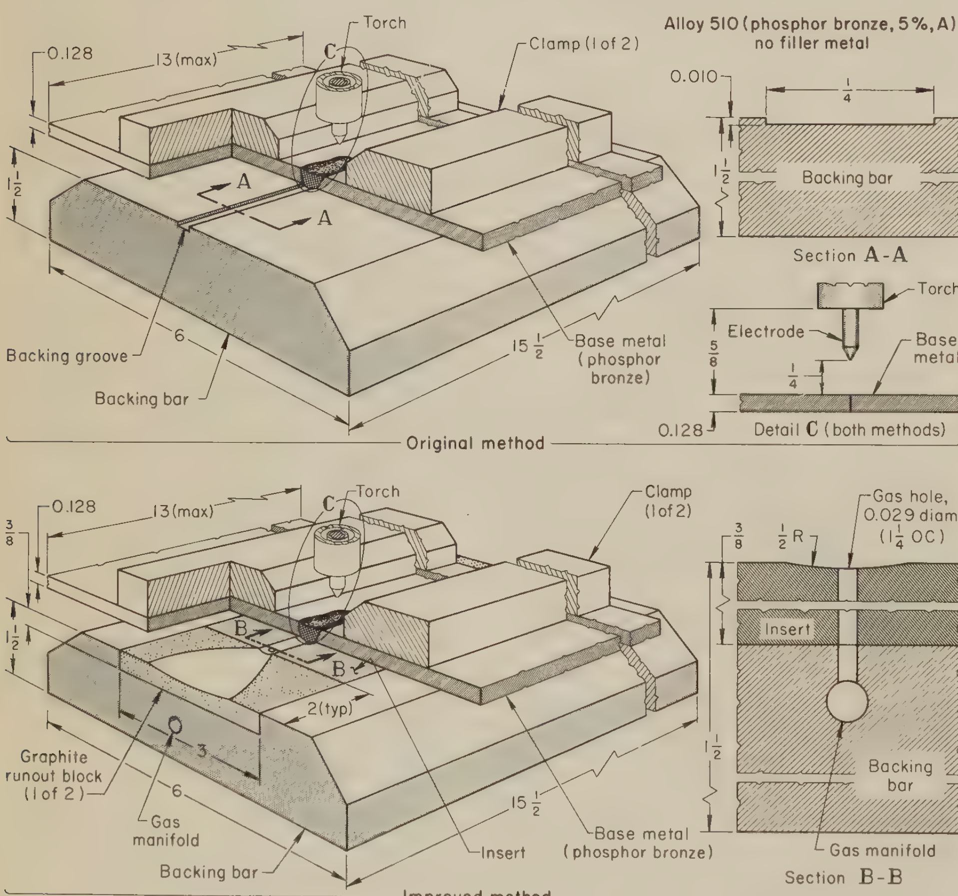
Although helium is the preferred shielding gas for this type of operation, argon was used successfully at a flow of 15 cu ft per hour. Some zinc fuming occurred when the welds were made, but the joints were uniformly sound and leakproof. Welding details are tabulated with Fig. 3.

Gas Tungsten-Arc Welding of Phosphor Bronzes

Gas tungsten-arc welding is used to join strip and other forms of wrought phosphor bronze up to about ½ in. thick. This process is also used to join or repair phosphor bronze castings.

Nominal conditions for gas tungsten-arc welding of square-groove butt joints in nonleaded phosphor bronzes are given in Table 8. The type of current used is straight-polarity direct current.

The nominal conditions shown in Table 8 are based primarily on the three phosphor bronzes shown in Table 1 to have low thermal conductivity (alloys 510, 521 and 524). Higher welding current or lower welding speed is needed for alloy 505 (phosphor bronze, 1.25% E), which contains 98.7% Cu and has three to four times the thermal conductivity of the three other alloys in this group.



Cost Data

Equipment	$75,000
Labor	2 operators at $2.95 and $3.57 per hour
Argon, 330-cu-ft tank	$19.00
Helium, 242-cu-ft tank	$17.00
Electric power	$0.012 per kwhr

Automatic Gas Tungsten-Arc Welding

Joint type	Butt
Weld type	Square groove
Electrode	⅛ or 5⁄32-in.-diam EWTh-1; 18 in. long, pointed
Shielding gas	Helium, at 45 to 50 cfh
Backing gas	Argon, at 3 cfh
Filler metal	None
Voltage	15 to 18 v
Current	250 to 275 amp, dcsp
Power supply	400-amp three-phase rectifier
Arc start	Nontouch, high-frequency ac
Travel speed	30 to 40 ipm

Fig. 4. Setup for welding coil ends of phosphor bronze strip into lengths to be fed into a rolling mill, and details of design changes in backing bar (Example 331)

Shielding Gas. Argon is most often used because of the desirability of restricting the size of the heat-affected zone, thus minimizing the area where mechanical properties are decreased.

Helium shielding gas was used, along with an argon backup flow, in Example 331, and argon shielding gas was used in Example 332.

Filler Metal. RCuSn-A or wire of approximately the same composition as the base metal is ordinarily used as the filler metal. When matching the composition of the base metal is not essential, RCuSi-A filler metal can be used instead, with stronger welds.

Welding Without Filler Metal. If not thicker than about ⅛ in., phosphor bronze strip can be butt welded by the gas tungsten-arc process without the addition of filler metal, as in the application described in the next example.

Table 7. Three Applications of Gas Tungsten-Arc Welding of High-Strength Beryllium Coppers (Examples 327 to 329)

Item	Pressure vessel (Example 327)	Generator liner (Example 328)	Cover to housing (Example 329)
Alloy	170	170 to 172	Cast BeCu (1.7 Be) to 170
Size of workpiece, in.	19 diam by 40	19½ ID by 48	11.6 diam
Thickness of work metal, in.	¾	(a)	0.060
Filler metal	0.062-in.-diam alloy 172	None	None
Current, amp	100 to 150, dcsp	122, ac(b)	275 ac(b)
Shielding gas	Argon and helium	Argon and helium	Argon
Gas-flow rate, cu ft per hour	25	25	20
Travel speed, in. per minute	20	10	12
Number of passes	....	One	One
Postheat	650 F, 3 hr	None	None
Testing method	X-ray(c)	....	(d)

(a) Reinforcing rings, 1½ by 1¼ in., welded to ¼-in.-sq longitudinal ribs. (b) High-frequency-stabilized. (c) Weld was tested by dye-penetration techniques, leak testing by helium mass spectrometry, and x-ray radiography. (d) Weld depth (0.060 in., min) was determined ultrasonically; weld was leak tested by helium mass spectrometry at 11,000 psi of helium.

Table 8. Nominal Conditions for Gas Tungsten-Arc Welding of Square-Groove Butt Joints in Phosphor Bronzes(a)

Work-metal thickness, in.	Root opening, in.(b)	Electrode (EWTh-2) diameter, in.	Diameter of welding rod, in.(c)	Current (dcsp), amp	Flow rate of argon, cfh	Travel speed, ipm	Number of passes	Preheat temperature, F
0.012 to 1⁄16	0	⅛	None used	90 to 150	15 to 35	60 to 80	One	None
1⁄16 to ⅛	0 to 1⁄16	⅛	1⁄16 to 5⁄32	100 to 220	15 to 35	45 to 60	One	None

(a) Data here can serve as starting points in establishing optimum joint design and conditions for welding parts for which prior experience is lacking; they may be adjusted as necessary to meet the special requirements of individual applications. Higher current or lower welding speed is used in welding alloy 505 (see text). (b) See illustration of joint in Table 5. (c) RCuSn-A, or rod of composition close to that of the base metal.

Example 331. Gas Tungsten-Arc Welding of Phosphor Bronze Strip Without Filler Metal (Fig. 4)

Phosphor bronze strip of an alloy similar to 510 was reduced in a rolling mill from 0.128-in. thickness to 0.002-in. foil. The strip was delivered in coils that weighed up to 500 lb. For efficient handling, four coils were joined into one 2000-lb coil by butt welding the ends of the strip together as shown in Fig. 4 (detail C). The joints had to pass through the mill rolls with a minimum of interference, and to withstand reduction down to 0.002 in.

The joints were welded by the automatic gas tungsten-arc process in a machine that combined an uncoiler, a leveler, a shear, hydraulic clamps, electrode holder and travel carriage, and a recoiler. A 400-amp, three-phase rectifier and a 500-amp high-frequency oscillator were used.

The electrode (EWTh-1) was ⅛ or 5⁄32 in. in diameter and 18 in. long, and was ground to a point. No filler metal was used.

Some experimentation was necessary on the shape of the backing groove in the backing bar (compare "original method" and "improved method" views in Fig. 4). At first, a groove of rectangular cross section was used, to lie beneath the joint (section A-A in Fig. 4). Weld beads made with this backing groove were of generally rectangular shape and did not pass through the rolling mill easily. The backing bar was modified by changing the groove to a radiused cross section as shown in section B-B in Fig. 4. The change was made by mortising an insert into the original backing bar. The rounded weld bead produced when using this groove passed through the rolling mills without difficulty and withstood reduction to 0.002-in. thickness and elongation to 4 in.

Another improvement was to add gas holes 0.029 in. in diameter and spaced at 1¼-in. intervals along the groove to provide shielding gas for the back side of the weld. The groove was supplied with argon at 3 cu ft per hour from a manifold cut in the backing bar (see improved method, Fig. 4).

At the same time, graphite runout blocks were added at each end of the joint zone to prevent burnout at the edges of the strip (Fig. 4, improved method). This allowed subsequent use of the full width of the strip, without trimming, and thus increased productivity.

The coil-handling equipment, shear and clamps were operated manually. Arc start, arc length and torch travel were operated automatically. Approximately 120 welds were made in 8 hr.

Cost data and additional welding conditions are given in the table with Fig. 4.

Preheating is not normally used in gas tungsten-arc welding thin sections of the phosphor bronzes. Thick sections are usually preheated at 350 to 400 F, and are cooled slowly after welding. Because phosphor bronze is hot short, weld layers should be thin, and interpass temperature should not exceed 400 F. The weld can be hot peened to refine grain and minimize distortion.

In the example that follows, in which only partial penetration was necessary and high strength was not needed, 5⁄16-in.-thick phosphor bronze was gas tungsten-arc welded to ¾-in.-thick phosphor bronze without preheating and with peening of the weld being done after cooling.

Example 332. Gas Tungsten-Arc Welding of End-Cap Rings to Drilled Phosphor Bronze Bushings (Fig. 5)

A design change in heavy-duty bushings centrifugally cast in SAE 65 phosphor bronze (89 Cu, 11 Sn), called for gun drilling longitudinal holes that had to be end capped. End capping was done by gas tungsten-arc welding a flat ring, also cast from SAE 65 phosphor bronze, to each end of the bushing, as shown in Fig. 5.

Since the function of the weld was to maintain a close fit of the rings during the service life of the bushing, joint design called for only a partial-penetration, single-V-groove weld. This design caused distortion of the rings, because of unbalanced thermal stresses during welding, and constriction of the bushing diameter from shrinkage stresses after cooling.

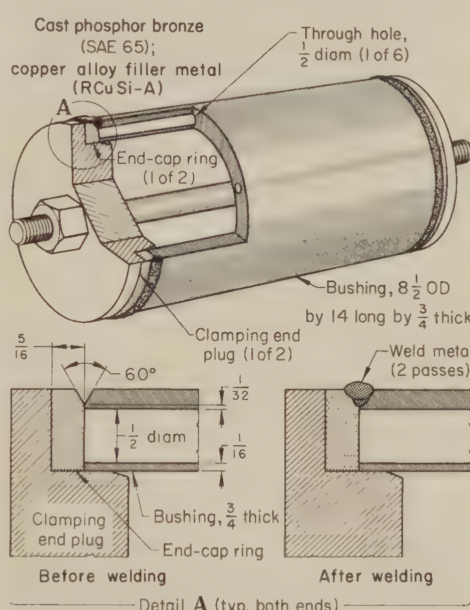
Both difficulties were overcome by designing a welding fixture consisting of a pair of flanged end plugs that could be drawn up tightly by means of a common threaded rod and nuts (Fig. 5). Machining the plugs for a close fit ensured accurate alignment of the parts during fit-up, welding, and cooling, and during subsequent peening. The plugs also served as a heat sink.

Gas tungsten-arc welding was done manually on the small quantities of bushings by rolling the bushing and its fixture on a steel-top table. A silicon bronze rod, RCuSi-A, was selected for filler metal for its weldability, strength, and color match. The shielding gas was argon.

The weld was made in two passes at approximately ½ rpm. Cracking from hot shortness was avoided by making relatively small weld deposits.

Before assembly, the semifinished machined parts were beveled by machining, and detergent cleaned. After cooling from welding, the welds were peened to relieve stresses, and examined visually and by liquid penetrants for porosity and cracks.

Other details of the welding operation are given in the table with Fig. 5.



Manual Gas Tungsten-Arc Welding

Joint type	Circumferential edge
Weld type	60° single-V groove (partial penetration)
Number of passes	Two
Power supply	250-amp rectifier
Electrode	1⁄16-in.-diam EWTh-2
Torch	250-amp, water cooled
Filler metal	1⁄16 or 3⁄32-in.-diam RCuSi-A
Shielding gas	Argon, at 10 to 12 cfh
Welding position	Horizontal rolled
Fixtures	Clamping end plugs
Current	130 amp, dcsp
Voltage	12 to 15 v
Arc starting	High open-circuit voltage (70 v)

Fig. 5. Heavy-duty bushing and setup for end-capping holes drilled longitudinally through the bushing wall (Example 332)

Table 9. Nominal Conditions for Gas Tungsten-Arc Welding of Aluminum Bronzes (a)
(For joint configurations, see Table 5)

Work-metal thickness, in.	Root opening, in.	Electrode diameter, in. (b)	Diameter of welding rod, in. (c)	Flow rate of argon, cfh	Current (ac, HF-stabilized), amp (d)	Number of passes
Square-Groove Butt Joints						
Up to 1/16	0	1/16	1/16 (e)	20 to 30	25 to 80	One
1/16 to 1/8	1/16 max	3/32	1/8	20 to 30	60 to 175	One

70° Single-V-Groove Butt Joints						
3/8	0	5/32 to 3/16	5/32	30	210 to 330	Four
Fillet-Welded T-Joints or Square-Groove Inside Corner Joints						
3/8	(f)	5/32 to 3/16	3/32	30	225	Three

(a) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding parts on which previous experience is lacking; they are subject to adjustment as necessary to meet the special requirements of individual applications. Preheating is not ordinarily used in welding the thicknesses shown. (b) Zirconiated or unalloyed tungsten electrodes are recommended with high-frequency-stabilized alternating current. (c) Preferred welding rod is RCuAl-A2; otherwise, RCuAl-B or rod of the same composition as the base metal. (d) Straight-polarity direct current can also be used in making single-pass welds; see text. (e) Use of welding rod is optional for thicknesses up to 1/16 in. (f) Zero root opening for T-joints; 3/8 in. max for corner joints.

Gas Tungsten-Arc Welding of Aluminum Bronzes

Aluminum bronzes up to about 3/8 in. thick are readily joined by gas tungsten-arc welds, although welding conditions differ somewhat from those for most copper alloys. Porosity is minimized by the presence of iron, manganese or nickel in the filler metal or base metal, or in both. Aluminum bronze castings also are repair welded by gas tungsten-arc welding.

Nominal conditions for welding these alloys are given in Table 9.

Welding conditions are selected to avoid difficulties that may be caused by tenacious, refractory aluminum oxide coatings, which form almost instantaneously during any heating process such as welding unless oxygen is completely excluded. Heat input requirements are not high (aluminum bronzes have a thermal conductivity near that of carbon steel).

Shielding Gas. Argon permits adequate heat input and is used exclusively for gas tungsten-arc welding of aluminum bronzes.

The shielding effect of the gas is augmented, where necessary, by the use of a special flux applied to the edge of the joint to increase fluidity and to help protect the base metal from oxide formation. Aluminum oxide forms even at room temperature, and the flux prevents access of air to the prepared edges until the protective argon atmosphere becomes effective.

Type of Current. To prevent oxide buildup, alternating current stabilized by high frequency is preferred to straight-polarity direct current for gas tungsten-arc welding of aluminum bronzes. High-frequency-stabilized alternating current is particularly desirable in multiple-pass welding of these alloys.

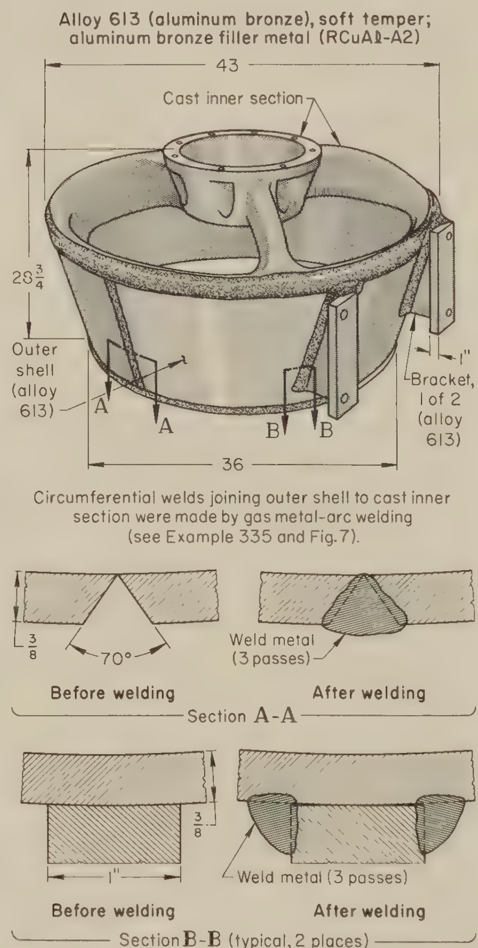
Straight-polarity direct current can be used in single-pass welding, particularly for automatic welding, when surfaces are well cleaned and protected and when the arc is closely controlled.

Electrodes for gas tungsten-arc welding of aluminum bronzes are usually zirconiated tungsten (EWZr) or unalloyed tungsten (EWP); thoriated tungsten electrodes cause the arc to wander when they are used with alternating current, although they may be used with direct current (Example 333). The electrode tip is flat, not tapered as in welding other copper alloys.

Filler metal RCuAl-A2 is ordinarily used. When a close match in composition and color with the base metal is needed, RCuAl-B or other aluminum bronze wire of a suitable composition should be used.

Preheating. Aluminum bronzes, which have relatively low thermal conductivity, do not usually need preheating for gas tungsten-arc welding of sections thinner than about 1/4 in. Preheating may be necessary in welding thicker sections, and was used in gas tungsten-arc welding 3/8-in.-thick aluminum bronze in Example 333. In contrast, no preheat was used in making gas metal-arc welds on the same assembly (Example 335).

Example of Application. Because gas tungsten-arc welding has a small, easily controlled arc, it is preferred to gas metal-arc welding for joining thin sections or where there is danger of damage from burn-through of adjacent surfaces, as in the following example.



Gas Tungsten-Arc Welding

Joint types .... Butt and T
Weld types .... Single-V groove and fillet
Welding position .... Flat
Number of passes .... Three
Power supply ...... 300-amp rectifier, constant-current type
Electrode 3/32-in.-diam EWTh-2
Torch .... Water cooled
Filler metal 3/32-in.-diam RCuAl-A2
Shielding gas .... Argon, at 15 to 20 cfh
Preheat and interpass temperature .... 300 F
Voltage .... 35 v
Current .... 225 amp, dcsp
Arc starting .... Contact and high frequency

Fig. 6. Propeller housing produced as an assembly welded by two processes. Weldment replaced a single-piece casting, reducing cost and improving serviceability. (Example 333)

Example 333. Use of Gas Tungsten-Arc Welding in Preference to Gas Metal-Arc Welding To Avoid Burn-Through of Neighboring Section (Fig. 6)

The propeller housing (Kort nozzle) shown in Fig. 6 had originally been made as a one-piece sand casting from aluminum bronze alloy 9B (ASTM B148), which contains 10% aluminum and 1% iron. However, difficulties experienced in the coring necessary to produce the thin outer shell led to the production of this outer shell as a separate piece that was welded to the casting to make a two-piece structure.

The inner section, faired to produce the most efficient flow from the propeller, was cast in propeller bronze, in one intricate piece that included an integral hub and shaft-mounting flange connected to the main body of the nozzle by four arms. The outer shell was cut from 3/8-in.-thick alloy 613 (aluminum bronze), soft temper, and was wrapped around the cast inner section after being cold formed into a truncated cone. Before cold forming, all edges of the shell were machined to a 35° bevel to provide a groove for subsequent welding.

The assembly was tack welded together, and then circumferential seams at the top and bottom were gas metal-arc welded, as described in Example 335. Then, to avoid burn-through of the faired cast inner section (and resultant poor effect on the propeller stream), gas tungsten-arc welding, under the conditions in the table with Fig. 6, was used for the longitudinal seam in the shell and for joining two alloy 613 brackets to the shell for mounting the housing to the hull of the vessel (Fig. 6).

Not only was the cost of production reduced by eliminating the complex and expensive coring in the casting, but the weight of the welded housing was less than that of the completely cast housing. Furthermore, the cast housing had been made of an alloy that (although easy to cast) did not resist erosion, corrosion and cavitation as well as did the alloys used in the welded assembly.

Gas Tungsten-Arc Welding of Silicon Bronzes

Gas tungsten-arc welding is used on thin to moderately thick nonleaded silicon bronzes, which are the most weldable of the copper alloys. One application of the process to these alloys is the welding of chemical-storage tanks,

for which smooth, clean, oxide-free welds can eliminate the need for grinding after welding. The welding of silicon bronze to other copper alloys and to copper is described in Example 323 and detailed in Table 3.

Nominal conditions for welding of silicon bronzes are given in Table 10. The data for manual welding include welding conditions for various positions. Because they have low fluidity, the silicon bronzes are the only group of copper alloys on which this process is applied extensively in the vertical and overhead positions.

The gas tungsten-arc welding of silicon bronze stock thinner than about 1/16 in. is best accomplished by using high-frequency-stabilized alternating current with zirconiated (EWZr) or unalloyed tungsten (EWP) electrodes.

Argon is used almost exclusively as the shielding gas for welding the silicon bronzes.

Filler Metals. The conventional silicon bronze filler metal, RCuSi-A, which is similar in composition to alloy 655 (high-silicon bronze A), the most commonly used silicon bronze, can be used to weld any of the silicon bronzes. Thin sections of silicon bronze can be gas tungsten-arc welded without the addition of filler metal, as described in Example 323.

Joint Design. On metal thicker than about 1/4 in., a V-groove with 60° included angle is used. Butt joints in thin stock can be welded without special preparation.

Preheating is not needed on silicon bronzes, some of which have lower thermal conductivity than do carbon steels (alloy 655, for instance). Further, because of the hot shortness of these alloys, preheating can be harmful, and interpass temperature on multiple-pass welds should not exceed 200 F.

Table 10. Nominal Conditions for Gas Tungsten-Arc Welding of Silicon Bronzes(a)

(Using zero root opening, no preheat, EWTh-2 electrodes, RCuSi-A welding rod, argon shielding gas, and straight-polarity direct current; for joint configurations, see Table 5)

1(c)	325 to 350	1/8	...	3/16, 1/4	20	20

(a) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding parts on which previous experience is lacking; they are subject to adjustment as necessary to meet the special requirements of individual applications. (b) Wire-feed rate, 115 to 125 in. per minute. (c) Thicknesses greater than about 1/2 in. are gas tungsten-arc welded only when it is not practicable to use gas metal-arc welding. (d) Root face is 1/16 in. for thicknesses of 1/2 in. or less, and 1/8 in. for thicknesses greater than 1/2 in. (e) Maximum root opening = t (work-metal thickness).

Gas Tungsten-Arc Welding of Copper Nickels

Gas tungsten-arc welding is the preferred process for joining copper nickels in thicknesses up to about 1/16 in. and may be used for greater thicknesses. Data on the automatic welding of alloy 715 (copper nickel, 30%) tubes to tube sheets of the same alloy are given in Table 3 for the welding operations described in Example 323.

Nominal conditions for automatic and manual gas tungsten-arc welding of the most common copper-nickel alloys are given in Table 11, for butt joints with square and single-V grooves.

Preferred conditions include the use of argon shielding gas, straight-polarity direct current, and thoriated tungsten electrodes, although these variables are not critical for copper nickels, because these alloys have low heat conductivity.

Current is slightly higher for alloy 706 (as shown in Table 11), because of its higher thermal conductivity; or a slower welding speed can be used. Preheating is not needed.

Backing strips or rings for use in welding copper nickels should not be made from carbon, graphite or steel; instead, copper or copper-nickel backing should be used.

Filler Metal. The only filler-metal composition ordinarily used in gas tungsten-arc welding of copper nickels is RCuNi. This filler metal contains 0.20 to 0.50% Ti to minimize porosity and the possibility of oxygen embrittlement, either in the weld metal or in the heat-affected zone, by acting as a deoxidizer.

Because the standard copper-nickel alloys do not contain titanium or a comparable deoxidizer, filler metal should be used, even in welding thin sheet of copper nickels, to avoid porosity. However, special compositions of alloys 706 and 715 that contain titanium are available, and thin sheet of these special alloys can be welded without the use of filler metal.

In multiple-pass welding, the welding-rod size and current may be increased with successive passes, as shown in Table 11, for the most efficient deposition rate.

Table 11. Nominal Conditions for Gas Tungsten-Arc Butt Welding of Copper Nickels(a)

Work-metal thickness, in.	Butt-joint groove(b)	Current (dcsp), amp	Electrode diameter, in.(c)	Travel speed, ipm	Diameter of RCuNi welding rod, in.(d)	Flow rate of argon, cfh	Number of passes
Automatic Welding of Alloy 706 (Copper Nickel, 10%)							
1/8	Square	310 to 320	3/16	15 to 18	1/16	25-30	1
Manual Welding of Alloy 706 (Copper Nickel, 10%)							
0 to 1/8	Square	300 to 310	3/16	5	1/8	25-30	1
1/8 to 3/8	70-80° single-V	300 to 310(e)	3/16	6	1/8, 3/16	25-30	2 to 4
Manual Welding of Alloy 715 (Copper Nickel, 30%)							
0 to 1/8	Square	270 to 290	3/16	5	1/8	25-30	1
1/8 to 3/8	70-80° single-V	270 to 290(e)	3/16	6	5/32	25-30	4

(a) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding parts on which previous experience is lacking; they are subject to adjustment as necessary to meet the special requirements of individual applications. Root opening is zero. Preheating is not needed. (b) See Table 5 for illustrations of joints. (c) Preferred electrode material is EWTh-2. (d) Filler metal (RCuNi) must be used on all welded joints; see text. (e) Current should be increased in equal increments with each pass, up to a maximum of about 375 amp, with larger welding rods.

Table 12. Filler Metals and Preheat and Interpass Temperatures Used in Gas Tungsten-Arc Welding of Coppers and Copper Alloys to Dissimilar Metals(a)

One metal to be welded	Filler metals (and preheat and interpass temperatures) for welding metal in column 1 to: Coppers	Phosphor bronzes	Aluminum bronzes	Silicon bronzes	Copper nickels

High-carbon steel	RCuAl-A2 or RCu or ERNi-3 (1000 F)	ECuSn-C(b) (500 F)	RCuAl-A2 (500 F)	RCuAl-A2 (400 F)	RCuAl-A2 or ERNi-3 (150 F max)
Low-alloy steel	RCuAl-A2 or RCu or ERNi-3 (1000 F)	ECuSn-C(b) (500 F)	RCuAl-A2 (500 F)	RCuAl-A2 (400 F)	RCuAl-A2 or ERNi-3 (150 F max)
Stainless steel	RCuAl-A2 or RCu or ERNi-3 (1000 F)	ECuSn-C(b) (400 F)	RCuAl-A2 (150 F max)	RCuAl-A2 (150 F max)	RCuAl-A2 or ERNi-3 (150 F max)
Cast Irons					
Gray and malleable irons	RCuAl-A2 or RCu (1000 F)	ECuSn-C(b) (400 F)	RCuAl-A2 (400 F)	RCuAl-A2 or RCuSi-A (300 F)	RCuAl-A2 (150 F max)
Ductile iron	RCuAl-A2 or RCu (1000 F)	ECuSn-C(b) (400 F)	RCuAl-A2 (150 F max)	RCuAl-A2 or RCuSi-A (150 F max)	RCuAl-A2 (150 F max)

(a) Filler-metal selections shown in table are based on weldability, except where mechanical properties are usually more important. Preheating is ordinarily used only when at least one member is thicker than about 1/8 in. or is highly conductive (see text). Preheat and interpass temperatures are subject to adjustment on the basis of the size and shape of the weldment. (b) ECuSn-C is classified by AWS as an electrode wire for gas metal-arc welding, but is used also as filler wire in gas tungsten-arc welding. (c) These combinations of work metals are only infrequently joined by welding; as a starting point in developing welding procedures for joining them, the use of RCuAl-A2 filler metal is recommended, except for welding of combinations that include phosphor bronzes.

Gas Tungsten-Arc Welding of Dissimilar Metals

Copper and many copper alloys can be gas tungsten-arc welded to other copper alloys, steels, stainless steels, and nickel and nickel alloys — usually with the aid of a filler metal. Because the use of gas tungsten-arc welding for this purpose is usually restricted to thin metal, the welding is ordinarily done without "buttering" with a preliminary surfacing weld. Combinations of dissimilar metals in thicknesses greater than about 1/8 in. are preferably joined by gas metal-arc welding or, where gas metal-arc welding is not applicable, by shielded metal-arc welding.

Usually, the arc is directed at the more conductive metal of the combination being welded.

Welding With Filler Metal. Table 12 shows combinations of dissimilar metals that are joined by gas tungsten-arc welding with the aid of copper alloy or nickel alloy filler metals, and gives the recommended filler metals and preheat and interpass temperatures for each combination.

Nearly all of the weldable copper alloys, as listed in Table 1, can be joined to dissimilar metals in this way. Copper-zinc alloys are not gas tungsten-arc welded to dissimilar metals, except for the welding of copper to low-zinc brass, which is done with phosphor bronze filler metal.

Ordinarily, joints between a ferrous metal and copper or a copper alloy by this method are welds on the copper side of the joint and braze welds on the iron side of the joint, because the melting point of the filler metal is lower than that of the base metal. Exceptions are gas tungsten-arc welds joining a copper or a copper nickel to a ferrous metal, using the nickel filler metal ERNi-3, as listed in Table 12. These are true welds on both sides of the joint.

The aluminum bronze filler rod RCuAl-A2 is compatible with most of the metals in Table 12, with the notable exception of the phosphor bronzes, and is by far the most widely used filler metal for gas tungsten-arc welding the dissimilar metals shown. Unlike copper, phosphor bronze and silicon bronze filler metals, RCuAl-A2 can tolerate substantial amounts of dilution with iron, and thus can be used for joining ferrous metals to copper alloys with minimum danger of cracking.

Preheating. Except where one or both members of a joint have high thermal conductivity, preheating is not needed for welding the dissimilar metals listed in Table 12 if both members are less than about 1/8 in. thick.

Referring to Table 12, in most cases the lower preheat temperature or an intermediate temperature applies when two alloys that have different preheat requirements are welded together. An exception is the joining of copper to other metals, in which the need to provide enough heat in this highly conductive metal overrides other considerations, and the preheat temperature of 1000 F shown for copper must be used to ensure successful welds.

(a) The data in this table are intended to serve as starting points for the establishment of optimum joint design and conditions for welding of parts on which previous experience is lacking; they are subject to adjustment necessary to meet the requirements of individual applications. Thicknesses up to about 1½ in. are sometimes welded, by use of slightly higher current and lower travel speed than shown for a thickness of ½ in. (b) Copper backing. (c) Grooved copper backing. (d) Or 75% argon, 25% helium. (e) Special welding sequence is used; see text.
(f) See Table 1 for compositions. (g) The final pass is made on the root side after back chipping. Grind after each pass. (h) The final pass is made on the root side after back chipping. Wire brush after each pass. (j) Similar to the double-V-groove weld shown in Table 5, but with a groove radius of ⅜ in. (k) Several passes are made on the face side, then several on the back side, until the weld is completed. Back chip the root pass before making the first pass on the back side. Wire brush after each pass. (m) Should not be overheated; as little preheat as possible should be used. (n) Welding conditions based on alloys 510, 521 and 524; current is increased or speed decreased for alloy 505.
(p) Or ECuSn-C. (q) Hot peening between passes is recommended for maximum strength. (r) Slight preheat may be needed on heavy sections; interpass temperature should not exceed 600 F. (s) With ⅛-by-1-in. aluminum bronze backing. (t) No preheat is used on any thickness; interpass temperature should not exceed 200 F. (u) With ⅛-by-1-in. silicon bronze backing. (v) Steel should be well penetrated; an overlay is not usually needed. (w) Steel should be well penetrated; an overlay should be applied to avoid excessive dilution of the silicon bronze. (x) Except in welding silicon bronze to high-carbon or low-alloy steel, for which preheat temperature is 400 F.

Interpass temperatures should not ordinarily be allowed to rise above the prescribed preheat temperature, because many of the copper alloys are hot short at higher temperatures.

Welding Without Filler Metal. Certain combinations of copper alloys, usually not differing widely in composition, can be gas tungsten-arc welded in thicknesses up to about ⅛ in. without filler metal.

Examples 323 and 330 describe the gas tungsten-arc welding of several combinations of dissimilar copper alloys without the use of filler metal.

Gas Metal-Arc Welding

Gas metal-arc welding is used to join all of the coppers and copper alloys listed in Table 1. It is preferred for joining the aluminum bronzes, silicon bronzes and copper nickels in section thicknesses greater than about ⅛ in. (Gas tungsten-arc welding is preferred for thicknesses less than about ⅛ in.)

The major application of gas metal-arc welding to copper alloys is in joining material from ⅛ to ½ in. thick, and the process is almost invariably selected for arc welding sections of copper alloys thicker than about ½ in., where its high deposition rate is a major advan-

Table 14. Electrode Wires Most Frequently Used in Gas Metal-Arc and Shielded Metal-Arc Welding of Copper and Copper Alloys (a)

Type of electrode	AWS classification	Principal constituents (b)
Copper	ECu (c)	98.0 min Cu+Ag, 1.0 Sn, 0.5 Mn, 0.5 Si, 0.15 P
Silicon bronze	ECuSi	2.8-4.0 Si, 1.5 Sn, 1.5 Mn, 0.5 Fe, rem Cu+Ag
Phosphor bronze	ECuSn-A	4.0-6.0 Sn, 0.10-0.35 P, rem Cu+Ag
Phosphor bronze	ECuSn-C	7.0-9.0 Sn, 0.05-0.35 P, rem Cu+Ag
Aluminum bronze	ECuAl-A1 (c)	6.0-9.0 Al, rem Cu+Ag
Aluminum bronze	ECuAl-A2	1.5 Fe, 9.0-11.0 Al, rem Cu+Ag
Aluminum bronze	ECuAl-B	3.0-4.25 Fe, 11.0-12.0 Al, rem Cu+Ag
Copper nickel	ECuNi	1.00 Mn, 0.6 Fe, 0.50 Si, 29.0 min Ni+Co, 0.6 Ti, rem Cu+Ag

(a) Based on AWS A5.6; see current edition of this specification for complete compositions and qualifications. All electrodes listed are available in both bare and covered forms except ECu and ECuAl-A1, which are not available as covered electrodes for shielded metal-arc welding. (b) Single percentages are maximums unless otherwise stated. Optional elements and impurities have been omitted. For covered electrodes, the compositions are of the metal core. (c) Available only as bare electrodes, for gas metal-arc welding.

tage over gas tungsten-arc welding or shielded metal-arc welding.

The greater rate of heat input to the weld, compared with that for gas tungsten-arc welding, is a disadvantage in some applications because of the wider heat-affected zone.

Nominal conditions for gas metal-arc welding of coppers and copper alloys are shown in Table 13.

Direct current, reverse polarity, is used exclusively for gas metal-arc welding of copper alloys. Argon is normally used for shielding. Helium or mixtures of argon and helium are used where hotter arcs are needed than are possible at given current levels with pure argon.

As shown in Table 13, a square-groove joint is not ordinarily used for welding thicknesses greater than ⅛ in. except for coppers; single-V grooves are used for thicknesses of ⅛ to ½ in. In material thicker than about ½ in., joints are usually prepared with double-V or double-U grooves.

Welding Position. Most gas metal-arc welding of copper alloys is done in the flat position, with spray transfer; fillet welds acceptable for many applications can be produced in the horizontal position. When it is necessary to weld in positions other than flat, gas metal-arc welding is preferred to gas tungsten-arc or shielded metal-arc welding. Gas metal-arc welding in the vertical and overhead positions is usually restricted to the less fluid copper alloys such as aluminum bronzes, silicon bronzes, and copper nickels. Small-diameter electrode wire and low currents are preferred for such applications, and a globular or short-circuiting mode of transfer is ordinarily used.

Electrode Wires (Filler Metals). Compositions of electrode wires used in gas metal-arc welding of copper alloys are shown in Table 14.

Methods. Both semiautomatic and automatic methods were used for gas metal-arc welding of circumferential butt joints in copper nickel tubing in Example 337. In the three other examples in this section, electrode-wire feed, gas flow and current level were automatically controlled.

Gas Metal-Arc Welding of Coppers

The effects of oxygen in causing porosity and reducing the strength of welds in copper, as described for gas tungsten-arc welding of copper, are more pronounced in gas metal-arc welding, because of the greater heat input associated with this process. Gas metal-arc welds of deoxidized coppers compare favorably in density and strength with the welds made using the gas tungsten-arc process. However, the greater heat input and the lesser localization of heat obtained with the gas metal-arc process result in greater porosity and lower strength in the heat-affected zone of welds in coppers that contain insufficient amounts of deoxidizer (especially electrolytic tough pitch copper). Consequently, gas metal-arc welding has less applicability than gas tungsten-arc welding for electrolytic tough pitch copper, oxygen-free copper (alloy 102, OF) or low-phosphorus deoxidized copper (alloy 120, DLP) up to about ½ in. thick.

Nominal conditions for gas metal-arc butt welding of coppers are given in Table 13. In welding joints for which the root opening is up to 1/16 or ⅛ in., argon-helium mixtures are sometimes used instead of pure argon, to obtain higher heat input.

Electrode Wires. The recommended ECu electrode wire contains phosphorus, tin, silicon and manganese as deoxidizers, to minimize porosity. This electrode produces sound, trouble-free welds that are also a good match to copper in color, and have good electrical conductivity. The ECu electrode was used as a basis for the conditions listed in Table 13.

Copper electrode wires of purity higher than ECu are seldom used in gas metal-arc welding of copper, because, as a consequence of the absence of deoxidizers, they usually make welds that are porous. Most of the electrodes listed in Table 14 can be used. Any of the electrodes other than ECu will make dense, strong welds, but the color match will be poor, and the electrical conductivity may be unacceptable.

Joint Design. A square-groove joint is used for single-pass welding of coppers up to ⅛ in. thick, in conjunction with a copper backing bar for zero root opening or a grooved copper backing bar where the root opening is 1/16 in. maximum. A square-groove joint is also used for one-pass-per-side welding of coppers up to about ¼ in. thick.

In welding the single-V-groove joints referred to in Table 13 for thicknesses of ⅜ to about ½ in., the metal is deposited on one side in three or more passes and the root pass is back gouged to sound metal before the last pass is applied to the back of the joint. In some applications, the root pass is applied by gas tungsten-arc welding, and subsequent passes are made by gas metal-arc welding for fast buildup.

Heavy sections (thicker than ½ in.) should be prepared with a double-V or a double-U groove and welded with alternate passes applied to opposite sides of the joint if readily accessible, to minimize distortion. In a small closed vessel, limited access may prevent the use of this technique, and in addition, heat buildup often prevents welding on both sides.

Preheating. Because of the high thermal conductivity of copper, sections thicker than ¼ in. are usually preheated. As shown in Table 13, single-V-groove joints in ¼-in.-thick copper, welded using 1/16-in.-diam electrode wire, are also preheated.

Deoxidized Coppers. Heavy-wall copper pressure vessels (up to about 1½-in. wall), which are usually made from phosphorus-deoxidized copper, in which the residual phosphorus helps obtain maximum weld strength and freedom from porosity, are frequently gas metal-arc welded. To meet the high heat demand in welding these heavy-wall vessels, welding currents and preheat temperatures may be higher than those shown in Table 13.

Similar operating conditions are employed in welding crucibles used for arc melting of refractory metals in controlled atmospheres. The crucibles are typically heavy-wall deoxidized copper cylinders with wall thicknesses up to 1¼ in., diameters of 12 to 48 in., and lengths of 3 to 25 ft. They are made of formed and welded copper plate, because seamless tubes of these sizes are not available. Longitudinal seams are welded, and flanges are welded to each end of the cylinders, by the gas metal-arc process. Such cylinders are heated to 1200 F before welding. Welding is done automatically, to avoid bringing operators into close proximity with heavy metal sections at such high temperature.

Oxygen-Free and Tough Pitch Coppers. The gas metal-arc process is used also in welding oxygen-free (OF) copper in producing crucibles of the type just described for arc melting of refractory metals, although the weld properties are inferior to those produced with deoxidized copper. Because OF copper contains no residual deoxidizer, heating and welding cycles must be kept as short as possible, and gas shielding must be completely effective, to avoid excessive porosity.

Although the strength and soundness of welds in oxygen-bearing coppers such as electrolytic tough pitch (ETP) copper are substantially less than in OF copper, the reduced strength and soundness are seldom important for welds in electrical conductors. Bus bars made of ETP copper are sometimes joined by gas metal-arc welding. The adverse effect of the relatively low electrical conductivity of the filler metal, such as ECu or one of the other standard filler metals listed in Table 14, on the electrical conductivity of the joint can be reduced by providing a large contact area at the joint. For better electrical conductivity, a filler metal with about 0.75% Sn, 0.25% Si and 0.20% Mn is sometimes used for welding of ETP copper bus bars.

Gas Metal-Arc Welding of High-Conductivity Beryllium Copper

Gas metal-arc welding is preferred to gas tungsten-arc welding for joining thicknesses of alloy 175 (high-conductivity beryllium copper) greater than 0.090 in. if the weldment is to be heat treated to obtain maximum weld strength, and for joining thicknesses greater than about ¼ in. if the welding is to be done on precipitation-hardened material. The maximum thickness normally joined by gas metal-arc welding is about ¾ in.

As pointed out in the discussion of gas tungsten-arc welding of alloy 175 (see page 342), important factors in arc welding this alloy are its high thermal and electrical conductivities, oxide-forming characteristics, and response to heat treatment. Although some compromise between weld strength and conductivity may be necessary, high thermal or electrical conductivity is ordinarily the prime objective in welded assemblies of this alloy.

Normal conditions for gas metal-arc butt welding of high-conductivity beryllium copper are given in Table 13. Reverse-polarity direct current is almost always used.

Although argon may be used for shielding gas, greater heat input (usually desirable for welding this alloy) can be obtained with an argon-helium mixture.

Electrode Wires. When high conductivity is desired, as in most welding applications of alloy 175, electrode wire of the same composition as the base metal is used. When lower conductivity is adequate, electrodes made of high-strength beryllium copper (alloys 170 and 172), can be used, and provide easier welding. Because of the precipitation-hardening characteristics of beryllium coppers, the joint strength is always somewhat lower than that of the base metal, depending on the initial condition of the base metal, the welding conditions, and the selection of filler metal.

Other electrode wires, such as ECuSi, ECuAl-A2 or ECuAl-B, also are used in gas metal-arc welding of alloy 175, but these electrode wires (which contain no beryllium) do not develop the high strength obtained with beryllium copper filler metals.

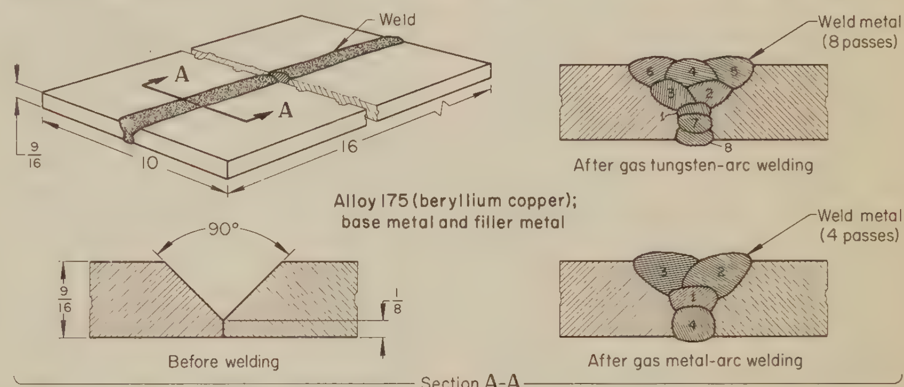
Preheating and Postweld Aging. Sections of alloy 175 thicker than ⅛ in. are usually preheated at 600 to 900 F, depending on section thickness. When beryllium copper filler metal is used, strength can be increased by aging after welding. For alloy 175 the aging treatment is 900 F for 3 hr.

Properties of Weldments. Because of high thermal conductivity and moderate to high strength, alloy 175 is used for welded water-cooled assemblies such as tuyeres for blast furnaces, attrition mills for grinding beryllium chips to powder, and molds for the continuous casting of steel.

Some strength is lost in the weld metal and in the heat-affected zone when alloy 175 is welded. The magnitude of this decrease is affected by the condition and thickness of the base metal, the joint design, welding process and welding conditions. In the following example, the decrease in strength for alloy 175 was less for gas metal-arc than for gas tungsten-arc welding.

Table 15. Decrease in Strength of Alloy 175 After Gas Metal-Arc and Gas Tungsten-Arc Welding (Example 334) (a)

Item	Gas metal-arc welding	Gas tungsten-arc welding
Properties, Using Solution Annealed Work Metal(b)		
Tensile strength, psi:		
Before welding	47,000	48,200
After welding	46,000	37,000
Decrease	2%	23%
Break:		
Before welding	Normal	Normal
After welding	Outside weld	Outside weld
Properties, Using Precipitation-Hardened Work Metal(c)		
Tensile strength, psi:		
Before welding	121,000	98,900
After welding	110,000	81,700
Decrease	9%	17%
Break:		
Before welding	Normal	Normal
After welding	In weld	In weld
Welding Conditions(d)		
Power supply	900-amp motor-generator	500-amp alternator(e)
Electrode	1/16-in.-diam alloy 175	¼-in.-diam EWTh-2
Filler wire	(Consumable electrode)	⅛-in.-diam alloy 175
Shielding gas	Argon, at 30 cfh	Helium, at 25 cfh
Current, amp	325 (dcrp)	240 to 260 (ac, hf-stabilized)
Voltage, v	22	...
Wire-feed rate, ipm	200	...
Travel speed, ipm	11	...
Number of passes	4	8
Preheat temperature, F	1000 to 1200	800 to 900



(a) Data are for welding specimens as illustrated above, in the solution annealed and the precipitation-hardened conditions. Each value for tensile strength is the average of two tests. (b) Solution annealing treatment consisted of heating to 1700 to 1750 F and water quenching. (c) Precipitation hardening was done by reheating the solution annealed specimens for 3 to 4 hr at 900 F and air cooling. (d) For butt joints and single-V-groove welds, as illustrated above; and by use of a manual, water-cooled electrode holder and flat-position welding in both gas metal-arc welding and gas tungsten-arc welding. (e) High-frequency.

Example 334. Comparison of Gas Metal-Arc and Gas Tungsten-Arc Welding for Joining High-Conductivity Beryllium Copper (Table 15)

Comparison studies were made on joining alloy 175 (high-conductivity beryllium copper, 0.6%) by gas metal-arc and gas tungsten-arc welding for several heat-transfer applications. Test specimens were prepared by welding together pieces 5 by 16 by 9/16 in. thick. Joint preparation consisted of beveling the edges to be joined to make a V-groove 7/16 in. deep with a 90° included angle, leaving a root face of ⅛ in., as shown in the drawing in Table 15.

The gas tungsten-arc welds were made by depositing metal in six passes on the face side, back gouging to sound metal, and completing the weld by making two back passes. Before welding, the joint was wire brushed, and each bead was wire brushed to remove any oxide before the next pass.

The work metal was preheated at 800 to 900 F and alternating current was used, both to help keep the surface free of oxide, and to avoid longitudinal bead cracking that might have occurred with direct-current welding.

The gas metal-arc welds were made with three passes on the face side and one back pass, with the root side being ground out to a depth of ⅛ to 3/16 in. before the back pass was made, and with wire brushing of each bead in the same way as for the gas tungsten-arc welds.

Sound welds free from cracking were produced by each process when using the procedure described above and the welding conditions in Table 15, without using a backing gas.

The gas tungsten-arc welding of beryllium copper slightly thicker than ½ in. produced specimens showing a 23% decrease in tensile strength for the solution annealed condition and a 17% decrease in the solution annealed and precipitation-hardened condition, as shown in Table 15. The usual thickness limit is ½ in.

Specimens welded by the gas metal-arc process, working well within its usual limit of ¾-in. thickness for this alloy, showed substantially less decrease in strength. Welded joints made in solution annealed alloys showed only a 2% decrease in tensile strength, while those made in alloys that had been solution annealed and precipitation hardened were 9% lower in strength than the base metal (Table 15). These results may have been affected to a minor extent by the differences in properties of the test specimens used for the two welding processes. As Table 15 shows, in the

precipitation-hardened condition, the specimens used for gas metal-arc welding had a tensile strength of 121,000 psi, while those specimens used for gas tungsten-arc welding had a tensile strength of only 98,900 psi. Considerable variation in the results from precipitation hardening is not unusual. In this instance, determining the percentage of decrease for the two welding processes was the primary objective.

Results of bend tests on specimens welded in the solution annealed condition were acceptable, with no specimen showing more than one crack; the cracks were located near the root edge and were less than ⅛ in. long.

Specimens for all of the tests for qualification of the welding procedure were prepared in the manner described in Section IX of the ASME Boiler and Pressure Vessel Code.

Results by both welding processes were considered acceptable for heat-transfer applications, with gas metal-arc welds being preferred where strength requirements were the most critical; both processes were used in welding a limited number of production assemblies.

Gas Metal-Arc Welding of High-Strength Beryllium Coppers

Alloys 170 (1.7% Be) and 172 (1.9% Be), high-strength beryllium coppers, are more easily welded than high-conductivity beryllium copper, because alloys 170 and 172 have lower melting temperatures, greater fluidity and 50% lower thermal conductivity. As it is for high-conductivity beryllium copper (see preceding section), the gas metal-arc process is generally preferred for welding precipitation-hardened high-strength beryllium coppers in thicknesses of more than ¼ in., and is preferred for thicknesses down to 0.090 in. if heat treatment is to be done after welding.

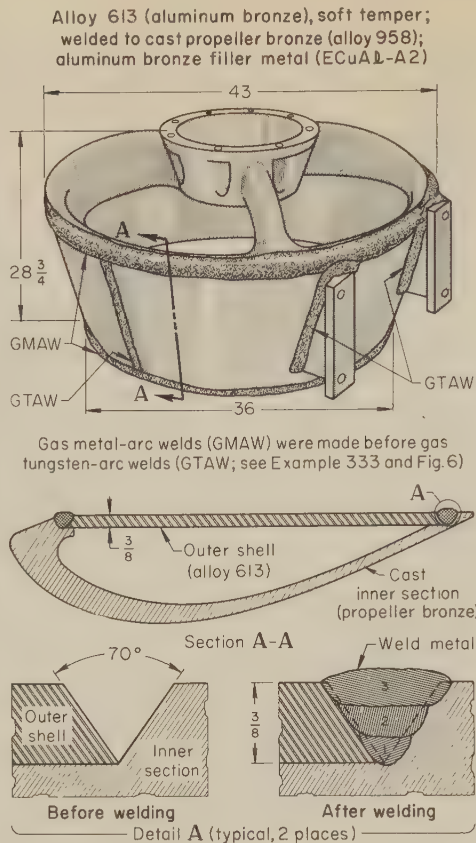
Nominal conditions for gas metal-arc butt welding of high-strength beryllium coppers are given in Table 13.

Mixtures of argon and helium are ordinarily used for shielding gas, in conjunction with reverse-polarity direct current, which helps to prevent oxide buildup during welding. The electrode wire is ordinarily of the same composition as the base metal for joints of maximum strength; electrode wires ECuSi, ECuAl-A2 and ECuAl-B can be used where joint strength is less critical. Preheating, postweld heat treating, and joint design are generally the same as described above for gas tungsten-arc welding of high-strength beryllium coppers.

Gas Metal-Arc Welding of Brasses and Nickel Silvers

Nonleaded brasses, of both the low-zinc type (red brasses) and the high-zinc type (including yellow brasses, tin brasses and special brasses), and nickel silvers can be gas metal-arc welded. Copper-zinc electrodes are not used, because of the violent fuming and loss of zinc that accompanies arc welding with zinc-containing electrodes.

Low-Zinc Brasses. Nominal conditions for butt welding the low-zinc brasses (up to 20% zinc) by the gas metal-arc process are presented in Table 13. Direct current with reverse polarity is always used.



Semiautomatic Gas Metal-Arc Welding

Joint type	Circumferential butt(a)
Weld type	Single-V groove
Welding position	Flat
Number of passes, each weld	Three
Power supply	500-amp rectifier(b)
Electrode wire	3/32-in.-diam ECuAl-A2(c)
Electrode holder	Water cooled
Shielding gas	Argon, at 40 to 45 cfh
Current	425 amp, dcrp
Voltage	35 v
Arc starting	Touch start
Preheat	None

(a) Self-backed joint (see illustration). (b) Constant-voltage type. (c) Spooled.

Fig. 7. Propeller housing, and section showing joints that were gas metal-arc welded (Example 335)

ECuSi electrode wire provides easy welding because it has good fluidity at low current. A 60° single-V-groove joint is used with ECuSi. When ECuSn-C electrode wire is used, principally for better color match, its sluggish flow characteristics make a 70° V-groove advisable for the heavier thicknesses shown in Table 13. The wider groove allows more room for manipulation of the molten weld metal. Except for color, weld-metal properties are comparable when using these two types of electrodes. For welds of redder color and slightly higher conductivity, the low-zinc brasses can also be welded with ECuSn-A electrode wires, but weld strength and hardness are lower.

High-Zinc Copper Alloys. Nonleaded copper alloys with zinc contents ranging from about 20 to 40%, or more (see compositions of high-zinc brasses, tin brasses, special brasses, and nickel silvers in Table 1), can be gas metal-arc welded, although with greater difficulty than the nonleaded low-zinc brasses. Zinc fumes are more severe and the welds have greater porosity and lower strength than in the low-zinc brasses. Both wrought and cast alloys are joined by gas metal-arc welding; massive sections such as manganese bronze ship propellers are regularly repair welded by this process.

Nominal conditions for gas metal-arc butt welding of high-zinc copper alloys (high-zinc or yellow brasses, tin brasses, special brasses, and nickel silvers) are given in Table 13. Operating variables are generally the same when using either ECuAl-A2 (for higher weld strength) or ECuSn-C (for better color match). Preheating is seldom necessary, because these alloys have relatively low heat conductivity. However, preheating helps to limit fuming in some applications, because it permits use of lower current.

Gas Metal-Arc Welding of Phosphor Bronzes

Nominal conditions for gas metal-arc butt welding of phosphor bronzes are given in Table 13. Lead-bearing or other free-machining types are not welded. As with gas tungsten-arc welding (Table 8), the welding conditions are based on the three poorly conductive phosphor bronzes (alloys 510, 521 and 524); higher welding current or slower welding speed is needed for the more conductive alloy 505 (phosphor bronze, 1.25% E).

For thicknesses of ⅜ to ½ in., 90° single-V grooves are used, rather than narrow grooves as for most other poorly conductive copper alloys (Table 13).

Electrode Wires. For joining phosphor bronzes with less than 8% Sn, ECuSn-A electrode wire is generally used. For joining phosphor bronzes with 8 to 10% Sn, ECuSn-C is more often used. Electrode wire that contains about ½% Si is sometimes used to minimize porosity in the weld.

Preheating helps in obtaining complete fusion. Also, it minimizes porosity because the freezing rate of the weld puddle is decreased and more gas is permitted to be evolved before solidification. However, preheating increases the susceptibility of the weld to hot-short cracking and to large columnar grain growth; thus it is common practice to weld with a stringer-bead technique and to peen between layers. A small weld puddle and rapid electrode travel are required.

Interpass temperature should not exceed the preheating temperature (Table 13), because these alloys are hot short.

Gas Metal-Arc Welding of Aluminum Bronzes

Gas metal-arc welding with aluminum bronze electrode wire is the preferred technique for welding aluminum bronze. Because of the comparatively high surface tension of the molten weld metal and the low thermal conductivity of the base metal, welding can be done in all positions. Welds in the vertical and overhead positions are usually made with either the globular or the short-circuiting mode of metal transfer, using electrode wire up to 1/16 in. in diameter.

Nominal conditions for gas metal-arc butt welding of aluminum bronze are given in Table 13. The use of aluminum bronze backing strips or rings in welding metal up to ⅛ in. thick may make it necessary to use helium or argon-helium mixtures as shielding gas, instead of argon as shown in Table 13, for adequate heat input.

Electrode wire ECuAl-A2 is ordinarily used in gas metal-arc welding of aluminum bronze. The 1.5% Fe in this electrode wire makes welds deposited from it less susceptible to hot-short cracking than welds from ECuAl-A1, as is illustrated in Example 336. Welds made with electrode wire ECuAl-B also are free from hot shortness. Joints made with ECuAl-B are also stronger and harder, but less ductile.

Joint Design. The joining of aluminum bronze thicker than about ½ in. requires wider root openings and groove angles than are indicated in Table 13, to avoid bridging and incomplete filling of the joint or to improve penetration because of the increased heat sink in the heavier sections. A short arc, less than ⅛ in. long, is preferred for groove welding of aluminum bronze by the gas metal-arc process.

Combined Processes. Gas metal-arc welding is used in combination with other processes for the fabrication of large and complicated aluminum bronze assemblies. It is often combined with gas tungsten-arc welding, as in the following example.

Example 335. Use of Gas Metal-Arc Welding To Join Outer and Inner Portions of a Propeller Housing (Fig. 7)

Gas metal-arc welding was used to make the circumferential welds on the propeller housing shown in Fig. 7. (The longitudinal seam in the outer shell, and two mounting brackets, were then welded by the gas tungsten-arc process, as described in Example 333.)

The gas metal-arc welds joined the cast inner section and the formed outer shell, as shown in section A-A in Fig. 7. A 35° angle was cast into the edges of the inner-section top and bottom, to mate with a 35° bevel machined on the edges of the formed shell, thus making grooves with 70° included angles for welding (see detail A in Fig. 7).

The shell was tack welded in place, and the two circumferential joints were gas metal-arc welded in three passes each. All welding was done in the flat position using $\frac{3}{32}$-in.-diam ECuAl-A2 electrode wire, reverse-polarity direct current, and argon shielding gas flowing at the rate of 40 to 45 cfh. Other welding conditions are given in the table with Fig. 7.

Preheating. Preheating is seldom necessary in gas metal-arc welding of aluminum bronze (compare Examples 335 and 333). Interpass temperature should not exceed 600 F, because some aluminum bronzes are hot short.

Effect of Base Metal on Weldability. For some applications, changing from one aluminum bronze base metal to another can significantly improve weldability, as in the large condenser shells described in the next example.

Example 336. Effect of Base-Metal Composition on Weldability of Aluminum Bronze (Fig. 8)

In gas metal-arc welding of 20-ton, aluminum bronze condenser shells of the type shown in Fig. 8, three types of joint were involved: butt joints in the shell, T-joints in the baffle section (also of aluminum bronze), and T-joints between external low-carbon steel stiffeners and the copper alloy shell.

Material for the first of three condenser shells was alloy 614, an aluminum bronze containing 2% iron. Neither preheating nor interpass heating was used.

The shell and baffle joints (Fig. 8) were originally joined by gas metal-arc welding with ECuAl-A1 electrode wire and an argon-helium mixture as the shielding gas. The welds cracked severely, because of hot shortness of the weld metal. A change was made to a higher-strength (ECuAl-A2) electrode wire, but then cracking occurred in the heat-affected zone of the base metal, about ⅛ in. from the weld.

The cracking in the heat-affected zone of the aluminum bronze plate was eliminated by changing to alloy 613 base metal, which had the same 7% aluminum content as alloy 614 but with 3.5% iron and 0.2 to 0.5% tin. This adjustment in base-metal composition, together with the change to the ECuAl-A2 electrode, eliminated cracking of welds and base metal, and welding was still done without preheating, to produce assemblies meeting quality standards.

Typical joints of the three types are shown in Fig. 8; welding conditions are given in the accompanying table. Automatic gas metal-arc welding was used on all joints that were easily accessible. Because of difficulties in positioning the heavy assembly in later stages of construction, shielded metal-arc welding was used on some of the less easily accessible stiffener joints.

Welds were inspected visually and with liquid penetrant. Completed condenser-shell assemblies were tested hydrostatically at 3000 psi and were found to be free from leaks. After the first three 20-ton units were completed, three 40-ton condenser-shell assemblies were made using the same welding procedures.

Gas Metal-Arc Welding of Silicon Bronzes

The nonleaded silicon bronzes are readily gas metal-arc welded.

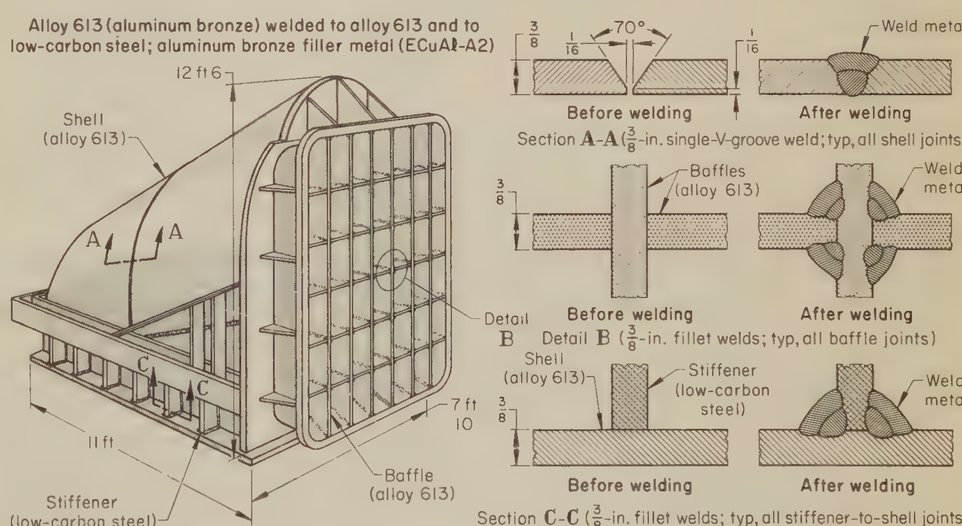
Nominal conditions for gas metal-arc butt welding of silicon bronzes in various thicknesses and joint designs are given in Table 13. To prevent excessive heat buildup in these hot-short alloys, travel speed should be as fast as possible (minimum of 8 in. per minute), and current, as shown in Table 13, is slightly lower than for most other copper alloys. The resulting low heat input to the weld is adequate for complete fusion and good penetration, because of the low thermal conductivity of the silicon bronzes (Table 1).

A thin layer of oxide forms on the weld metal after each pass and must be removed by wire brushing before the next pass.

Electrode Wire. Any silicon bronze alloy can be gas metal-arc welded with ECuSi electrodes. These electrodes are similar in composition to alloy 655 (high-silicon bronze A), the most frequently used silicon bronze, except that they may include up to 1.5% tin instead of, or in addition to, the 1.5% manganese specified as maximum for alloy 655.

Joint Preparation. For thicknesses of ¼ to ¾ in., single, 60° V-grooves are suitable. For silicon bronze alloys thicker than ¾ in., U-grooves or 60° double-V grooves can be used.

Preheating should not be used, because the silicon bronze alloys are hot



Welding condition	Shell joints (section A-A)	Baffle joints (detail B)	Stiffener-to-shell joints (section C-C)
Welding process	Gas metal-arc	Gas metal-arc	Shielded metal-arc
Joint type	Butt	T	T

Preheat	None	None
Interpass temperature	150 F max	150 F max

(a) Each bead was deposited in three 120° increments, with assembly being turned counterclockwise after each increment. (b) Mixed-gas measurements were based on use of a helium flowmeter.

Fig. 9. Setups and weld-buildup sequences for gas metal-arc butt welding of copper nickel tube by semiautomatic and automatic methods (Example 337)

short; interpass temperature must be held below 200 F. Because silicon bronzes have low thermal conductivity, there is no difficulty in obtaining enough heat at the joint for satisfactory welding. Stress relieving of silicon bronze weldments is recommended, to prevent stress-corrosion failure.

Gas Metal-Arc Welding of Copper Nickels

Gas metal-arc welding is the preferred arc welding process for nonleaded copper nickels thicker than about 1/16 in. Welding in the flat position is preferred, but the vertical and overhead positions can be used.

Nominal conditions for gas metal-arc butt welding of nonleaded copper nickels in various joint designs and thicknesses are given in Table 13. Selection of processing conditions is not critical in gas metal-arc welding of these poorly heat-conductive alloys. Alloy 706 is usually welded at slightly higher current or slower speed than alloy 715.

Electrode Wire. Copper nickels are commonly gas metal-arc welded with ECuNi electrode wire, which resembles alloy 715 in that it has a 70-to-30 ratio of copper to nickel. The titanium content (0.15 to 1.00%; see Table 14) of ECuNi serves as a deoxidizer, to minimize porosity and to prevent oxygen embrittlement, and also improves the fluidity of the weld metal.

Joint Design. For gas metal-arc welding of butt joints in nonleaded copper nickels ⅛ in. thick, joint design usually includes a square-groove weld and grooved copper backing, as indicated in Table 13. For thicknesses between ⅛ and ½ in., single-V grooves of 60° to 80° and grooved copper backing are usually employed. (An 80° single-V groove was used in Example 337). For thicknesses greater than about ½ in., double-V or double-U grooves are used.

Backing should be made of copper (or of copper nickel), rather than of carbon, graphite or steel, to avoid reaction with copper and nickel.

Preheating and Postheating. The copper nickel alloys have thermal conductivity equal to or lower than that of low-carbon steel, and no preheating or postheating is needed. Interpass temperature should be kept below 150 F.

Joining of Tubing. Gas metal-arc welding is used extensively for joining copper nickel tubing. The automatic method described in the following example is applicable to tubes larger in outside diameter than 5 in. The offset angles for positioning the electrodes (see Fig. 9) were as follows:

5-in. diam	16 ± 2½° offset
6-in. diam	14 ± 2½° offset
8-in. diam or over	12 ± 2½° offset

A semiautomatic method, usable for pipes 3½ in. in diameter and larger, is compared with the automatic method in the example.

Example 337. Use of Gas Metal-Arc Welding To Butt Weld Copper Nickel Tubing (Fig. 9)

Alloy 715 copper nickel tubing 6½ in. in outside diameter, as shown in Fig. 9, was successfully gas metal-arc butt welded. Wall thickness varied, but was ¼ in. minimum. The joints were prepared by beveling the ends of the tubes to make a V-groove with an 80° included angle and 0.000 to 0.031-in. root face. A backing ring of copper nickel was provided with a minimum outside diameter 0.015 in. smaller than the inside diameter of the tubes. The backing ring was not removed after welding. Before the tubes and backing ring were assembled, the inner surfaces of the tubes, where they were to be in contact with the backing ring, were cleaned to bright metal, as were the beveled ends of the tubes and the outer surfaces for ¼ in. to each side of the joint.

The two tubes and the backing ring were assembled, using a ¼-in. minimum root opening, and tack welded. The tack welds were ground back almost to base metal, and the joint was carefully inspected for starts, stops, crevices and other irregularities that would need to be ground smooth before welding was continued.

Two different methods were used to weld the tube, a semiautomatic method and an automatic method, as detailed in the table with Fig. 9. In the semiautomatic method, the tube assembly was laid flat on a work surface, and each weld bead was applied in three 120° increments from the 12 o'clock position to the 4 o'clock position, with the assembly stationary during each third of a pass. After each 120° increment, the assembly was rolled counterclockwise to present the next 120° segment of the groove to the welder. The weld was completed in eight passes (including two root passes), for each of which the assembly was in three different attitudes on the table, to weld in the horizontal-fixed pipe position from 12 to 4 o'clock (Fig. 9, Section A-A).

In the automatic method, the tube was supported on rolls that turned it continuously while the electrode holder remained fixed for flat-position welding (Section B-B).

Development of the automatic process provided data to ensure that satisfactory results were obtained with only one root pass. By carefully controlling clearance of the backing ring, subsequent passes were made without formation of crevices.

Variations of the technique described in Example 337 were used in similar applications, depending on quantity, lead time, pipe size, service requirements, and availability of equipment. In one such variation, gas tungsten-arc welding was used to fuse a consumable insert in the root of the joint, and the joint was completed by gas metal-arc welding. Another variation was to deposit the root layers by gas metal-arc welding, and to complete the weld manually by the shielded metal-arc process. A similar application on copper nickel pipe, in which the weld was made entirely by shielded metal-arc welding, is described in Example 338.

Table 16. Electrodes and Preheat and Interpass Temperatures Used in Gas Metal-Arc Welding of Coppers and Copper Alloys to Dissimilar Metals (a)

One metal to be welded	Electrodes (and preheat and interpass temperatures) for welding metal in column 1 to: Coppers	Low-zinc brasses	High-zinc brasses, tin brasses, special brasses	Phosphor bronzes	Aluminum bronzes	Silicon bronzes	Copper nickels

Low-alloy steel	ECuAl-A2 or ECu or ERNi-3 (1000 F)	ECuAl-A2 (600 F)	ECuAl-A2 (600 F)	ECuSn-C (500 F)	ECuAl-A2 (500 F)	ECuAl-A2 (400 F)	ECuAl-A2 or ERNi-3 (150 F max)
Stainless steel	ECuAl-A2 or ECu or ERNi-3 (1000 F)	ECuAl-A2 or ECuSn-C (600 F)	ECuAl-A2 (600 F)	ECuSn-C (400 F)	ECuAl-A2 (150 F max)	ECuAl-A2 (150 F max)	ECuAl-A2 or ERNi-3 (150 F max)
Cast Irons							
Gray and malleable irons	ECuAl-A2 or ECu (1000 F)	ECuAl-A2 or ECuSn-C (600 F)	ECuAl-A2 (600 F)	ECuSn-C (400 F)	ECuAl-A2 (400 F)	ECuAl-A2 or ECuSi (300 F)	ECuAl-A2 or ECuNi (150 F max)
Ductile iron	ECuAl-A2 or ECu (1000 F)	ECuAl-A2 (600 F)	ECuAl-A2 (600 F)	ECuSn-C (400 F)	ECuAl-A2 (150 F max)	ECuAl-A2 or ECuSi (150 F max)	ECuAl-A2 or ECuNi (150 F max)

(a) Electrode selections in table are based on weldability, except where mechanical properties are usually more important. Preheating is usually used only when at least one member is thicker than ⅛ in. or is highly conductive; see text. Preheat and interpass temperatures are subject to adjustment based on size and shape of weldment. (b) These combinations are seldom welded; as a starting point in developing welding procedures, use of ECuAl-A2 electrodes is recommended, except for combinations including phosphor bronzes.

Gas Metal-Arc Welding of Unlike Copper Alloys

Gas metal-arc welding can be used for joining nearly all combinations of the weldable copper alloys, with the major factor in developing the welding procedures being the selection of suitable electrode-wire compositions and preheat temperatures. As in other welding of dissimilar metals, the arc is usually directed at the more conductive metal of the combination.

Electrodes and preheat and interpass temperatures for gas metal-arc welding of various combinations of unlike copper alloys are given in Table 16. This table includes all of the alloys listed for gas tungsten-arc welding in Table 12, plus the high-zinc brasses, tin brasses and special brasses.

As shown in Table 16, ECuAl-A2 comes close to being a universal electrode for gas metal-arc welding of unlike copper alloys, although it is incompatible with phosphor bronzes. Silicon bronze (ECuSi) and phosphor bronze (ECuSn-C) electrodes are useful for many combinations of copper alloys that do not contain nickel. Copper electrodes (ECu) are suitable for the final welding passes for welding copper to any of the commonly welded copper alloys, using alloy electrodes to produce the preliminary weld deposits. Copper nickel electrodes (ECuNi) are generally used to join copper to copper nickel.

Usually, a suitable electrode for welding unlike copper alloys is one that is used for welding one of the metals of the combination to itself. A notable exception to this general rule is in the welding of silicon bronzes to copper nickel. The only electrode that can be used successfully for joining this combination is ECuAl-A2.

Preheating. As with gas tungsten-arc welding, preheating is not needed in joining metal less than about ⅛ in. thick, unless at least one member has high thermal conductivity. In joining greater thicknesses, the need for preheating and the choice of preheat temperature are influenced by the joint design and welding conditions.

When joining copper to other copper alloys, the need to provide enough heat to melt the highly conductive copper overrides other considerations,

and the preheat temperature for copper must be used. For instance, when thick copper is welded to copper nickel, required preheat temperature is 1000 F, although copper nickel ordinarily is held below 150 F between passes. The need for enough heat to melt the copper overrides the concern with hot shortness of the copper nickel. The welded assembly is handled carefully until it has cooled below 150 F. Table 16 also shows that the heat sensitivity of copper nickel overrides other considerations when it is welded to other copper alloys and to other metals.

Gas Metal-Arc Welding of Copper Alloys to Dissimilar Metals

The main consideration in gas metal-arc welding of copper or a copper alloy to a ferrous or nickel alloy is dilution. It is not difficult to make welds as strong as the weaker of the base metals, but it may be difficult to retain the ductility demanded by service requirements. The most serious effect of excessive dilution is unsoundness in the form of shrinkage cracks, which can start in the weld metal and propagate into the base metal.

Either of two methods is frequently used to control dilution when gas metal-arc welding combinations involving copper alloys: (*a*) braze weld one side of the joint, thus promoting a minimum amount of dilution on that side, and weld the other side; and (*b*) overlay one or both joint surfaces with a buffer metal.

Braze Welding Method. Braze welds can be used to join copper, aluminum bronzes or copper-zinc alloys to low-carbon or alloy steel, stainless steel, cast iron or nickel alloys. Other copper alloys are more difficult to join to ferrous and nickel alloys by this method. Silicon bronzes make brittle welds; phosphor bronzes and copper nickels make porous welds, especially with ferrous alloys, when welded in this way.

Overlay Method. The other method of controlling dilution is the application of an overlay, on one or both sides of the joint. The overlay metal can be the same as the electrode (filler metal) chosen to weld the joint, or it can be another type chosen principally for its ability to act as a buffer between two incompatible base metals to minimize or eliminate their mixing.

With one or both joint surfaces overlaid, the electrode for welding the remainder of the joint can be chosen with much more freedom, on the basis of its compatibility with the overlay metal and the opposite base metal, or with the two overlay metals, rather than its compatibility with the two original base metals.

When coppers or copper nickels are welded to nickel alloys by the overlay method, the copper side usually is coated with a filler metal that has a substantial content of nickel (see Table 16), to produce a high-nickel surface to weld to the copper or copper nickel.

When silicon bronzes are joined to ferrous or nickel alloys, the silicon bronze side of the joint is ordinarily overlaid with ECuAl-A2. This filler metal is generally suitable for overlaying copper alloys that are being gas metal-arc welded to a ferrous or nickel alloy (see Table 16).

Welding Copper Alloys to Ferrous Metals. Besides the possibility of dilution of filler metal by copper in welding copper alloys to ferrous metals, there is the possibility of iron pickup from the ferrous side.

Aluminum bronzes can tolerate considerable dilution of this type, and copper nickels can tolerate a somewhat lesser amount. In welding these alloys to ferrous metals, care must be taken to be sure the iron is well penetrated, in order that the joint will be stronger than a braze welded joint, which might separate at the iron interface under heavy stress. Overlaying is not usually necessary in welding copper nickels or aluminum bronzes to steel. Nominal conditions for welding these two combinations are given in Table 13.

In the application described in Example 336 (Fig. 8), low-carbon steel stiffeners were gas metal-arc welded to a shell of alloy 613 without any precautions beyond those used on bronze-to-bronze welds; the filler metal was ECuAl-A2.

Commercial coppers can be joined to ferrous metals, in most cases also without the use of an overlay, when the nickel filler metal ERNi-3 is used. Table 13 shows nominal conditions for gas metal-arc welding commercial coppers to steel.

The electrode (filler metal) most often used for gas metal-arc welding copper and copper alloys to ferrous metals is ECuAl-A2 (see Table 16). Both overlaying and weld buildup can be done with the same electrode, or a different electrode can be used for buildup. A common practice is to use ECuAl-A2 for overlaying and to complete the weld with any desired electrode that is shown as compatible in Table 16. This technique cannot be used where one member of the combination to be joined is a phosphor bronze.

Table 13 gives conditions for using ECuAl-A2 for gas metal-arc welding silicon bronze to steel. Excessive dilution of the silicon bronze should be avoided, by the use of an overlay. In all welds between copper alloys and ferrous alloys, it is important for maximum weld strength that enough penetration be achieved on the ferrous side of the joint to effect a weld interface rich with an iron alloy.

Welding to Nickel Alloys. The welding of copper alloys to nickel alloys by the overlay method is generally straightforward, as a result of the mutual solubility of copper and nickel in all proportions. As shown in Table 16, electrodes used in gas metal-arc welding nickel alloys to coppers and copper nickels are ERNi-3 (nickel), ERNiCu-7 (nickel copper), and ECuNi (copper nickel). The copper alloy joint surface should be overlaid with a weld deposit at least ⅛ in. thick before the remainder of the joint is welded.

Aluminum bronze electrodes (ECuAl-A2) are generally suitable for welding alloy combinations in this category. They are the only electrodes that can be used to weld silicon bronzes to nickel alloys such as Monel without cracking. Even with aluminum bronze electrodes, it is advisable to overlay the nickel with filler metal before completing the weld, to minimize the interaction of silicon and nickel that might result in crack-prone weld metal.

Shielded Metal-Arc Welding

Compared with shielded metal-arc welding as applied to low-carbon steel, the process as applied to copper and copper alloys uses larger root openings, wider groove angles, more tack welds, higher preheat and interpass temperatures, and higher currents. For list of covered electrodes, see Table 14.

Shielded metal-arc welding of copper and copper alloys is almost always restricted to flat-position welding; out-of-position welding by this process is usually limited to the joining of phosphor bronzes and copper nickels.

Shielded metal-arc welding is not recommended for most alloys (Table 1) because of the reduced mechanical properties and the possibility of unsoundness that can be expected.

Coppers. Problems of porosity and low weld strength due to oxygen content of the base metal and oxygen absorption during welding, are more severe in joining coppers by this process than by gas-shielded processes. Shielded metal-arc welding is not advised for joining commercial coppers (Table 1).

Brasses and Nickel Silvers. The low-zinc brasses, high-zinc brasses, tin brasses, special brasses and nickel silvers listed in Table 1 are not generally recommended for welding by the shielded metal-arc process. However, some brasses are occasionally welded by this process when requirements are not rigorous.

Phosphor bronze electrodes such as ECuSn-A and ECuSn-C have been used for welding the low-zinc brasses. The base metal is preheated and held at 400 to 500 F. Weld metal is applied in narrow and shallow stringer beads.

The high-zinc copper alloys can be welded with ECuAl-A2 (aluminum bronze) electrodes. Preheat and interpass temperatures are 500 to 700 F. The arc is held directly on the molten weld puddle rather than toward the base metal, and advanced slowly in order to minimize zinc volatilization.

Phosphor Bronzes. Shielded metal-arc welding is done to a limited extent on the phosphor bronzes listed in Table 1. Covered electrodes ECuSn-A and ECuSn-C are used interchangeably.

The phosphor bronzes flow sluggishly and must be preheated to 300 to 400 F, especially for thick sections. However, because of the hot shortness of these alloys, the interpass temperature must not be permitted to go above the preheat temperature. This is achieved by welding rapidly with light passes. In groove welding, the first two passes are made with a weaving technique. Width of the weave should not exceed two electrode diameters. The remaining passes are made without appreciable transverse weaving and with the use of narrow stringer beads. The development of a coarse dendritic structure of low strength and ductility is minimized by control of preheat and interpass temperature and the use of this method

of deposition. Hot peening after welding helps to break up coarse grain structure. For maximum ductility, the welded assembly should be postheated to 900 F and cooled rapidly.

Joint grooves should be wide (80° to 90°), to achieve proper "washing" of the groove walls.

Aluminum Bronzes. Shielded metal-arc welding is done readily on aluminum bronzes in both the wrought and cast forms. The aluminum oxides that form on the surface of these alloys are removed by the fluxing action of the electrode coatings.

Except for thin sections, a 70°-to-90° V-groove joint is used, usually with a backing strip of the same composition as the base metal. Deposition technique and bead thickness are not critical, because the weld metal has excellent hot strength and ductility.

Aluminum bronze ECuAl-A2 and ECuAl-B electrodes are used for welding the aluminum bronze alloys 613 and 614, which contain about 7% Al. Thick sections of these alloys may need preheating, usually to 400 F, and control of interpass temperature at 400 F. Depending on section thickness and over-all mass, however, preheat and interpass temperature may vary between about 150 and 800 F. Weldments of the 7% aluminum bronzes need not be heat treated after welding.

Aluminum bronzes having an aluminum content higher than 7% are usually welded with electrodes that contain more aluminum than do ECuAl-A2 and ECuAl-B. The higher-aluminum bronze electrodes are ECuAl-C, ECuAl-D and ECuAl-E, which are best known as surfacing electrodes (see AWS A5.13), and which have nominal aluminum contents of 12.5, 13.5 and 14.5%, respectively, and correspondingly increasing strength. In welding high-aluminum bronzes, thick sections may require preheating up to 1150 F, and fan cooling may be necessary to avoid cracking. Also, these alloys may require annealing at 1150 F, followed by fan cooling, for stress relief.

Silicon Bronzes. Shielded metal-arc welding of silicon bronzes is usually done with ECuAl-A2 aluminum bronze electrodes. Welding temperature is easily attained, since silicon bronzes have low thermal conductivity. However, because the alloys are hot short, the metal should not be preheated and interpass temperature should not exceed 200 F.

Groove dimensions are similar to those used for welding similar steel joints. Metal thicknesses up to 5/32 in. can be welded with square grooves; thicker sections, with a single-V or double-V groove of 60° included angle.

Properties of welds made in silicon bronzes by shielded metal-arc welding are usually substantially lower than those of welds made by the gas-shielded processes, and may not meet code or design requirements for strength. Peening will reduce residual stress and minimize distortion.

Copper Nickels. Shielded metal-arc welding is done on copper nickels in both the wrought and cast forms. Having thermal conductivity close to that of low-carbon steel, these alloys behave like steel in most respects and are as readily welded as steel by the shielded metal-arc process. The 70-30 copper nickel ECuNi electrodes (Table 14) are used in welding the copper nickel alloys 706 and 715, usually with reverse-polarity direct current.

The weld deposits ordinarily have a high center crown, and the slag is viscous when molten and adherent when cold. Therefore, special care is needed to ensure complete slag removal before complete solidification of the weld, to prevent slag entrapment when cleaning between passes.

These alloys can be shielded metal-arc welded in all positions with good results, although best results are obtained in flat-position welding. This process is preferred in some applications where access to the joint is limited, as in the butt welding of copper nickel pipe described in the example that follows.

Example 338. Shielded Metal-Arc Butt Welding of Copper Nickel Pipe

In an application similar to the gas metal-arc welding described in Example 337, various sizes of pipe made of alloy 715 (copper nickel, 30%) were butt welded by the shielded metal-arc process, because of limited access to the joint. The pipe ranged in outside diameter from 2½ to more than 6 in.

The butt joints most commonly welded were accessible from the outside only, and therefore had V-grooves and backing. For wall thicknesses of ¾ in. and less, a single-V joint was used with an 80° included angle, 1/16-in. root face, and minimum root openings of 3/16 in. for pipe of 3-in. OD or less, and ¼ in. minimum for larger diameters. For thicknesses over ¾ in., a single-U joint was used with the same root face and root openings. For either single-V or single-U joints, a maximum clearance of 0.015 in. was maintained between the backing ring and the inside diameter of the pipe. Tight fit of the backing in all joints was important, to prevent slag from entering between the base metal and backing.

Weld were made in all positions, using ECuNi electrodes with direct current, reverse polarity. Typical electrode diameters and welding currents were:

3/32-in.-diam electrode	50-100 amp
1/8-in. diam	70-130
5/32-in. diam	90-160

No preheat was used, and interpass temperature did not exceed 150 F. A stringer-bead technique was used for the root passes and, where necessary, for other passes. At no time did average bead width exceed four electrode diameters. All starts, stops and crevices were ground or burred to remove porosity or to prevent slag entrapment. Starts and stops were staggered both within and between weld layers.

Liquid-penerant and visual inspection were done on completion of each layer (root, intermediate, and finish). The completed welds were inspected radiographically.

Shielded metal-arc welding was also used for butt welding of pipe joints without a backing ring where the inside of the pipe was accessible for welding. Under such conditions, one or more passes were deposited in the root from the back side (inside) of the weld. The opposite side (outside) of the root was ground to sound metal before subsequent passes were deposited on the outside of the joint. From the standpoint of welder accessibility in this type of double-welded joint, the maximum distance, *L*, of any part of the weld groove from the open end of the pipe varied with the outside diameter of the pipe as follows:

OD, in.	*L* (max), in.	OD, in.	*L* (max), in.
2½	4	4	7
3	5	5	8
3½	6	6 up	10

Safety

During welding of copper alloys, the use of an effective ventilation system that protects operators and recovers dusts, fumes and mists is more critical than in welding most other metals, because most copper alloys contain at least small amounts of volatile toxic alloying elements.

Zinc fumes will produce an illness known as "zinc chills", but the effect is not cumulative. Small amounts of arsenic, antimony, lead or tellurium also may be hazardous.

Welding of beryllium-containing alloys is of special concern. Airborne particles of beryllium compounds are a health hazard if inhaled. Operations such as welding or grinding, which create a fine, inhalable dust or fume, should not be permitted to raise the beryllium concentration in the air above minimum-recommended limits. A system providing the required ventilation may be needed to avoid unsafe occupational exposures.

The ANSI standard Z49.1, "Safety in Welding and Cutting", should be followed strictly when welding copper and copper alloys. Recommendations on respiratory protection and on ventilation during welding are given in the AWS "Welding Handbook", 6th Ed., Section 1, p 9.24-9.31. Another source of useful information on safety is "Beryllium and Its Compounds" (revised 1964), Hygiene Guide Series, American Industrial Hygiene Assn.

Other Examples on Welding of Copper Alloys

Examples of arc welding of copper in other articles in this volume are listed in Table 17. In addition to examples of processes described in this article are examples of plasma-arc welding, electron beam welding, and percussion welding. The second half of the table refers to examples of welding copper or copper alloys to other metals.

Resistance welding of copper and copper alloys is dealt with in the article that begins on page 475; brazing, in the article beginning on page 685.

Table 17. Examples of Welding of Copper and Copper Alloys in Other Articles in This Volume

Welding of Copper

Example 144. Change from gas tungsten-arc to plasma-arc welding of BCuP-5-clad copper terminals on a computer memory grid

Example 478. Comparison of gas tungsten-arc welding, furnace brazing, and electron beam welding of restrained joints in alloy 175

Example 482. Multiple-tier electron beam welding of BCuP-5-clad copper terminals

Welding of Copper to Other Metals

Example 135. Change from shielded metal-arc to gas tungsten-arc welding of naval brass to low-carbon steel

Example 175. Percussion welding of tinned copper leads to copper alloy terminals

Example 177. Percussion butt welding of a 60Pt-40Rh wire to tinned copper wires

Example 180. Change from silver brazing to percussion welding of a silver – cadmium oxide contact to a copper backing strip

Example 497. Electron beam welding of a flanged copper (alloy 102) nozzle to a type 304 stainless steel tube

Arc Welding of Magnesium Alloys

*By the ASM Committee on Fabrication of Magnesium**

MOST MAGNESIUM ALLOYS can be welded by the gas tungsten-arc and gas metal-arc processes. These welding processes are described in the articles that begin on pages 113 and 78.

Weldability. All magnesium alloys in Table 1 are weldable, but they are not equivalent to each other in weldability. Table 1 rates their weldability on a scale of A (excellent) to D (limited). The rating is based largely on freedom from susceptibility to cracking, and to some extent on joint efficiency. Under the most favorable welding conditions, including favorable joint design, it is possible to obtain joint efficiencies of 60 to 100% for virtually all of the magnesium alloys. Alloys rated A in Table 1 are likely to have correspondingly high joint-efficiency ratings.

In the magnesium-aluminum-zinc alloys (AZ31B, AZ61A, AZ63A, AZ80A, AZ81A, AZ91C and AZ92A), aluminum content up to about 10% aids weldability by helping to refine the grain structure, while zinc content of more than 1% increases hot shortness, which may cause weld cracking. The alloys that have high zinc content (ZH62A and ZK51A) are highly susceptible to cracking, and have poorer weldability.

The thorium-containing alloys HK31A, HM21A and HM31A have excellent arc weldability and are rated B+ or A in Table 1.

Welds in magnesium alloys are characterized by a fine grain size, averaging less than 0.01 in. Magnesium alloys containing more than 1.5% aluminum are susceptible to stress corrosion, and residual stresses must be relieved.

Filler Metals

Compositions of the four most commonly used electrode wires for gas metal-arc welding, and filler metals (when used) for gas tungsten-arc welding, are given in Table 2. The choice of electrode wire or filler metal is governed by the composition of the base metal.

Electrode wires or filler metals having compositions conforming to ER AZ61A or ER AZ92A are considered satisfactory for welding wrought alloys AZ10A, AZ31B, AZ31C, AZ61A, AZ80A, ZE10A and ZK21A (to themselves or to each other). ER AZ61A is usually preferred because it is the less costly. The same electrode wires or filler metals are used for joining any one of the above alloys to elevated-temperature alloys HK31A, HM21A, and HM31A. However, when the elevated-temperature alloys are joined to each other, ER EZ33A is recommended.

The choice of electrode wire or filler metal for welding wrought alloys to cast alloys should follow the recommendations outlined above, except that ER AZ101A may be used instead of ER AZ61A or ER AZ92A.

When cast alloys are joined to cast alloys, ER AZ101A electrode wire or filler metal is usually recommended. However, for joining HK31A and HZ32A (to themselves or to each other), ER EZ33A is preferred; for joining HK31A and HZ32A to any of the other cast alloys, ER AZ101A is used.

Shielding Gases

Only the inert gases are used for shielding in arc welding of magnesium alloys. Argon is the most widely used. Helium and various mixtures of argon and helium have also proved satisfactory, but because of the higher cost per unit volume of helium, and because two to three times more helium than argon is required for the same degree of shielding, the use of pure helium has gradually decreased. In 11 of the 13 examples in this article, argon was the shielding gas (see Table 12).

Joint Design

Typical joint designs for gas-shielded arc welding of various thicknesses of magnesium alloy sheet and plate are presented in Table 3. As shown there, the metal-thickness ranges vary for gas tungsten-arc welding in accordance with the type of current used (alternating, straight-polarity direct, and reverse-polarity direct), and vary for gas metal-arc welding in accordance with the mode of metal transfer.

Table 1. Relative Arc Weldability of Magnesium Alloys
(A = excellent; B = good; C = fair; D = limited weldability)

Alloy	Rating	Alloy	Rating
Casting Alloys		ZH62A	C−
AM100A	B+	ZK51A	D
AZ63A	C	ZK61A	D
AZ81A	B+	**Wrought Alloys**	
AZ91C	B+		
AZ92A	B	AZ10A	A
EK30A	B	AZ31B,C	A
EK41A	B	AZ61A	B
EZ33A	A	AZ80A	B
HK31A	B+	HK31A	A
HZ32A	C	HM21A	A
K1A	A	HM31A	A
QE22A	B	ZE10A	A
ZE41A	C	ZK21A	B

Edges are prepared by milling, sawing, shearing, arc cutting, chipping, planing, routing, sanding or filing.

Sheet up to about 0.080 in. thick is generally single sheared; double shearing is preferred for sheet thicker than 0.080 in.

Double-bevel edges are preferred over single-bevel edges because less distortion occurs in welding.

Fit-up. Components of weldments should fit closely at abutting edges, preferably with no root opening, although a root opening up to 1/16 in. is usually permissible. If tack welds are used, the first tack should be a short distance from the end of a seam.

Best practice in tack welding is to use 1/8-in. tacks spaced 1 to 2 in. on centers for sheet up to 0.065 in. thick, and 1/4-in. tacks spaced 4 to 5 in. on centers for sheet or plate from 0.065 through 1/4 in. thick.

Welding fixtures must be rigid enough to resist movement of the workpieces during welding. Hold-down bars must exert enough pressure to keep the edges from overlapping or rising away from the backing bar or plate. Backing plates are made of steel, magnesium, aluminum or copper, and are cut with a small groove that is positioned directly under the seam. They prevent excessive metal drop-through and minimize distortion. Depth of the grooves in backing plates depends on base-metal thickness, on the welding process used, and on whether or not the joint has a root opening. Typical groove depths are given in Table 4.

Surface Preparation

Magnesium alloys are usually supplied with either an oil coating, an acid pickled surface, or a chromate coated surface. Surfaces and edges must be cleaned just before welding to remove oxides and dirt picked up during forming, assembly and fixturing. It is also important that the electrode wire or filler metal be mechanically or chemically cleaned. A partly used spool of electrode wire or filler metal should

YOUNG, Materials Evaluation, Thomson Laboratory, Aircraft Engine Group, General Electric Co.

Several of the examples presented in this article were contributed by members of other Metals Handbook welding committees.

be stored in a manner that will protect it from dirt between welding jobs.

Mechanical cleaning with aluminum or stainless steel wool, aluminum oxide abrasive cloth, or power wire brushes (stainless steel bristles) is preferred for most production jobs. In shops where chemical finishing equipment is available, a cleaning bath of 24 oz chromic acid, 5⅓ oz ferric nitrate, 1/16 oz potassium fluoride, and water to make 1 gal can be used. Parts are dipped in this bath, which is maintained at 70 to 90 F, for about 3 min, then are rinsed thoroughly in hot water and dried in air. The tank should be made of ceramic or stainless steel, or lined with lead, synthetic rubber, or a vinyl-base material.

Preheating

The need for preheating is determined largely by section thickness and amount of restraint. Thick sections, particularly if the magnitude of joint restraint is small, seldom need preheating. Thin sections and highly restrained joints often require preheating to prevent weld cracking, particularly in the high-zinc alloys.

Maximum preheat temperatures for all of the common cast magnesium alloys are given in Table 5. In practice, if preheating is used, the temperature is usually less than the maximum shown in Table 5. (As Table 12 shows, preheating was used in only four of the 13 examples in this article, and the preheat temperatures were substantially lower than the maximum temperatures given in Table 5.)

Gas Metal-Arc Welding

Power supplies used for welding magnesium alloys furnish reverse-polarity direct current. Constant-voltage machines must be used for short-circuiting welding and are generally preferred for spray-arc welding. Constant-current (drooping volt-ampere output) machines can be used for spray-arc welding and are sometimes advantageous for welding that is performed at a current level near the minimum for spray-arc transfer, because weld spatter is less. Special constant-voltage machines designed to pulse the current output must be used in pulsed-arc welding. For detailed information on power supplies and modes of metal transfer, see the article on Gas Metal-Arc Welding, page 78.

Electrode holders, wire feeders, and related equipment used for gas metal-arc welding of magnesium alloys are generally the same as those used for welding other metals. Detailed discussions and illustrations will be found in the above-cited article.

Modes of Metal Transfer. Three modes of metal transfer are suitable for welding magnesium alloys: short-circuiting, pulsed-arc, and spray transfer. Pulsed-arc transfer can be achieved only with a power supply designed to produce a pulsing secondary current. Without the pulsing feature, the type of transfer that would be obtained in the specific operating range of current, wire feed, and wire size for this process would result in globular transfer, which is not suitable for welding magnesium alloys.

Each of the three modes of transfer is best suited to a specific (sometimes overlapping) range of base-metal thickness and welding current, as shown in Table 6. Curves that show the relations among current, electrode-wire size, and wire-feed rate for each mode are presented in Fig. 1.

It is important to select the mode of transfer that is best suited to the metal thickness. In the example that follows, welding was first done with

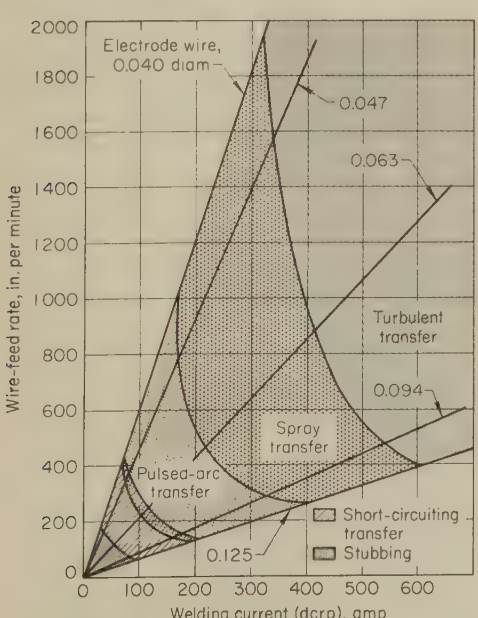

Fig. 1. Effect of wire-feed rate and welding current on mode of metal transfer for various sizes of electrode wire in argon-shielded gas metal-arc welding of magnesium alloys

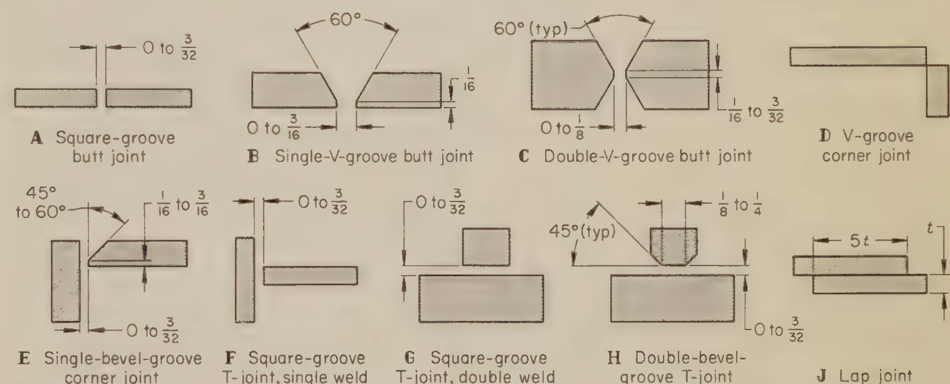
J(q)	0.040(h)	0.040(h)	0.025(h)	0.040 to 5/32	0.090 to ¼	5/32(h)



A Square-groove butt joint; B Single-V-groove butt joint; C Double-V-groove butt joint; D V-groove corner joint; E Single-bevel-groove corner joint; F Square-groove T-joint, single weld; G Square-groove T-joint, double weld; H Double-bevel-groove T-joint; J Lap joint

(a) Suggested minimum and maximum thickness limits. (b) Using 300-amp ac or dcsp, or 125-amp dcrp. (c) Using 400-amp dcrp. (d) Single-pass complete-penetration weld. Suitable for thin material. (e) Complete-penetration weld. Suitable for thick material. On material thicker than suggested maximum, use double-V-groove butt joint to minimize distortion. (f) Not recommended because spray-arc welding is more practical or economical, or both. (g) Complete-penetration weld. Used on thick material. Minimizes distortion by equalizing shrinkage stress on both sides of joint. (h) No maximum. Thickest material in commercial use could be welded in this type of joint. (j) Single-pass complete-penetration weld. For material thicker than suggested maximum, use single-bevel-groove corner joint because it requires less welding, especially if a square corner is required. (k) Single-pass or multiple-pass complete-penetration weld. Used on thick material to minimize welding. Produces square joint corners. (m) Single-weld T-joint. Thickness limits are based on 40% joint penetration.

(n) Double-weld T-joint. Suggested thickness limits based on 100% joint penetration. (p) Double-weld T-joint. Used on thick material requiring 100% joint penetration. (q) Single or double-weld joint. Strength dependent on size of fillet. Maximum strength in tension on double-weld joints is obtained when lap equals five times the thickness of the thinner member.

globular transfer, but was changed to spray transfer, with improved quality and an accompanying decrease in cost. In this application, pulsed-arc transfer could probably have been used successfully if the appropriate type of power supply had been available.

Example 339. Short-Circuiting vs Globular Transfer in Gas Metal-Arc Welding of Sheet (Table 7)

A fabricator had been using automatic gas metal-arc welding with the globular mode of transfer (not generally recommended) for production welding of 58-in.-long butt joints in 0.110-in.-thick ZE10A-H24 sheet. The tightly fitted square-groove joints were single-pass seam welded in a mechanized setup that included hold-downs and a backing bar. Welding was done at the maximum practical speed that could be attained within the narrow operating range of current used for this procedure. When welding speed was increased, without increasing welding current, cold laps or skips occurred; when welding current was increased, erratic arc action resulted. Much higher currents, such as those used for spray transfer, were not feasible because the sheet was too thin for the energy input.

By changing to short-circuiting transfer, good results were consistently obtained.

Table 4. Typical Depth of Grooves in Backing Bars or Plates Used in Arc Welding of Magnesium Alloys

Base-metal thickness, in.	Depth of groove, in.: Gas tungsten-arc welding	Gas metal-arc welding: No root opening (a)	Gas metal-arc welding: Root opening
0.025	0.015	0.020	0.020
0.040	0.020	0.030	0.020
0.063	0.025	0.040	0.030
0.090	0.030	0.060	0.040
0.125	0.030	0.070	0.040
0.160	0.040	0.070	0.050
0.190	0.040	0.070	0.050
0.250	0.050	0.070	0.060
0.375	0.060	0.080	0.060

(a) With no root opening, grooves in backing bars or plates are deeper to permit better balance between top and bottom weld reinforcement. Use of a root opening permits balancing reinforcement with a shallower groove depth.

Table 5. Preheat Temperatures and Postweld Heat Treatments for Magnesium Alloy Castings

Alloy	Temper of alloy(a): Before welding	Temper of alloy(a): After treatment	Maximum preheat temperature(b), F	Postweld heat treatment(c)
AZ63A	T4	T4	720	½ hr at 730 F
	T4 or T6	T6	720	½ hr at 730 F + 5 hr at 425 F
	T5	T5	500(d)	5 hr at 425 F
AZ81A	T4	T4	750	½ hr at 780 F
AZ91C	T4	T4	750	½ hr at 780 F
	T4 or T6	T6	750	½ hr at 780 F + 4 hr at 420 F(e)
AZ92A	T4	T4	750	½ hr at 770 F
	T4 or T6	T6	750	½ hr at 770 F + 4 hr at 500 F
AM100A	T6	T6	750	½ hr at 780 F + 5 hr at 425 F
EK30A	T6	T6	500(d)	16 hr at 400 F
EK41A	T4 or T6	T6	500(d)	16 hr at 400 F
	T5	T5	500(d)	16 hr at 400 F
EZ33A	F or T5	T5	500(d)	2 hr at 650 F(f) + 5 hr at 420 F
HK31A	T4 or T6	T6	500	1 hr at 600 F(f) + 16 hr at 400 F
HZ32A	F or T5	T5	500	16 hr at 600 F
K1A	F	F	None	None
QE22A	T4 or T6	T6	500	8 hr at 985 F(g) + 8 hr at 400 F
ZE41A	F or T5	T5	600	2 hr at 625 F + 16 hr at 350 F(f)
ZH62A	F or T5	T5	600	2 hr at 625 F + 16 hr at 350 F
ZK51A	F or T5	T5	600	2 hr at 625 F + 16 hr at 350 F(f)
ZK61A	F or T5	T5	600	48 hr at 300 F
	T4 or T6	T6	600	2 to 5 hr at 930 F + 48 hr at 265 F

(a) T4 = solution heat treated; T6 = solution heat treated and artificially aged; T5 = artificially aged; F = as cast. "After treatment" means after postweld heat treatment. (b) Heavy and unrestrained sections usually need no preheat; thin and restrained sections may need preheating up to maximum temperatures shown, to avoid weld cracking. A sulfur dioxide or carbon dioxide atmosphere is recommended when temperature exceeds 700 F. (c) Temperatures shown are maximum allowable; furnace controls should be set so temperature does not exceed indicated maximum. A sulfur dioxide or carbon dioxide atmosphere is recommended when temperature exceeds 700 F. (d) For 1½ hr max. (e) 16 hr at 335 F may be used instead of 4 hr at 420 F. (f) This phase of heat treatment is optional and serves to induce greater stress relief. (g) Quench in water at 140 to 220 F before second heat treatment.

Table 6. Typical Operating Conditions for Gas Metal-Arc Butt Welding of Magnesium Alloys(a)

(a) Welding speed, 24 to 36 in. per minute. (b) Zero root opening. (c) Root opening, 0.090 in. (d) Pulse voltage of 55 volts, except for metal 0.190 in. thick, which uses a pulse voltage of 52 volts. (e) ¹⁄₁₆-in. root face and zero root opening. (f) Settings also apply to fillet welds in the same thickness of metal. (g) ⅛-in. root face and zero root opening.

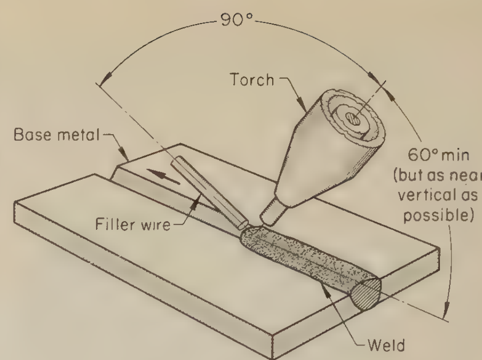

Fig. 2. Angular relations among torch, filler wire, and joint, in gas tungsten-arc welding

This procedure, which is generally recommended for thicknesses up to approximately ³⁄₁₆ in., also resulted in lower welding costs through increased welding speed and lower electrode cost.

A comparison of the welding conditions and deposition costs for the two procedures is given in Table 7. Although higher current was used with short-circuiting transfer than with globular transfer, the current density was much lower because of the increased electrode size.

Welding positions are restricted, by the high deposition rate and fluidity of the weld metal, to flat, horizontal and vertical-up.

Typical operating conditions for gas metal-arc butt welding of magnesium alloys in the thickness range from 0.025 to 1 in. are presented in Table 6. These operating conditions are intended as a guide and should be altered to the extent required by experience with specific applications.

Gas Tungsten-Arc Welding

Gas tungsten-arc welding is used more extensively than gas metal-arc welding for joining magnesium alloys.

Alternating-current machines with a high-frequency current superimposed on the normal welding current for arc stabilization, and direct-current machines with continuous amperage control are used. For thin sheets, both alternating current and reverse-polarity direct current are used. On material over ³⁄₁₆ in. thick, alternating current is preferred, because it provides deeper penetration. Straight-polarity direct current is seldom used on magnesium alloys, because the arc lacks cathodic cleaning action.

Alternating-current machines should be equipped with a primary contactor, actuated by a switch on the torch or by a foot switch, for starting and stopping the arc. Otherwise, the arcing that occurs while the electrode approaches or draws away from the workpiece may result in burned spots on the work.

Pure tungsten, zirconiated, and thoriated electrodes, from 0.010 to 0.250 in. in diameter, are used for gas tungsten-arc welding of magnesium alloys.

Additional information on power supplies, electrodes and related items for the gas tungsten-arc process is given in the article on Gas Tungsten-Arc Welding, pages 113 to 137.

Manual Welding. Data on current settings, electrode diameter, shielding-gas flow, filler-metal diameter, and fill-

er-metal consumption for manual gas tungsten-arc welding of butt joints in magnesium alloys 0.040 to 0.500 in. thick are given in Table 8.

For best results, the electrode should be held close to the work, to produce an arc about 1/32 in. long. The preferred angles of torch, joint and filler metal are given in Fig. 2.

Welding should be done at a uniform speed in a straight line. A weaving or rotary motion should be used only for fillet welds or large corner joints. Forehand welding is preferred. Best practice is to minimize the number of stops. If stops are required, the weld should be restarted on weld metal, about ½ in. from the end of the previous weld.

To minimize the risk of weld cracking, either of the methods shown in Fig. 3 should be used: method A, in which starting and runoff plates (or tabs) are used to start and end the weld; or method B, in which the weld is made in two increments, by passes that begin in the middle and progress toward opposite ends. Also, the base metal (and fixture, if used) should be preheated to at least 200 to 300 F.

If the thickness of the two components to be welded differs by ¼ in. or more, the thicker section should be preheated to approximately 300 F.

Short-Run Production. For short production runs for which the cost of elaborate fixtures cannot be justified, tooling costs can be minimized by fabricating the components so that they can be tack welded into position. The example that follows describes the fabrication of an assembly consisting of 13 components, using tack welds and manual gas tungsten-arc welding.

Example 340. Use of Tack Welding Instead of Fixturing for Short-Run Production (Fig. 4)

To minimize tooling costs on short production runs of electronic deck assemblies, which were essentially two rectangular boxes 2 in. high by 2 in. wide by 4 in. long, as shown in Fig. 4, tack welds were used to position some of the component pieces.

Formed sheet sections of 0.050-in.-thick AZ31B-H24 were tack welded into position by gas tungsten-arc welding, using 1/16-in. ER AZ61A filler wire. The tack welds were ⅛ in. long and were spaced on 2-in. centers (starting at each corner). A tool plate and toggle clamps held the pieces for tack welding. Tack welds were not used to hold angle pieces.

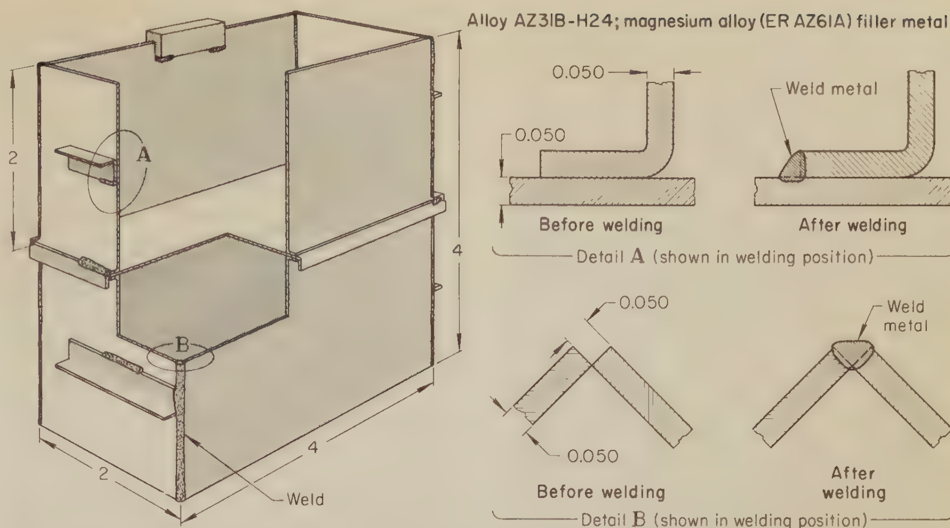
Welding of the assembled and tack welded components was completed by manual gas tungsten-arc welding with 1/16-in.-diam ER AZ61A filler wire. The corner joints were welded with continuous beads about 2 in. long, and the flanged bottom of the top part of the assembly was joined to the sides with 1-in.-long fillet welds. Extruded angle sections were fillet welded to the ends of the boxes with welds about 1 in. long (see detail A in Fig. 4).

The assembly was repositioned manually so that all welds could be made in either the flat or the horizontal position.

A standard alternating-current power supply with a high-frequency arc stabilizer was used.

Helium was selected as the shielding gas because a hotter and more stable arc was produced than would have been possible with argon shielding gas.

Preheating was not used, but after welding, the assemblies were stress relieved at 350 F for 3½ hr to prevent stress-corrosion cracking. Welds were inspected visually.



Conditions for Manual Gas Tungsten-Arc Welding

0.250	B	2	5/32	175	20	⅛	0.026
0.375	B	3	5/32	175	20	5/32	0.057
0.375	C	2	3/16	200	20	⅛	0.024
0.500	C	2	3/16	250	20	⅛	0.047

(a) A = square-groove butt joint, zero root opening; B = 60°-bevel, single-V-groove butt joint, 1/16-in. root face, zero root opening; C = 60°-bevel, double-V-groove butt joint, 3/32-in. root face, zero root opening. (b) Thorium-containing alloys will require about 20% higher current. With helium shielding, required welding current will be reduced by about 20 to 30 amp.

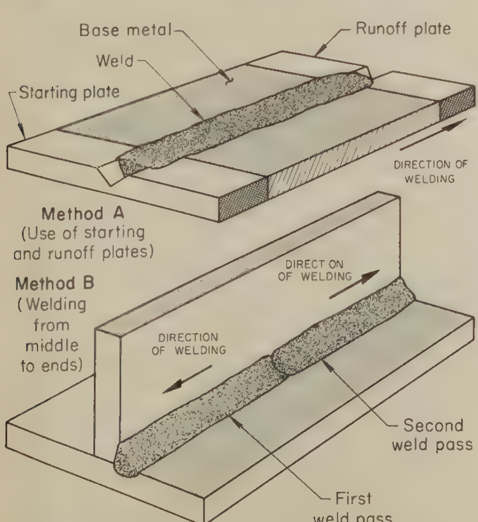

Fig. 3. Two methods of welding magnesium alloys that help to prevent weld cracking

In the three examples that follow, manual welding was used.

Examples 341 to 343. Three Types of Joints Welded Manually (Table 9)

Example 341 — T-Joint. The welding of a single ⅛-in. fillet in an 8-in.-long T-joint between sheets of alloy AZ31B ¹⁄₁₆ and ⅛ in. thick (see Table 9) was used as a quick shop test for welder qualification. The welder adjusted the machine settings, gas flow and welding speed suitable for producing a sound weld with proper contour and adequate penetration, using manual gas tungsten-arc welding. After welding, the joint was broken by striking a blow against the unwelded side of the vertical stem so as to open and expose the root of the weld. The fracture was then examined for depth of penetration, porosity, lack of fusion, and other defects. Welding conditions and a view of the joint are given in Table 9.

Example 342 — Single-V-Groove Butt and Corner Joints. Structural frames were fabricated by welding the mitered ends of 1-by-1-by-³⁄₁₆-in. angles extruded from alloy AZ31B. One of the four right-angle corners of one of these structural frames is shown in Table 9. Manual gas tungsten-arc welding was used because production quantity was less than 50 pieces per month.

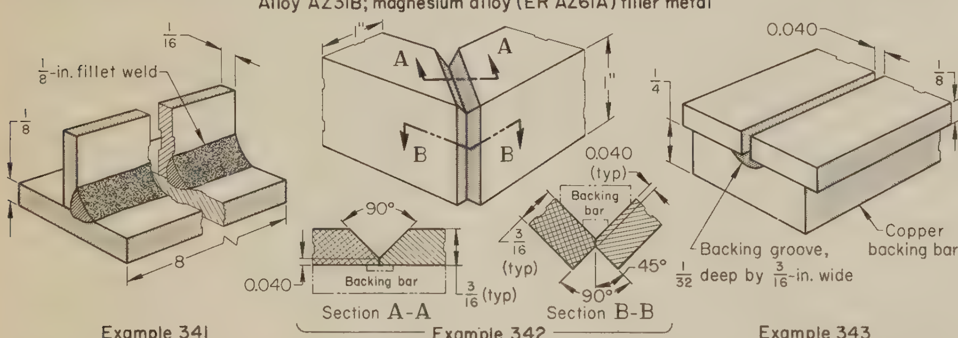
Procedure consisted of mitering, edge beveling, cleaning, assembling on a fixture, and welding. Horizontal joint edges were beveled 45° with a 0.040-in.-deep root face; vertical joint edges were beveled to form a similar root face for a 90° corner joint. After acid pickling and rinsing, the angles were assembled on a clamping fixture provided with flat backing bars for the horizontal joints and with corner backing bars for the vertical joints. The backing bars for both the horizontal and the vertical joints were provided with backing grooves that were ⅛ in. wide by 0.020 in. deep. The outside corner joint was single-pass welded, vertical-up; the grooved butt joint was single-pass welded in the flat position. No preheat was used, but the frames were postweld stress relieved at 350 F for 1½ hr. Welding conditions are given in Table 9.

Example 343 — Square-groove-welded butt joints (with 0.040-in. root opening) in ⅛-in.-thick AZ31B-H24 sheet were originally to be gas metal-arc welded, but contact-tube arcing occurred and contamination of the filler metal resulted. Rather than delay production while the arcing problem was being eliminated, it was decided to use manual gas tungsten-arc welding instead of gas metal-arc. Good mechanical properties were obtained in single-pass welds, using argon shielding on the torch side and a grooved copper backing bar, but no gas backing, on the underside. Joint alignment was maintained with bolted hold-down bars. Other welding details are given in Table 9.

Table 9. Manual Gas Tungsten-Arc Welding of Alloy AZ31B (Examples 341 to 343) (a)

Item	Example 341	Example 342	Example 343
Joint type	T	Corner; butt	Butt
Weld type	Single fillet	Single-V groove	Square groove
Welding position	Horizontal	Vertical-up; flat	Flat
Shielding gas and flow rate	Argon; 18 cfh	Argon; 18 cfh	Argon; 18 cfh
Electrode (EWP) diameter	³⁄₃₂ in.	⅛ in.	⅛ in.
Filler-metal (ER AZ61A) diameter	¹⁄₁₆ in.	³⁄₃₂ in.	¹⁄₁₆ in.
Current (ac, HF-stabilized)	110 amp	125 amp	135 amp
Welding speed	10 ipm	5 pcs per hr (b)	10 ipm
Postweld heat treatment	500 F, 15 min	350 F, 1½ hr	350 F, 1½ hr

Alloy AZ31B; magnesium alloy (ER AZ61A) filler metal



(a) A 300-amp ac/dc power supply with continuous high frequency was used for all three applications, with a light-duty water-cooled welding torch. All workpieces were preweld cleaned by chromic-sulfuric pickling. No preheat was used. (b) Includes fixturing, welding and unloading.

Table 10. Operating Conditions for Automatic Gas Tungsten-Arc Welding of Butt Joints in Two Magnesium Alloys (a)

Type of current	Current, amp	Diameter of tungsten electrode, in.	Arc length, in.	ER AZ61A or ER AZ92A filler metal, 0.063-in. diameter — Feed rate, ipm	Consumption, lb/ft of weld	Travel speed, ipm

ZE10A, 0.250 In. Thick						
Alternating, balanced wave	460	0.250	0.010	180	0.020	22

(a) With helium shielding for AZ31B, and argon for ZE10A; flow rate, 20 cfh. (b) Maximum speed limitation because of undercutting or arc instability. (c) Diameter of filler metal, 0.094 in.

Automatic welding of magnesium alloys by the gas tungsten-arc process is similar to manual welding, except that higher currents and welding speeds are used. The data in Table 10 can be used as a guide to determine settings for automatic welding. Alternating current is best, although reverse-polarity direct current can be used. A balanced-wave alternating-current machine, or a conventional alternating-current machine equipped with a battery bias for wave balancing, should be used.

Constant alignment of electrode and filler metal is important in automatic welding. Filler metal is fed into the arc at a low angle to the work, so that the filler rod touches the weld surface just ahead of the electrode. The arc length shown in Table 10 should be preset and maintained.

Travel speeds up to 95 in. per minute can be used on thin sheet, but 24 to 36 in. per minute is more common.

Automatic welding is not necessarily restricted to high-production applications; sometimes the high degree of control that can be attained with automatic welding is required regardless of quantity. A low-production application is described in the next example.

Example 344. Extrusions Joined to Sheet by Automatic Welding (Fig. 5)

Airtight doors for an aerospace application were made by welding panels of alloy AZ31B-H24 sheet to frames extruded from alloy AZ31B. The frames, which acted as stiffeners, also contained a groove for an air seal. Cross sections of similar offset-butt joints in two designs of door assemblies are shown as joints A and B in Fig. 5. The offset lip of the extruded frames provided a single-bevel-groove butt joint and supplied backing for the weld; the lap joint on the underside was not welded.

Although production quantities were low, automatic gas tungsten-arc welding was used, because weld quality was good and the equipment was available. Automatic travel was obtained by mounting the welding equipment on the motorized carriage of a cutting machine. Differences in welding conditions for the two joints (see table with Fig. 5) resulted from operator choice or judgment. Both procedures produced satisfactory welds, but the difference in welding speeds would have been significant had production quantities been large.

Repair Welding of Castings

A significant portion of the total amount of welding that is done on magnesium alloy castings is for repair.

The type, size and location of defects in castings vary so much that each repair job presents its own welding problems; procedures cannot be standardized. However, most repairs are subject to the general procedures that follow:

1. The casting must be stripped of paint, and the effects of chrome pickling must be removed at broken edges and around cracks, with steel wool or with a power wire brush having stainless steel bristles.
2. The casting should be clamped in place and the surface adjoining the fracture should be beveled for the weld (see illustrations with Table 3).
3. Preheating, if necessary, should be done at the temperatures recom-

mended in Table 5. Either local heating with a torch or furnace heating can be used. The use of a protective atmosphere during furnace heating will reduce the possibility of oxidation at temperatures above 700 F.

4 Welding should be done immediately after preheating. Reheating may be necessary if the temperature of the casting drops significantly below the preheat temperature.

5 Medium-size weld beads should be used.

6 Welding should progress from the center of the break to the outside edges. The arc should not be allowed to dwell too long in any one area, because weld cracking may result.

7 A foot control should be used to fade out the arc gradually so as to minimize thermal shock from arc stops. Thermal shock may cause cracking.

Examples of Repair Welding. The seven examples that follow describe procedures that were used in successful repair welding of specific castings.

Example 345. Repair of Sand Holes in a Wheel-Rim Casting (Fig. 6)

After machining, aircraft wheel-rim castings of AZ91C-T4 were occasionally found to have small sand holes (Fig. 6). Defects of a size that could be removed by cutting a groove about ⅛ in. deep and ½ in. wide were repaired by welding, following the procedure described below.

The defective area was cleaned out by cutting a smoothly blended groove (see "Before welding" in Fig. 6), using a burring tool. After complete removal of defective material was verified by dye-penetrant inspection, the groove and surrounding area were wire brushed to prepare for gas tungsten-arc welding.

The relatively thick section of the casting in the repair area and the wide groove for the deposit ensured that the weld would be under low restraint; therefore, preheating was not necessary. Ordinarily, a standard filler metal, such as ER AZ92A or ER AZ101A, would prove satisfactory for welding the AZ91C base metal, but in this application, a filler metal of the same composition as the base metal was specified.

The weld was made by striking the arc at the bottom of the groove and proceeding in a circular direction along the groove wall to fill the groove, as shown in the "After welding" view in Fig. 6. Welding conditions are given in the table with Fig. 6.

After welding, the weld reinforcement was ground to ⅓₂ in. above the base-metal surface and surface weld quality was verified by dye-penetrant inspection. After passing inspection, the casting was heat treated to the T6 condition. The casting was accepted after radiographic inspection indicated satisfactory internal weld quality.

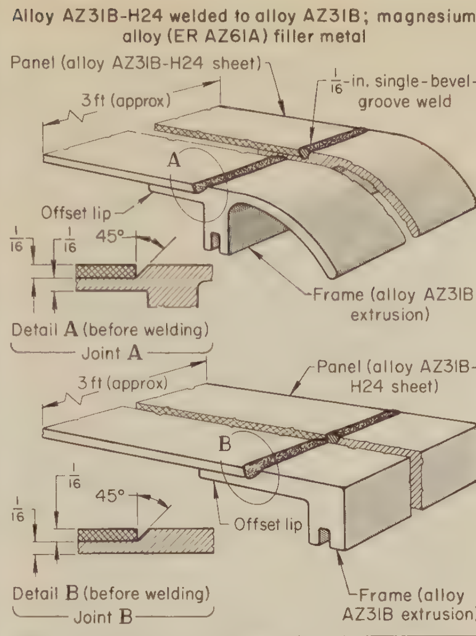
Example 346. Repair of a Defect in a Partly Machined Casting (Fig. 7)

Small defects in cast AZ91C-T6 alloy oil sumps for aircraft engines were caused by core shifts or other errors in the foundry. Sometimes, such defects were not detected until after considerable machining had been done on the part. Local surfacing by the gas tungsten-arc method was accepted as a means of salvaging such parts.

A typical casting error that qualified as repairable was an undersize wall thickness, shown in Fig. 7. The defect, which was discovered after most of the machining had been completed, covered an area less than 2 sq in. and was in a low-stress region.

The casting had been given a dichromate treatment to remove surface oxide film, and therefore thorough preweld cleaning was required. The casting was vapor degreased with trichlorethylene, and the surface of the area to be welded was further cleaned by brushing with a stainless steel wire brush. Preheating was not needed.

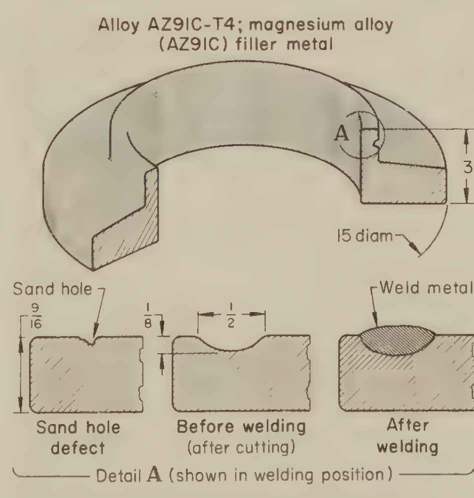
The casting was positioned on a welding table in the flat position and welded in two



Automatic Gas Tungsten-Arc Welding

Joint type	Offset butt
Weld type	Single-bevel groove
Preweld cleaning	Chromic-sulfuric pickle
Welding position	Flat
Preheat	None
Shielding gas	Argon, at 18 cfh, for joint A; argon, at 16 cfh, for joint B
Electrode	⅛-in.-diam EWP
Filler metal	1⁄16-in.-diam ER AZ61A
Torch	Water cooled
Power supply	300 amp ac (HF-stabilized)
Current (ac)	175 amp for joint A, 135 amp for joint B
Wire-feed rate	65 ipm
Travel speed	20 ipm for joint A, 15 ipm for joint B
Postweld heat treatment	350 F for 1½ hr

Fig. 5. Two similar joints in different door assemblies that were welded under slightly different conditions (Example 344)



Manual Gas Tungsten-Arc Welding

Weld type	Surfacing, for repair
Welding position	Flat
Preheat	None
Shielding gas	Helium, at 20 cfh
Electrode	3⁄32-in.-diam EWP
Filler metal	⅛-in.-diam AZ91C
Torch	300 amp, water cooled
Power supply	300-amp transformer, with high-frequency generator
Current	60 amp, ac
Postweld heat treatment	780 F for ½ hr plus 420 F for 4 hr

Fig. 6. Aircraft wheel-rim casting that was salvaged by repair welding of sand holes (Example 345)

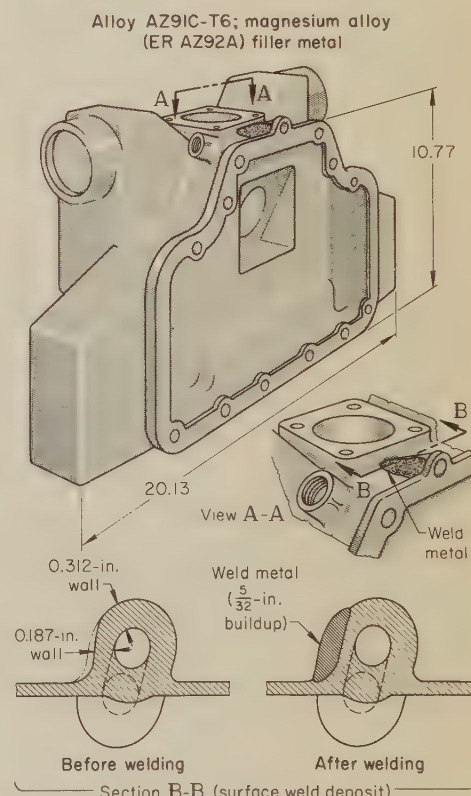
passes under the conditions listed in the table with Fig. 7. Because too much heat input could cause burn-through or weld cracking, and too little could result in porosity, good welding skill was required. The use of a foot-operated control was an aid in regulating welding current for heat input and for obtaining a smoothly blended weld contour. The weld was brushed with a stainless steel wire brush after each pass.

The repaired casting was stress-relieved for 1 hr at 500 F in a furnace, to avoid possible stress corrosion. Finishing of the completed weld was not required, as there was no reason to conceal the repair. A spot radiographic inspection was made to check for porosity, tungsten inclusions, and general weld soundness.

Example 347. Repair of a Crack in a Jet-Engine Casting (Fig. 8)

During an aircraft jet-engine overhaul, fluorescent-penetrant inspection revealed a 2½-in.-long crack near a rib in the cast AZ92A-T6 compressor housing shown in Fig. 8. The thickness of the section containing the crack ranged from 3⁄16 to 5⁄16 in. Repair welding was permissible.

The part was vapor degreased to remove surface grease and dirt and soaked in a commercial, alkaline paint remover. The crack was then marked with a felt-tip marker, and the part was stress relieved at 400 F for 2 hr.



Manual Gas Tungsten-Arc Welding

Weld type	Surfacing, for repair
Welding position	Flat
Number of passes	Two
Preheat	None
Shielding gas	Argon, at 13 to 15 cfh
Electrode	3⁄32-in.-diam EWP
Filler metal	3⁄32-in.-diam ER AZ92A
Torch	300 amp, water cooled(a)
Power supply	400-amp transformer, with high-frequency starting
Current	10 to 85 amp, ac(b)
Arc length	1⁄16 to ⅛ in.
Postweld stress relief	500 F for 1 hr (furnace)

(a) Ceramic nozzle, ½ in. (b) Current was regulated by foot switch.

Fig. 7. Oil-sump casting for an aircraft engine that was repair welded to increase wall thickness (Example 346)

The crack was removed by slotting the flange through to the periphery (see Fig. 8). Each side of the slot was beveled to approximately 30° from vertical to form a 60° double-V groove. The area to be welded was cleaned with a power wire brush with stainless steel bristles.

Welding was done by the manual gas tungsten-arc process, without preheating, under the conditions listed with Fig. 8.

The welding technique consisted in maintaining a low-amperage arc (less than 70 amp) directed onto the base metal while filler metal was deposited on the sides of the groove, working from the innermost point outward. After a weld puddle formed, the arc was weaved slightly while depositing a bead on the sides of the groove. During welding, heat input was adjusted by a foot-operated current-control rheostat, to maintain a uniform weld puddle.

After welding was completed on one side of the slot, the casting was turned over. Excess drop-through and areas of incomplete penetration were removed by grinding. The underside was then welded by the same technique used for the first side.

After welding, the casting was stress relieved at 400 F for 2 hr, and inspected by the fluorescent-penetrant method.

Example 348. Correction of a Machining Error (Fig. 9)

After machining an AZ92A-T6 alloy aircraft-engine oil sump, it was found that six stud holes had been spotfaced 0.093 in. deeper than specified, as shown in Fig. 9. The affected areas were small and well spaced. The casting was subject to low stress in service, and although the defective areas were located on a bolting flange that was subject to stresses from bolting, there was no other loading of consequence on the affected areas. Therefore, the part was judged repairable by welding.

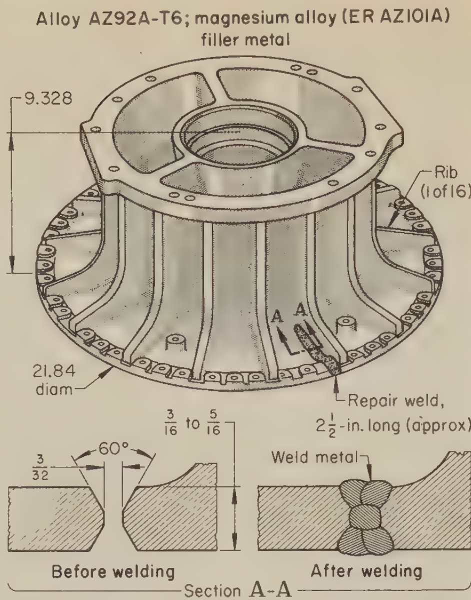
As a precaution, to minimize any possibility of cracking, the casting was preheated and heat input during welding was reduced. The preheating was done in a furnace at 450 to 500 F for 1 hr, after which the entire casting was kept wrapped in an asbestos blanket, except for the one boss area at a time that was exposed for welding. After completing each weld, the workpiece temperature was checked with a temperature-indicating crayon, and if temperature had dropped below 400 F, the piece was reheated before welding was resumed.

To reduce heat input, the torch was fitted with a 1/16-in.-diam tungsten electrode and a 3/8-in.-diam ceramic cup which delivered argon gas at 15 cu ft per hour. Initial current setting was 65 amp, which, by means of a foot-operated control, was varied from 10 to 65 amp, as required. Figure 9 shows the weld deposit, with allowance for machining. Details of other welding conditions are given in the table with Fig. 9. All other operations, including preweld cleaning, and inspection, were the same as those described in Example 346.

Examples 349 to 351. Gas Tungsten-Arc Repair Welding of Sand Castings (Fig. 10)

Figure 10 shows three sand castings that represent typical applications of manual gas tungsten-arc welding for the correction of surface flaws that occur in machining, of defects resulting from the casting process, and of deficiencies in design. As shown in the table that accompanies Fig. 10, welding was done with high-frequency-stabilized alternating current.

The castings were preheated and maintained at temperature during welding, to avoid weld cracking. The postweld heat treatments shown in the table are a compromise between stress relieving and an aging treatment, to avoid distortion. However, when repair welded areas were large enough so that the heat of welding caused a significant reduction in mechanical properties of the casting, welding was followed by a full heat treatment. For all three of the castings shown in Fig. 10, radiographic inspection was used in establishing the



Manual Gas Tungsten-Arc Welding

Joint type	Butt

Manual Gas Tungsten-Arc Welding

Weld type	Surfacing, for repair
Welding position	Flat
Number of passes	Two
Preheat in furnace	450 to 500 F for 1 hr(a)
Shielding gas	Argon, at 13 to 15 cfh
Electrode	1/16-in.-diam EWP
Filler metal	3/32-in.-diam ER AZ92A
Torch	300-amp, water cooled(b)
Power supply	400-amp transformer, with high-frequency starting
Current	10 to 65 amp, ac
Postweld stress relief	500 F for 1 hr (furnace)

(a) Casting was wrapped in asbestos blanket during welding. (b) Ceramic cup, 3/8 in.

Fig. 9. Section of an oil-sump casting for an aircraft engine that was salvaged by repair welding six spot-facing areas that had been machined undersize (Example 348)

welding procedure, and all repair welds were subjected to fluorescent-penetrant inspection. Fillet welds were left as welded; other types of welds were finished to conform to the contour of the casting or to desired shape.

Example 349 — Repairing of a Machining Scratch. The views at the top in Fig. 10 show a portion of an alloy AZ92A-T6 sand casting with a machining scratch, ¼ in. long and 0.030 in. deep, that was repaired by gas tungsten-arc surface welding, under the conditions given in the table with Fig. 10. Machining flaws up to 3/8 in. square, in castings of various shapes and sizes, have been corrected by this method.

Example 350 — Welding a Patch for Correction of Wall Thinning Due to Core Shift. The middle views in Fig. 10 show a flanged cylindrical alloy EZ33A sand casting that was one of about 200 such castings in which core shift caused the ¼-in. wall to thin to ⅛ in., beginning about 1 in. away from one of the flanges. To repair these thin areas without distortion of the cylinder, a 3-by-4-in. piece of ¼-in. alloy HK31A plate was formed to fit the outside wall of the cylinder, drilled in the center with a ½-in.-diam hole, and clamped in place over the thin area. The patch was tack welded at the four corners, and then gas tungsten-arc welded along the periphery with intermittent ¼-in. fillet welds 1 in. long. During welding, the inside of the cylinder was flushed with helium to prevent oxidation of heated portions.

After the patch had been fillet welded to the cylinder, the center hole was plug welded, using successive small beads to ensure fusion to the wall of the casting, and to minimize the possibility of cracking, which can occur when large beads are deposited. The part was then finish machined, using plates to hold the flanges. Welding conditions are given in the table with Fig. 10.

Example 351 — Applying an All-Weld-Metal Boss to a Flange. Because a design change was made after the first run of flanged, cylindrical alloy EZ33A castings had been produced, a boss had to be added to one of the flanges on each casting, as shown in the views at the bottom in Fig. 10. Using a buildup welding procedure of successive small beads, a cylindrical boss 1 in. in diameter by ¼ in. high was produced on the flange by manual gas tungsten-arc welding, under the conditions given in the table with Fig. 10. In later production, the pattern was changed, and the boss was cast integrally with the flange.

Defects in repair welds and their causes are discussed in the following paragraphs.

Oxide inclusions are caused by welding on unsound base metal, by inadequate cleaning of base metal or filler metal, by maintaining too long an arc, by insufficient flow of shielding gas, by leaky gas connections, and by defective shielding-gas hoses that allow air to be drawn in.

Tungsten inclusions are caused by maintaining too long an arc, by using too high a current, and by touching the weld puddle, base metal or filler metal with the electrode.

Porosity is usually caused by welding on unsound base metal, by poor preweld cleaning of base metal or filler metal, and by contamination of the shielding gas.

Microshrinkage, a defect consisting of interdendritic voids detectable on magnification, is caused by too rapid current decay at the end of a weld, which results in too rapid freezing of the weld puddle. As a result, the weld puddle is unable to serve as a riser to feed the solidifying weld metal below.

Base-metal cracks are usually caused by excessive heat input or by carrying the arc too far over onto the base-metal surface during repair welding.

Heat Treatment After Welding

Heat treated castings are often heat treated again after welding. The heat treatments shown in Table 5 depend on the temper before welding and that required after welding. Only the minimum heat treating time (½ hr) for complete solution is used for welded AZ81A, AZ91C and AZ92A castings, so as to avoid abnormal grain growth in the deposited weld metal. As noted in Table 5, some solution treatments require an SO_2 or CO_2 atmosphere.

If complete solution treatment is not required, magnesium castings containing more than 1.5% aluminum should always be stress relieved to prevent corrosion cracking in service. Postweld stress-relieving temperatures and times are given in Table 11.

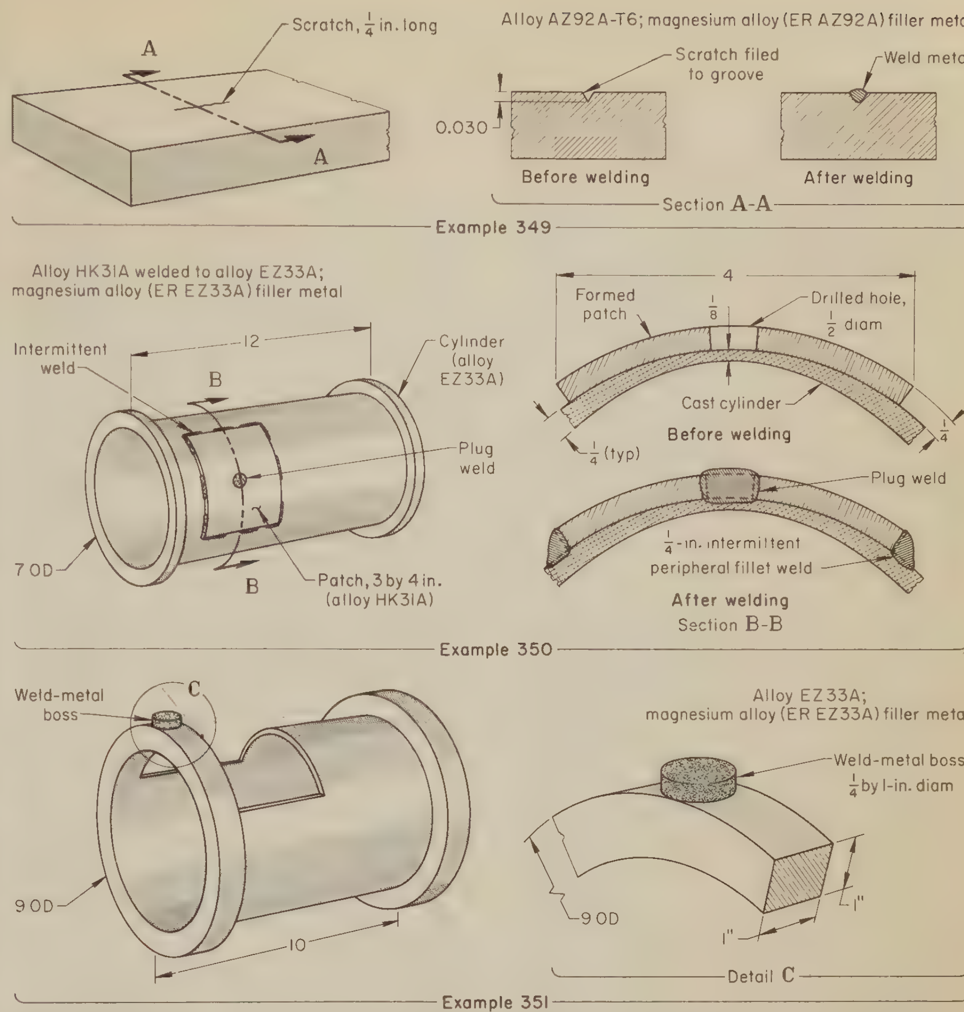
Summary of Examples

Table 12 summarizes the welding conditions used for the 13 examples of practice described in this article.

Table 11. Postweld Stress-Relief Treatments for Magnesium Alloys(a)

Alloy	Temperature, F	Time, min
Sheet		
AZ31B-O(b)	500	15
AZ31B-H24(b)	300	60
HK31A-H24	600	30
HM21A-T8	700	30
HM21A-T81	750	30
ZE10A-O	450	30
ZE10A-H24	275	60
Extrusions		
AZ10A-F	500	15
AZ31B-F(b)	500	15
AZ61A-F(b)	500	15
AZ80A-F(b)	500	15
AZ80A-T5(b)	400	60
HM31A-T5	800	60
Castings(c)		
AM100A	500	60
AZ63A	500	60
AZ81A	500	60
AZ91C	500	60
AZ92A	500	60

(a) Treatments given will produce approximately 80 to 95% stress relief in all alloys except HM31A-T5, where 70% stress relief will be provided. (b) Requires postweld heat treatment to avoid stress-corrosion cracking. (c) Requires postweld heat treatment for maximum strength (see Table 5 for postweld heat treatments).



Welding condition	Example 349	Example 350	Example 351
Conditions for Manual Gas Tungsten-Arc Welding(a)			
Fixtures	None	Plates	None
Welding position	Flat	Flat	Flat
Shielding gas	Argon; 20-24 cfh	Argon; 24-28 cfh(b)	Argon; 24-28 cfh
Electrode (⅛-in. diam)	EWP	EWP	EWP
Filler metal (1/16-in. diam)	ER AZ92A	ER EZ33A	ER EZ33A
Current (ac, hf-stabilized)	80-140 amp	160-180 amp	160-180 amp
Preheat and interpass temperature	250 F	300 F	250-350 F
Postweld heat treatment	300 F, 3 hr	400 F, 2 hr	300 F, 4 hr
Total time per piece(c)	½ hr	2 hr	½ hr

(a) For all three applications, preweld cleaning was done with a wire brush or a rotary file, power supply was a 300-amp transformer with high-frequency (balanced-wave) stabilizer, and electrode holder was a 300-amp water-cooled type. (b) Helium at 8 cfh was used for backing. (c) Not including time for postweld heat treatment.

Example 349: Part of an AZ92A-T6 casting on which a small machining scratch was filed to a groove and surface welded. **Example 350:** Flanged EZ33A casting onto which an HK31A patch was fillet and plug welded, to build up a wall that was thin as the result of core shift. **Example 351:** Cylindrical EZ33A casting on one flange of which a boss, added in a design change, was built up of weld metal deposited in successive passes, each depositing a small amount of filler metal.

Arc Welding of Nickel Alloys

THE WROUGHT NICKEL ALLOYS listed in Table 1 can be arc welded under conditions similar to those used in the arc welding of austenitic stainless steel. Cast nickel alloys, particularly those of high silicon content, present difficulties in welding. The arc welding of heat-resisting nickel alloys is described in the article on Arc Welding of Heat-Resisting Alloys, beginning on page 277 in this volume.

The most widely employed processes for welding the non-age-hardenable (solid solution) wrought nickel alloys are gas tungsten-arc, gas metal-arc, and shielded metal-arc welding. Submerged-arc welding has limited applicability. The gas tungsten-arc process is preferred for welding the precipitation-hardenable alloys, although gas metal-arc and shielded metal-arc welding are also used.

Preweld Heating and Heat Treating. Preweld heating of wrought alloys is not required unless the base metal is below 60 F, in which case a path 10 to 12 in. wide on both sides of the joint should be warmed to 60 to 70 F to avoid condensation of moisture, which might cause porosity in the weld metal. Cast alloys should be heated to 200 to 400 F, depending on the mass of the casting at the joint.

Nickel alloys are usually welded in the solution-treated condition. Precipitation-hardenable alloys should be annealed before welding if they have been severely formed (see the section in this article on Welding of Precipitation-Hardenable Alloys).

Postweld Treatment. No postweld treatment, either thermal or chemical, is needed or recommended to maintain or restore corrosion resistance. Heat treatment may be necessary to meet specification requirements, such as stress relief of a fabricated structure to avoid stress-corrosion cracking of the weldment in hydrofluoric acid vapor or caustic soda, or age hardening (see the section in this article on Welding of Precipitation-Hardenable Alloys).

Cleaning of Workpieces

Nickel and nickel alloys are susceptible to embrittlement by lead, sulfur, phosphorus and some low-melting-point metals. These materials may be present in grease, oil, paint, marking crayons, marking inks, forming lubricants, cutting fluids, shop dirt, and processing chemicals. Before workpieces are heated or welded, they must be completely free of foreign material. Both sides of the workpiece in the area that will be heated by the welding operation should be cleaned. When no subsequent heating is involved, the cleaned area may be restricted to 2 in. on each side of the joint.

Shop dirt, oil and grease can be removed by vapor degreasing or by swabbing with acetone or other nontoxic solvent. Paint and other materials that are not soluble in degreasing solvents may require the use of methylene chloride, alkaline cleaners, or special proprietary compounds. If alkaline cleaners containing sodium sesquisilicate or sodium carbonate are used, the cleaners themselves must be removed prior to welding; spraying or scrubbing with hot water is recommended. Marking ink can usually be removed with alcohol. Processing material that has become embedded in the work metal can be removed by grinding, abrasive blasting, and swabbing with a 10% (by volume) hydrochloric acid solution, followed by a thorough water wash. (Further information on the cleaning of nickel and nickel alloys is given in Volume 2 of this Handbook, beginning on page 661.)

Oxide must also be removed from the area involved in the welding operation, largely because of the difference in melting point between the oxide and the base metal. Oxide can usually be removed by wire brushing.

Joint Design

Various joint designs are used in the arc welding of nickel alloys. The same design can be used for gas tungsten-arc welding and for shielded metal-arc welding. Joint design requires special consideration in gas metal-arc and submerged-arc welding, as discussed in the sections in this article on these two processes. A joint design developed for other metals is not necessarily suitable for nickel alloys, and should not be used unless proved satisfactory by experience or by tests.

Beveled Joints. Beveling is usually not required for metal 0.093 in. or less in thickness, although thinner sections of certain alloys sometimes are beveled (see Table 2). Metal thicker than 0.093 in. should be beveled to form a V, U or J-groove, and should be welded using a backing, unless it is welded from both sides. Otherwise, erratic penetration will result, leading to crevices and voids that will be potential areas of joint weakness and accelerated corrosion in the underside of the joint. For the best underbead contour on joints that cannot be welded from both sides, gas tungsten-arc welding should be used for the root pass.

For metal more than ⅜ in. thick, a double-U-groove or double-V-groove design is preferred. The added cost of preparation is justified because less welding time and material are needed and less residual stress will be developed than with a single-groove design.

Beveling is done best by machine, usually a plate planer or other machine tool. Plasma-arc and electric-arc cutting can be used for joint preparation, but all oxidized metal must be removed from the joint area by grinding or chipping for a depth of $\frac{1}{32}$ to $\frac{1}{16}$ in.

Corner and lap joints may be welded where service stresses will not be high. These joints should be avoided if service temperatures are high or if service conditions involve thermal or mechanical cycling. When corner joints are used, a full-penetration weld must be made, usually with a fillet weld on the root side. Lap joints should be welded on both sides.

Design Considerations. Unlike steel weld metal, molten nickel alloy weld metal does not flow. This characteristic cannot be compensated by extra heat input or by puddling, because serious loss of residual deoxidizers may result.

For joints in metal up to ⅝ in. thick, ample accessibility will be provided by V-groove butt joints beveled to an 80° groove angle. For thicker work metal, U-groove butt joints machined to a 15° bevel angle and a $\frac{3}{16}$ to $\frac{5}{16}$-in. radius are used (see Table 3 in the article on Arc Welding of Heat-Resisting Alloys, page 280). Single bevels used to form T-joints should have an angle of 45°. The bottom radius of a J-groove for T-joints should be at least ⅜ in. and the bevel angle should be about 15°. A root face of ⅛ in. should be used for J-grooves and U-grooves.

Welding Fixtures

Proper fixturing and clamping will hold the workpieces firmly in place, minimize buckling, maintain alignment and, when needed, provide compressive stress in the weld metal. A backing bar or any portion of a fixture that might be contacted by the arc should be made of copper.

When backing bars are used, they should incorporate a groove of suitable contour to permit penetration of weld metal and to avoid the possibility of trapping gas or flux at the bottom of the weld. Grooves in backing bars for shielded metal-arc welding usually have a shallow semielliptical shape — 0.015 to 0.035 in. deep and $\frac{3}{16}$ to ¼ in. wide. Square-corner grooves are used with gas metal-arc and gas tungsten-arc welding to accommodate the backing gas; a machined passageway is connected to the gas supply, and holes $\frac{1}{16}$ in. in diameter are drilled 3 in. apart from the bottom of the groove to the passageway, so that the backing gas can flow along the weld. The gas flows out of the groove at the ends of the bar. Groove designs for backing bars are shown in Fig. 1.

Nickel alloys require about the same amount of clamping and restraint as low-carbon steel. The hold-down bars should be located close enough to the line of weld to maintain alignment and to provide the proper degree of heat transfer. Generally, hold-down pressure should be just enough to maintain alignment, but in welding square-groove joints in thin metal by the gas tungsten-arc process without a filler metal, high restraint can be used to advantage. When the pieces to be welded are positioned with a zero root opening, and the hold-down bars are brought very close to the line of weld-

ing and a high hold-down pressure is used, an expansive force is created by the heat of welding that will result in a compressive force in the line of weld. This compression will have an upsetting effect on the hot weld metal, and the weld will develop a slight top and bottom crown, or weld reinforcement, without the use of filler metal.

Welding of Precipitation-Hardenable Alloys

The precipitation-hardenable alloys require special welding procedures because of their susceptibility to cracking. Cracks can occur in the base-metal heat-affected zone on aging or in service at temperatures above the aging temperature, as a result of residual welding stress and stress induced by precipitation.

Preweld and Postweld Treatments. Any part that has been subjected to severe bending, drawing or other forming operation should be annealed before welding. If possible, heating should be done in a controlled-atmosphere furnace, to limit oxidation and minimize subsequent surface cleaning.

The aluminum-titanium-hardened alloys must be stress relieved (solution treated) after welding and before precipitation hardening. To avoid prolonged exposure of the welded structure to temperatures within the precipitation-hardening range, a rapid heating in a furnace preheated to the appropriate temperature is recommended. When the workpiece is large in comparison with the furnace area, it may be necessary to preheat the furnace 200 to 500 F above the solution-treatment temperature and then to reset the furnace controls when the workpiece has reached the solution-treatment temperature. The stresses created by repair or alteration welding must be relieved in a similar fashion — by rapid heating to the solution-treating temperature prior to re-aging. When it is not feasible, particularly if the structure is complicated, to stress relieve the weldment satisfactorily, preweld treatments may be helpful, but preheating is not a satisfactory substitute for postweld heat treatment.

Precipitation-hardenable alloys can be welded in the aged condition, but if temperatures encountered in service are in the precipitation-hardening range, the weldment must be solution treated and re-aged.

General Welding Procedures. Precipitation-hardenable alloys are usually welded by the gas tungsten-arc process, but shielded metal-arc and gas metal-arc welding are also applicable. Heat input during the welding operation should be held to a moderately low level to obtain the highest possible joint efficiency. For multiple-bead or multiple-layer welds, many narrow stringer beads should be used rather than a few large, heavy beads.

If oxides form during welding, they should be removed by abrasive blasting or grinding. If such films are not removed as they accumulate on multiple-pass welds, they may become thick enough to inhibit weld fusion and to produce laminar-type oxide stringers along the weld axis, which act as mechanical stress raisers, and may cause stress-corrosion cracking in service.

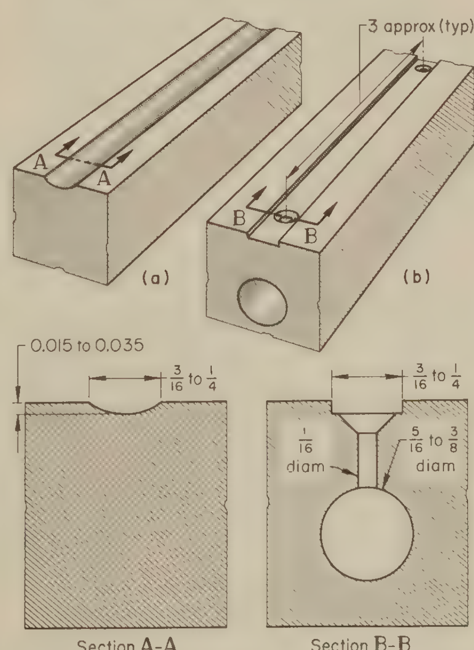
Table 1. Nominal Compositions of Weldable Wrought Nickel and Nickel Alloys

Alloy	Composition
Nickel and Solid-Solution Alloys	
Nickel 200	99.5 Ni, 0.06 C, 0.25 Mn, 0.15 Fe
Nickel 201	99.5 Ni, 0.01 C, 0.20 Mn, 0.15 Fe
Nickel 205	99.5 Ni, 0.06 C, 0.20 Mn, 0.10 Fe, 0.04 Mg
Nickel 211	95.0 Ni, 0.10 C, 4.75 Mn, 0.05 Fe
Nickel 220	99.5 Ni, 0.06 C, 0.12 Mn, 0.05 Fe, 0.04 Mg
Nickel 230	99.5 Ni, 0.09 C, 0.10 Mn, 0.05 Fe, 0.06 Mg
Nickel 233	99.5 Ni, 0.09 C, 0.18 Mn, 0.05 Fe, 0.07 Mg
Nickel 270	99.98 Ni, 0.01 C
Monel 400	66.0 Ni, 31.5 Cu, 0.90 Mn, 1.35 Fe
Monel 401	44.5 Ni, 53.0 Cu, 1.70 Mn, 0.20 Fe, 0.50 Co
Monel 404	55.0 Ni, 44.0 Cu
Monel R-405	66.0 Ni, 31.5 Cu, 1.35 Fe
Precipitation-Hardenable Alloys	
Monel K-500	65.0 Ni, 29.50 Cu, 0.60 Mn, 1.00 Fe, 0.60 Ti, 2.73 Al
Monel 502	66.5 Ni, 28.0 Cu, 0.75 Mn, 1.0 Fe, 0.25 Ti, 3.0 Al
Special-Purpose Alloys Cited in Examples in This Article	
4-79 Moly-Permalloy	79 Ni, 4 Mo, rem Fe
Mumetal (AMS 7701)	80 Ni, 15 Fe, rem Cu, Mo or Cr
Nichrome	57 Ni, 16 Cr, 27 Fe
Invar 36	35.5 Ni, 0.18 C, 0.42 Mn, rem Fe

Welding of Cast Nickel Alloys

Cast nickel alloys can be joined by gas tungsten-arc, gas metal-arc, and shielded metal-arc welding. For optimum results, castings should be solution annealed before welding, to relieve some of the casting stresses and to provide some homogenization of the cast structure.

Preheating to 200 to 400 F, depending on casting mass at the joint, reduces cracking of weld metal from thermal shock. Light peening of solidified metal after the first pass will relieve stresses and thus reduce cracking at the junction of the weld metal and the cast metal. Peening of subsequent passes is of little if any benefit. Stress relieving after welding is also desirable.



(a) Standard groove for use without a backing gas; (b) square-corner groove employed with backing gas (groove depth depends on gas flow required and length of bar)

Fig. 1. Groove designs for backing bars

Gas Tungsten-Arc Welding

Nickel alloys, both cast and wrought, either solid-solution-strengthened or precipitation-hardenable, can be welded by the gas tungsten-arc process. The addition of filler metal is usually recommended.

Straight-polarity direct current (dcsp) is recommended for both manual and machine welding. If close control of arc length is feasible, alternating current can be used for machine welding, but a superimposed high-frequency current is required.

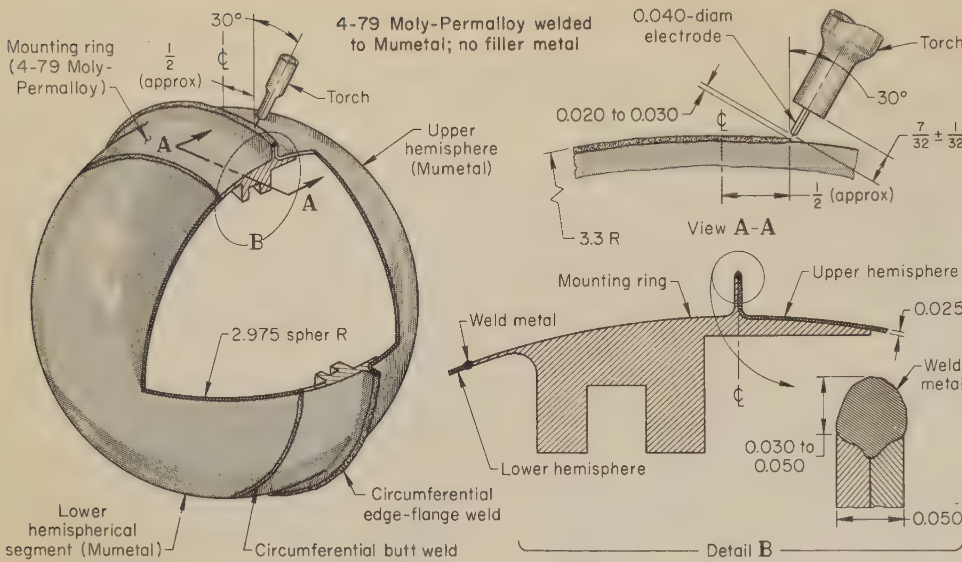
The welding torch should be set or held at an angle of 90° to the work; a slight deviation is permissible to provide a better view of the work. An acute angle can lead to pulling in of the surrounding air and contamination of the shielding gas. The largest gas-nozzle size applicable to the job should be used, and a minimum practical distance between the nozzle and the work should be maintained. A gas lens is sometimes used to control gas flow, as in Example 352.

For details of the process and equipment, see the article "Gas Tungsten-Arc Welding", beginning on page 113. Conditions for gas tungsten-arc welding of Monel 400 are given in Table 2.

Shielding Gas. Either argon or helium, or a mixture of the two, is used as a shielding gas for welding nickel and nickel alloys. Additions of oxygen, carbon dioxide, or nitrogen to argon gas will usually cause porosity, or erosion of the electrode. Argon with small quantities of hydrogen (approximately 5%) can be used for single-pass weld-

Table 2. Conditions for Manual Gas Tungsten-Arc Welding of 0.062-In.-Thick Monel 400

Joint type	Beveled butt, 1/16-in. root opening
Electrode	3/32-in.-diam EWTh-2, tapered to 1/64-in. diameter
Filler metal	1/16-in.-diam Monel 60 (ERNiCu-7)
Number of passes	Three
Welding current	70 to 90 amp, dcsp
Voltage	10 to 12 v
Shielding gas:	
At torch	20 cfh
Backing gas	3 to 5 cfh
Welding speed	2 to 3 ipm
Preheat and postheat	None
Interpass temperature	350 F max



Conditions for Automatic Gas Tungsten-Arc Welding

Weld type	Edge-flange	Power supply	320-amp transformer-rectifier with slope control; high-frequency unit
Filler metal	None	Torch	Light duty, air cooled, with gas lens
Electrode	0.040-in.-diam EWTh-2	Auxiliary equipmt	Positioner; sequence timer
Shielding gas, torch	Argon, at 45 cfh	Welding speed	18.8 ipm
Backing gas	Helium (purge)		

Fig. 2. Gyroscope instrument enclosure that was welded by the gas tungsten-arc process, and details of the edge-flange weld and torch position (Example 352)

ing, and may help to avoid porosity in pure nickel. Helium has shown the following advantages over argon in welding thin metal without the addition of filler metal:

1 **Improved Soundness.** Porosity-free welds are more easily obtained in Monel 400, and there is less porosity in welds in Nickel 200.
2 **Increased Welding Speed.** With straight-polarity direct current, welding speed can be increased as much as 40% over that achieved with argon at the same current setting, because welding speed is a function of heat input, and heat input is considerably greater with helium.

Because purity and dryness of the welding gas are important, welding-grade shielding gas should be used.

Disruption of the shielding atmosphere and drawing in of air can cause porosity in the weld metal. The welding area should be screened to avoid drafts.

Electrodes. Pure tungsten electrodes or tungsten alloyed with thorium or zirconium can be used. The alloyed electrodes are more economical because of their lower operating temperature and lower vaporization loss. Overheating through use of excessive amperage must always be avoided.

The best arc stability and penetration control are achieved by tapering the electrode tip. The taper angle should be approximately 30°, with a flat land of about 0.015-in. diameter on the tip end. Larger taper angles are used to produce a narrower bead and deeper penetration.

Electrode extension (stickout) should be short, and based on joint design. For example, a maximum extension of 3/16 in. is used for butt welds in thin metal, but a 3/8 to 1/2-in. extension may be required for some fillet welds.

The electrode should be inclined slightly in the forehand position. When filler metal is used, it should be added carefully at the leading edge of the weld puddle to avoid contact with, and contamination of, the electrode. If contamination should occur, the electrode should be cleaned and reshaped.

Filler Metals. Compositions of the filler metals used with gas tungsten-arc welding are, in general, similar to those of base metals with which they are employed. Because of high arc currents and high welding temperatures, filler metals are alloyed to resist porosity and hot cracking of the weld metal. Filler-metal additions and dilution ratios should be adjusted to ensure that the weld metal contains at least 50% filler metal.

Table 3 lists the compositions of filler metals used for gas tungsten-arc welding of nickel and nickel alloys.

Filler metals of the ERNi-3 classification are used for welding the high-nickel alloys, such as Nickel 200 and 201, and those of the ERNiCu-7 classification are used for welding nickel-copper alloys, such as Monel 400 and 404.

Filler metals ERNiCu-8 are used for welding nickel-copper-aluminum alloys, such as Monel K-500. The weld metal will age harden if heated to 1100 F and held for 16 hr, followed by furnace or air cooling. The weldment should be stress relieved before aging; if not, cracking may result during aging.

Joint Design. All of the joint designs shown in Table 3 of the article on Arc Welding of Heat-Resisting Alloys can be used in welding nickel alloys by the gas tungsten-arc process. Where no filler metal is used, the sections to be joined must be held tightly together to promote satisfactory fusion.

Welding Techniques. When a filler metal is used, the wire diameter should be related to the work-metal thickness. During welding, the hot end of the wire must be kept under the shielding gas. The molten puddle must be kept as quiet as possible; otherwise the deoxidizing elements will burn out.

To ensure a sound weld, the arc should be maintained at the shortest possible length. When no filler metal is added, the arc length should be 0.05 in. max and preferably 0.02 to 0.03 in. When filler metal is used, the arc can be longer, but it should be kept as short as possible, consistent with filler-metal diameter.

Speed of welding affects penetration and width of weld and weld soundness, especially when no filler metal is added. For a given thickness of metal, there is a range of welding speeds that results in minimum porosity. Speeds outside this range, either faster or slower, result in increased porosity. Also, for a given welding speed, the likelihood of porosity decreases as metal thickness increases.

Complete-penetration welds call for the use of grooved backing bars that permit local gas shielding such as that shown in Fig. 1(b), or the purging of the inside of the workpiece.

Production Examples. The two examples that follow describe an application of gas tungsten-arc welding in which overheating and undue stressing had to be prevented, and one in which the presence of a flux was undesirable because it might cause corrosion.

Example 352. Hermetic Sealing of 0.025-In.-Thick Mumetal to 4-79 Moly-Permalloy (Fig. 2)

The gyroscope assembly shown in Fig. 2 consisted of two hemispheres, approximately 6 in. in diameter and 0.025 in. thick, joined at the equator. A 4-79 Moly-Permalloy ring, which provided internal support for the gyro mechanism, was welded to a Mumetal hemispherical segment to form one hemisphere. The other was of Mumetal. All joints, including several connections not shown, had to provide hermetic sealing, with leak rates not to exceed 1×10^{-6} cu cm per second under internal helium pressure. Gas tungsten-arc welding was used because it could meet the precision and joint-reliability requirements.

The edge-flange weld (shown in Fig. 2) was most critical, because of the two-stage fabricating sequence. First, the outer envelope was completely assembled and welded at all joints, without the gyro mechanism. The welds were then leak tested and, after all necessary repairs had been made, the edge-flange weld was milled off so that the upper hemisphere could be removed. Then the gyro was mounted in the Permalloy equator ring, and the upper hemisphere was replaced and rewelded to seal the assembly. Considerable care was taken in rewelding the edge flange because any repair after final leak testing was highly undesirable.

Several techniques were used to obtain a smoothly contoured weld with controlled

Table 3. Compositions of Filler Metals or Electrode Wires for Gas Tungsten-Arc, Gas Metal-Arc, and Submerged-Arc Welding of Nickel Alloys(a)

AWS classification	C	Mn	Fe	S	Si	Cu	Ni + Co(b)	Al	Ti	Other, total
ERNi-3	0.15	1.0	1.0	0.01	0.75	0.25	93 min	1.5	2.0 to 3.5	0.50
ERNiCu-7	0.15	4.0	2.5	0.02	1.25	Rem	62 to 69	1.25	1.5 to 3.0	0.50
ERNiCu-8	0.25	1.5	2.0	0.01	1.0	Rem	63 to 70	2 to 4	0.25 to 1.00	0.50

(a) Values are maximum except where ranges are shown. (b) Cobalt, if determined, 1% max.

penetration, at a speed sufficient to minimize heat input to the ring. To avoid erratic arc action and porosity, all joint surfaces were required to be chemically clean. Straight-polarity direct current was used with external argon shielding to obtain good penetration. Use of a 0.040-in.-diam thoriated tungsten electrode provided high current density at relatively low current to minimize heat input. A purging flow of helium provided internal backing. The power supply incorporated sequenced arc-current and gas-flow control for starting and stopping welding. Superimposed high-frequency current provided arc stability.

A light-duty air-cooled welding torch, with a lens-type gas nozzle to reduce turbulence, was carefully positioned over the joint (Fig. 2). The torch position enabled arc force to work against gravity on the molten weld puddle to obtain a crown on the weld bead. To assist in maintaining the desired weld-bead contour, the distance of the torch from the vertical centerline (shown as approximately ½ in. in Fig. 2) was varied during welding. No filler metal was used. The entire assembly was fixtured on a special positioner that rotated at about 1 rpm. Except for the torch adjustments described above, the operation was automatically sequenced. Details of conditions and equipment used in automatic gas tungsten-arc welding are summarized in the table that accompanies Fig. 2.

The 4-79 Moly-Permalloy ring had been made by rolling a rectangular bar into a ring, flash welding the joint, and then machining the required contour. After machining, the ring was annealed at a high temperature to obtain optimum electrical properties.

Example 353. Gas Tungsten-Arc Welding of Nichrome Wire to a Nickel Tab (Fig. 3)

Originally, resistance spot welding was chosen for welding a long Nichrome (57Ni-16Cr-27Fe) lead wire to a nickel (99 Ni) tab (Fig. 3), because it was necessary to avoid the use of a flux (which might cause corrosion), but flexing at the joint caused early failure of the connection and an alternative joining method was sought. Gas tungsten-arc welding, in addition to resistance spot welding, improved the reliability of the joint. No change in workpiece design was necessary. The wire was resistance spot welded to the tab for location, and the workpiece was positioned in a welding vise (electrically grounded) and was manually gas tungsten-arc welded, without filler metal, using an air-cooled torch, a 0.040-in.-diam EWTh-2 electrode, and argon shielding gas at 18 cu ft per hour. Welding was done with 70-amp straight-polarity direct current. To facilitate arc starting and to avoid tungsten inclusions in the weld, high-frequency current was added to the welding circuit. Production rate was 30 welded connections per hour.

Nichrome (57Ni, 16Cr, 27Fe) welded to nickel (99%); no filler metal

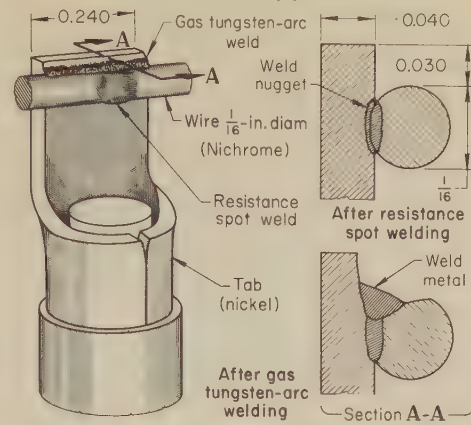


Fig. 3. Electrical connection that was gas tungsten-arc welded for high reliability (Example 353)

Welding Current. All standard direct-current power supplies have been found satisfactory, but constant-voltage power supplies are most widely used. The direct current should have reverse polarity. Deposition rates are higher with straight polarity, but weld spatter is excessive. Amperage should be well within the maximum rating of the equipment, but sufficient to obtain the desired melting rate.

Shielding Gas. For gas metal-arc welding of nickel alloys by spray or globular transfer, good results are obtained with argon as the shielding gas. The addition of 15 to 20% helium is beneficial when welding nickel alloys. The weld beads become progressively wider and flatter, and penetration decreases, as the helium content is increased from 0 to 20%. The addition of oxygen or carbon dioxide to argon results in heavily oxidized and irregular bead surfaces. The addition of hydrogen to argon causes gross porosity in nickel alloys and weld metals. Helium by itself has been used as a shielding gas, but it creates an unsteady arc with excessive weld spatter.

Gas flow rates vary from 25 to 100 cu ft per hour, depending on joint design and welding position. A flow rate of 50 cu ft per hour is most frequently used.

The choice of gas for use with short-circuiting metal transfer is influenced by the type of equipment available. Argon, without additions, is suitable for use with equipment that has both inductance and slope control. Argon gas produces convex beads, which may cause cold lapping (lack of fusion), but it also provides a pronounced pinch effect, which can be controlled by inductance. An addition of helium is helpful when induction and slope cannot be varied. Helium imparts a wetting action, and the arc is hotter; these factors greatly decrease the possibility of cold lapping. As the percentage of helium is increased, the gas flow rate must be increased to ensure adequate protection.

The size of the gas nozzle is important when using a short-circuiting arc. For example, when using a one-to-one mixture of argon and helium at a flow rate of 40 cu ft per hour through a ⅜-in.-diam nozzle, a wire-feed rate of 250 in. per minute and a current of 110 to 120 amp are maximums when good weld quality is required. With a ⅝-in.-diam gas nozzle, the wire-feed rate can be increased to over 400 in. per minute and the current can be increased to 160 to 180 amp without affecting weld quality adversely.

An argon-helium mixture is recommended as the shielding gas with a pulsed arc. Gas flow rate should be from 25 to 45 cu ft per hour. Excessive flow rate can interfere with the arc.

Electrode wires used in gas metal-arc welding are listed in Table 3. The appropriate wire diameter depends on the method used and the thickness of the base metal. With globular or spray transfer, 0.035, 0.045 and 0.062-in.-diam wire is used. The short-circuiting arc generally requires wire 0.045 in. or less in diameter.

Joint designs recommended for the gas metal-arc processes are shown in Table 3 in the article on Arc Welding of Heat-Resisting Alloys, but for the U-groove designs, using globular or spray transfer, the root radius should be decreased by about 50% and the bevel angle should be doubled. With these types of transfer, the use of high amperage on small-diameter wire produces a high level of arc force, with the result that the arc cannot be deflected from a straight line, as it can when welding is done with covered electrodes. Because the arc must contact all areas to be fused, the joint design must provide intersection with the arc force line.

When a short-circuiting arc is used, the U-groove designs are the same as those that are employed with the other arc welding processes.

Welding Techniques. Best results are obtained when the electrode holder is positioned vertical along the centerline of the joint. Some slight inclination is permissible to allow a better view of the work, but excessive displacement can cause the surrounding atmosphere to be drawn into the shielding gas, and porous or heavily oxidized welds will result. Arc length is important; too short an arc causes spatter, and too long an arc results in loss of control and reduced penetration.

Table 4. Typical Conditions for Gas Metal-Arc Welding of Nickel 200 and Monel 400

Item	Nickel 200	Monel 400
With Spray-Type Metal Transfer(a)		
Electrode wire	ERNi-3	ERNiCu-7
Voltage, v (avg)	29 to 31	28 to 30
Current, amp (avg)	375	290
Wire feed, ipm	205	200
With Short-Circuiting Transfer(b)		
Electrode wire	ERNi-3	ERNiCu-7
Voltage, v (avg)	20 to 21	16 to 18
Current, amp (avg)	160	130 to 135
Wire feed, ipm	360	275 to 290
With Pulsed-Arc Transfer(c)		
Electrode wire	ERNi-3	ERNiCu-7
Peak voltage, v	46	40
Voltage, v (avg)	21 to 22	21 to 22
Current, amp (avg)	150	110
Wire feed, ipm	160	140

(a) Argon shielding gas at 60 cu ft per hour; flat welding position; 0.062-in.-diam electrode wire. (b) Argon-helium shielding gas at 50 cu ft per hour; vertical welding position; 0.035-in.-diam electrode wire. (c) Argon or argon-helium shielding gas at 25 to 35 cu ft per hour; vertical welding position; 0.045-in.-diam electrode wire.

Gas Metal-Arc Welding

The high-nickel and nickel-copper alloys can be joined by gas metal-arc welding and, with special procedures, so can precipitation-hardenable alloys, such as Monel K-500.

Spray, globular and short-circuiting metal transfer can be used. Varying the power input will produce the different types of metal transfer. The pulsed arc, which switches from spray to globular transfer, is also used. All of these methods are based on the use of comparatively small-diameter wire that serves as both electrode and filler metal.

Table 4 lists some typical conditions for gas metal-arc welding of Nickel 200 and Monel 400 using spray-type metal transfer, short-circuiting metal transfer, and a pulsed arc.

Cold lapping (lack of fusion) can occur with the short-circuiting arc if manipulation is faulty. The torch should be advanced at a rate that will keep the arc in contact with the base metal just ahead of the weld puddle.

The manipulation and angle used with the pulsed-arc torch are similar to those used in shielded metal-arc welding. To avoid undercutting, a slight pause should be made at the limit of the weave.

Production Example. In the following example, gas metal-arc welding was used rather than shielded metal-arc welding, because it reduced alloying and increased production.

Example 354. Use of an Expanding Fixture and Gas Metal-Arc Welding To Simplify Installation of Sleeves in a Bellows Joint (Fig. 4)

Steel piping that had been nickel plated on the inside and that ranged in diameter from 30 to 54 in. was fitted with Monel bellows joints for service in transporting uranium fluoride gas. Pipe ends at the bellows joints were formed with opposing finger stops, as shown in Fig. 4. Because excessive vibration of the piping was traced to impingement of the gas stream on the finger stops, it was decided to shield these stops by installing Monel sleeves on the inside of all joints.

Pipe sections ranging from 2 to 12 ft in length were dismantled by air carbon-arc cutting. The sections were then degreased in hot trichlorethylene vapor, rinsed in water, and wiped dry. An overhead crane was used for lowering the pipe sections into large vats for cleaning.

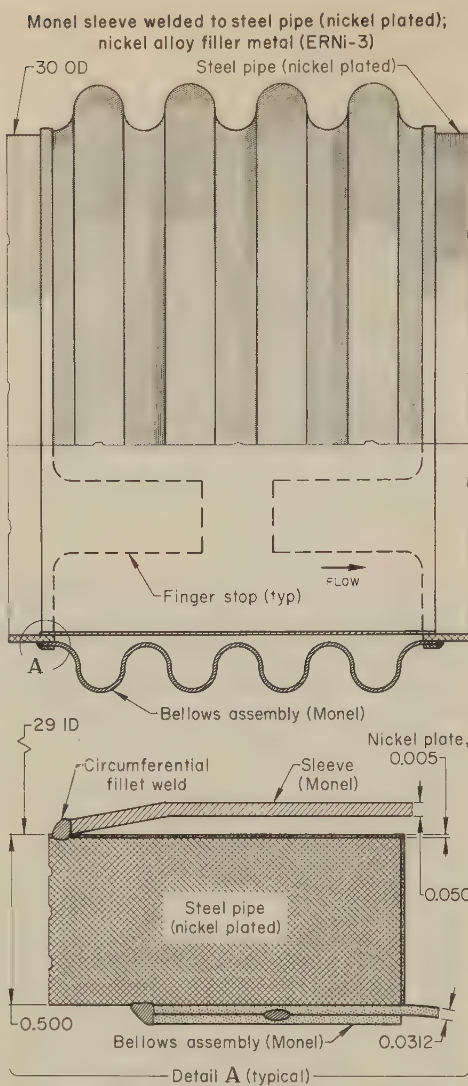
Initially the sleeves were attached in the following manner:

1 Monel sheets were rolled approximately to size with a very slight flare on the upstream side to aid in making positive contact for welding; the downstream side was left "free floating". Allowance was made on the circumference for a 1-in. overlap on the longitudinal seam.
2 The sleeves were tack welded to the pipe on the upstream side of the bellows joint, the sheet being pressed against the inside wall of the pipe by hand.
3 The sleeves were then welded to the pipe. Both tack welding and fillet welding were done by the manual shielded metal-arc process, using a ⅛-in.-diam ENiCu-4 (Monel-type) electrode at 90 amp, 30 volts. Welding speed, although not recorded, was quite low.
4 Next, the longitudinal lap joint was tacked and welded in the same manner.

This procedure was awkward and time consuming. In addition, the rather loose fit of the sleeve caused frequent melt-through, and too much alloying occurred among the nickel plating, the steel pipe, and the Monel electrode.

To improve the procedure, because a number of joints had to be repaired, the following changes were made:

1 After rolling the sheet for the sleeve approximately to size, it was fitted to the interior of the pipe and held in proper alignment for welding by means of a split ring that was expanded with a turnbuckle. This eliminated the awkward fitting and tacking operation.
2 Welding was done by the gas metal-arc process, using a bare nickel electrode wire (ERNi-3) under argon shielding. (For other welding details, see the table with Fig. 4.)



Item	Welding process: Shielded metal-arc (original)	Welding process: Gas metal-arc (improved)
Joint type	Lap	Lap
Weld type	Fillet	Fillet
Electrode	ENiCu-4	ERNi-3
Electrode size	⅛-in. diam	0.030-in. diam
Electrode holder	Standard	200 amp, air cooled
Shielding gas	None	Argon; 20-24 cfh
Welding position	Horizontal-rolled and flat	Horizontal-rolled and flat
Fixtures	None	Expandable ring and turning rolls
Current, amp	90, dcrp(a)	125 to 150, dcrp(b)
Voltage	30 v(a)	22 to 24 v(b)
Welding speed	Not recorded	18 ipm

(a) From a 400-amp constant-current rectifier. (b) From a 400-amp constant-voltage rectifier.

Fig. 4. Cutaway view of bellows joint in large-diameter nickel-plated steel pipe, showing Monel sleeve (Example 354)

Power consumption was higher with gas metal-arc welding, but welding was much faster. Joint fit-up was tighter, and so welding was simplified and took less time. Melt-through was eliminated, and alloying was reduced to a tolerable level. The original method of installing the sleeve required 16 man-hours, but the new method required only 10 man-hours. The table with Fig. 20 gives welding conditions for both methods.

Plasma-Arc Welding

Plasma-arc welding, using the keyholing mode, can produce acceptable welds in nickel alloys up to about 0.3 in. thick.

Argon-hydrogen mixtures are used as orifice and shielding gas, 5 to 8% H_2 being optimum. Current needed for keyholing decreases as hydrogen content is increased, up to about 7% H_2, above which (or when helium is used) torch starting is more difficult.

Typical relations of travel speed and current for keyhole welding are:

	Nickel 200	Monel 400
8 ipm	185 amp	155 amp
10	200	175
12	220	195
14	235	215

Typical conditions for welding 0.235-in.-thick Nickel 200, using 95% argon – 5% hydrogen gas, are: 245 amp; 31.5 v; 14 ipm; gas flow, 10 cfh (orifice) and 45 cfh (shielding). (References: A. C. Lingenfelter, *Welding Engineer*, Jan 1970, p 42-45; see also A. C. Lingenfelter and others, *Welding Journal*, May 1966, p 417-422.)

Shielded Metal-Arc Welding

The shielded metal-arc process can be used for welding nickel and nickel alloys. Although the minimum metal thickness usually is about 0.050 in., thinner metal can be welded when appropriate fixtures are provided. The types of joints used and bead and groove dimensions are given in Table 3 on page 280 in the article on Arc Welding of Heat-Resisting Alloys.

Electrodes. Compositions of electrodes used for shielded metal-arc welding are given in Table 5. Electrode composition is selected to be similar to that of the base metal with which the electrode is to be used.

Electrodes of the ENi-1 classification are used for welding wrought and cast forms of nickel and nickel alloys to themselves and to steel.

ENiCu-1 and ENiCu-2 electrodes can be used for welding nickel-copper alloys to themselves, for surfacing steel with a nickel-copper alloy, for welding the clad side of a nickel-copper clad steel, and for welding nickel-copper alloys to steel. ENiCu-2 electrodes, ³⁄₃₂ or ⅛ in. in diameter, can also be used for welding in other than the flat position. Electrodes of the ENiCu-4 classification are used for welding nickel-copper alloys to themselves for applications where the presence of columbium would decrease corrosion resistance.

ENiCuAl-1 electrodes are used for welding nickel-copper-aluminum alloys to themselves, in the unaged condition. The weld metal will respond to subsequent age hardening, but not as much as the base metal. The weldment must be stress relieved before aging, by placing it in a furnace preheated to 1450 F min, rapidly heating it to 1450 F, and holding at temperature for an appropriate length of time.

Table 5. Composition of Electrodes Used for Shielded Metal-Arc Welding of Nickel, High-Nickel Alloys, and Nickel-Copper Alloys (a)

AWS classification	C	Mn	Fe	S	Si	Cu	Ni + Co	Al	Ti	Cb + Ta	Other, total
ENi-1	0.10	0.75	0.75	0.020	1.25	0.25	92 min	1.0	1 to 4	...	0.50
ENiCu-1	0.15	4.0	2.5	0.025	1.25	Rem	62 to 70	1.0	1.5	3.0	0.50
ENiCu-2	0.15	6.0	2.5	0.025	1.5	Rem	60 to 68	1.0	1.0	2.5	0.50
ENiCu-4	0.40	4.0	2.5	0.025	1.0	Rem	62 to 70	1.5	1.0	...	0.50
ENiCuAl-1	0.45	4.0	2.5	0.025	1.25	Rem	60 to 68	1 to 4	1.0	...	0.50

(a) Single values are maximum percentages, unless otherwise noted.

Before use, covered electrodes should be kept in their sealed, moistureproof containers in a dry storage area. All opened containers of unused electrodes should be stored in a cabinet equipped with a desiccant or heated to 10 to 15 F above ambient temperature before use. If the electrodes have been exposed to excessive moisture, they can be reclaimed by rebaking.

Choice of electrode diameter should be based on quality requirements, rather than on speed of production.

Welding Current. Shielded metal-arc welding is done with reverse-polarity direct current. Each electrode size has an optimum amperage range in which it has good arcing characteristics and outside which the arc becomes unstable or the electrode overheats. Suggested electrode diameters and current settings for various metal thicknesses are shown in Table 6. Such variables as type of backing, tightness of clamping, and joint design will influence the current density needed. Actual welding currents should be developed by making sample welds in metal of the same composition and thickness as the metal to be welded.

Welding Position. Flat-position welding should be used whenever possible because it is faster and more economical and produces welds of good quality. The recommended electrode position for flat-position welding is an inclination of about 20° from the vertical, ahead of the weld puddle. This position will facilitate control of the molten flux and prevent slag entrapment. A short arc must be maintained.

For vertical welding, the arc should be slightly shorter than for flat-position welding, and the amperage should be 10 to 20% lower than the values in Table 6. The electrode should be at approximately a 90° angle to the joint.

For overhead welding, the arc should be slightly shorter than for flat-position welding, and the welding current should be reduced by 5 to 15 amp from the values shown in Table 6.

Welding Techniques. Because molten nickel alloy weld metal does not flow, it must be deposited where it is needed. Therefore, it is necessary to weave or oscillate the electrode slightly. The amount of weave will depend on joint design, welding position, and type of electrode. A straight stringer bead laid down without weaving can be used for single-pass work, and will be satisfactory at the bottom of a deep groove on thicker sections, but a weave is generally desirable.

When a weave is used, it should be no wider than about three times the electrode diameter. Some deviation from this rule may be necessary during vertical welding.

Weld spatter should be avoided. When spatter occurs, it is an indication that the arc is too long, excessive amperage is being used, or current is straight polarity.

Arc blow can occur when the arc is deflected from its normal path by a magnetic force in the work metal. One method of overcoming arc blow is to change the location of the ground connection on the workpiece to reduce the length or change the direction of the electrical path to the arc.

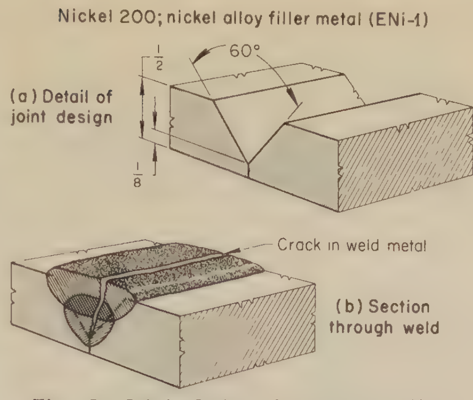


Fig. 5. Joint design for welding ½-in. Nickel 200, and crack in weld metal caused by excessive heat input

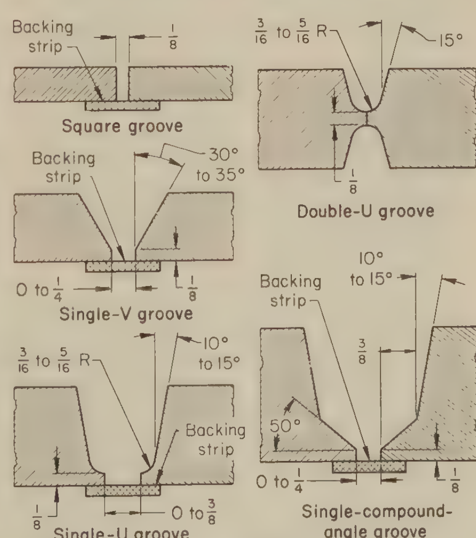
When the arc is to be broken, it should be shortened slightly and the rate of travel increased to reduce the size of the weld puddle. This practice reduces the probability of crater oxidation, ensures that the crater does not develop a rolled leading edge, and prepares the way for restriking the arc.

The manner in which the arc is restruck has a significant effect on the soundness of the weld. A reverse (or T) restrike is recommended. The arc should be struck at the leading edge of the crater and carried back to the extreme rear of the crater at a normal welding speed. The direction is then reversed, weaving is commenced, and the weld continued. This procedure has three advantages: (*a*) the welder has an opportunity to establish the correct arc length before actual welding commences; (*b*) some preheat is applied to the cold crater; and (*c*) the first drops of rapidly cooled weld metal are deposited where they will be remelted, thus keeping porosity to a minimum.

Another technique is to make the restrike where the weld metal can be readily removed — for example, ½ to 1 in. behind the crater on top of the previous pass. Later the restrike area can be ground level with the rest of the bead. This technique is used when the welds must meet rigid radiographic standards, and calls for less welder skill than the reverse-restrike method.



Backing strips are optional with zero root openings. See Table 7 for filler-metal requirements for single-compound-angle-groove, single-U-groove, and single-V-groove joints of various sizes in plate from 1 to 4 in. thick.

Fig. 6. Joint designs for submerged-arc welding of nickel alloys

0.500(d)	3/32-3/16	60-180

(a) Where a range is shown, the smaller-diameter electrodes are used for the first passes at the bottom of the groove, and the joints are completed with the larger-diameter electrodes. (b) Current should be in the range recommended by the electrode manufacturer. (c) Use minimum amperage at which arc control can be maintained. (d) And thicker.

Welding procedures should be qualified, using scrap material, before production is begun. In one plant, this was not done, and when cracks appeared in the weld metal of a joint in a ½-in.-thick Nickel 200 cylinder, it was decided to run qualifying tests of the welding procedure before further welds were made.

The original procedure specified a V-groove butt joint with a 60° included angle, a ⅛-in. root face, and zero root opening, as shown in Fig. 5(a). An ENi-1 electrode that was 14 in. long by 3/16 in. in diameter was used with a welding current of 235 amp. On the first pass, a weld bead 6½ in. long was deposited with each electrode, and on the second pass, a weld bead 3 in. long was deposited with each electrode. A cross section of the completed weld is shown in Fig. 5(b). Investigation showed that cracks in the weld metal were caused by the high welding current and low filler-metal deposition rate, which had resulted in the weld puddle being held in a superheated condition for an excessively long time.

A qualified procedure was therefore established that specified a welding current of 210 amp and a filler-metal deposition rate of about 12 in. for each electrode on the first pass and 9 in. on the second pass. Electrode type and length, and all other welding conditions were unchanged.

An included angle of 80° and a 1/16 to 3/32-in. root face would have produced a

better welded joint, but the workpieces had been machined and roll formed before the problem arose.

Cleaning the Weld Bead. In multiple-pass welding, all flux and slag must be removed before each succeeding bead is deposited. All slag should be completely removed from completed welds, especially if service is to be at high temperature. The slag is easily removed with hand tools or a hand or power wire brush.

Submerged-Arc Welding

Submerged-arc welding can be used for joining solid-solution nickel alloys, Monel 400 being the alloy most commonly welded by this process. Joints in metal up to 3 in. thick have met ASME codes and other specification requirements. The submerged-arc process cannot be used for welding the precipitation-hardenable nickel alloys.

Joint Design. Some joint designs used in the submerged-arc welding of nickel alloy plate are shown in Fig. 6. Single-compound-angle grooves, single-U grooves, and double-U grooves are used for metal ¾ in. or more thick. The double-U groove is usually preferred. It results in a lower level of residual stress, and it can be completed in less time and with less filler metal. A single-V groove is used for stock up to 1 in. thick.

Electrodes. The compositions of the electrode wires used in submerged-arc welding are the same as the filler metal or electrode wires used for gas tungsten-arc and gas metal-arc welding (see Table 3). Electrode ERNiCu-7, with a suitable flux, is suggested for welding Monel 400.

Wire ranging from 0.045 to 3/32 in. in diameter can be used for all nickel alloys. The 1/16-in.-diam wire is generally preferred. Small-diameter wires are used for welding metal up to ½ in. thick, and 3/32-in.-diam wires for heavier sections.

The approximate amount of filler metal needed for single-compound-angle, single-U and single-V grooves is given in Table 7.

Fluxes used in submerged-arc welding of carbon and stainless steels are not satisfactory for welding nickel alloys. Special proprietary fluxes are available and must be used. Poor weld contour, flux entrapment, weld cracking, and inclusions can result when the wrong flux is used.

Only enough flux cover to prevent arc breakthrough should be used — excessive flux can cause a deformed bead surface. Slag entrapment can be prevented by use of an appropriate joint design and by correct placement of beads. Slag is easily removed from welds in the bottom of grooves. Fused flux is self-lifting from exposed welds and should be discarded. Unfused flux can be recovered by means of a vacuum system and, if clean, it can be reused. Screening to adjust particle size is not required.

Fluxes should be stored in dry storage areas. Opened containers should be resealed to prevent moisture pickup, but flux that has absorbed moisture can be reclaimed by drying at 600 F for 1 hr. Hoppers used for fluxes for welding steel and other metals should be thoroughly cleaned before being filled with flux for welding nickel alloys.

Welding Current. Direct current with either straight or reverse polarity is used. Reverse polarity is preferred for butt welding because it produces a flatter bead with deeper penetration, at a rather low arc voltage (30 to 33 volts). Straight polarity will result in a slightly higher rate of deposition at increased voltage (over 35 volts), but the flux covering must be appreciably deeper, and there will be a consequent increase in flux consumption and a greater risk of slag entrapment.

Alternating current and the two-wire series technique for multiple-arc welding are not suited to use with the available fluxes.

Bead Deposition. Location of a bead in a multiple-pass layer should be such as to provide an open, or reasonably wide, root area for the next bead. Flat or slightly convex beads are preferred to concave beads. Bead contour is controlled by voltage, travel speed, and the position of the electrode.

Production Example. The following example describes submerged-arc welding of an iron-nickel alloy. The application is unique. Submerged-arc welding produced satisfactory results.

Example 355. Submerged-Arc Welding Technique for Fabricating a Large Pressure Vessel From Invar 36 (Fig. 7)

Invar 36, because of its dimensional stability, was used to make a cylinder that was 48 ft long by 10 ft in diameter, with a ¾-in. wall. This large cylinder was made by welding together eight 6-ft-long cylinders. Each 6-ft cylinder had to be welded longitudinally, as shown in Fig. 7.

Because Invar 36 is not generally used in structures of this size, welding procedures had not been developed. Gas tungsten-arc welding was the only process that had been qualified for welding Invar 36, but use of this process would have been expensive for eight 6-ft-long welds and the possible use of a faster process was explored, using 5-by-10-in. test plates.

Gas metal-arc welding was tried first, but radiographic inspection showed porosity in the welds, and the process was rejected. Next, submerged-arc welding was tried, using practices developed for welding nickel-copper alloys; this process produced satisfactory welds on the test plates (see Fig. 7) and was used for the production welds. The conditions finally adopted for submerged-arc welding of the Invar 36 cylinders are given in the table with Fig. 7.

A V-groove, as shown in Fig. 7, was machined on the inside of the joint, and the cylinder was tack welded and set on turning rolls so that welds on the inside and outside could be made in the flat position. A root pass was made without preheating, the work was allowed to cool to 200 F max, and a second pass completed the weld on the inside of the cylinder.

The outside of the joint was arc-air gouged to sound weld metal and then ground, leaving a smooth U-groove. The outside of the joint was then welded in nine passes. The work was cooled to 200 F max between passes. The electrode extension of ⅞ ± ⅛ in. allowed close control of metal deposition and was adequate for the flux cover.

The time for making a longitudinal weld by submerged-arc welding was approximately 25% of that estimated for making the weld by gas tungsten-arc welding, and the estimated cost saving was 75%.

Causes and Prevention of Weld Defects

The defects and metallurgical difficulties encountered in arc welding of nickel alloys are porosity, susceptibility to high-temperature embrittlement by sulfur and other contaminants, cracking in the weld bead because of high heat input, and stress-corrosion cracking in service.

Porosity in welds can be caused by oxygen, carbon dioxide, nitrogen or hydrogen. In shielded metal-arc and

submerged-arc welding, porosity can be minimized by using electrodes that contain deoxidizing or nitride-forming elements such as aluminum and titanium, which have a strong affinity for oxygen and nitrogen and form stable compounds with them.

In gas metal-arc and gas tungsten-arc welding, porosity can be avoided by preventing access of air to the molten weld metal. Gas backing on the underside of the weld is sometimes used.

In gas tungsten-arc welding, the use of argon with up to 20% hydrogen as a shielding gas will help to prevent porosity. The hydrogen acts as a scavenger, the nitrogen diffusing into the bubbles of hydrogen that form in the weld puddle. Too much hydrogen in the shielding gas can result in hydrogen porosity.

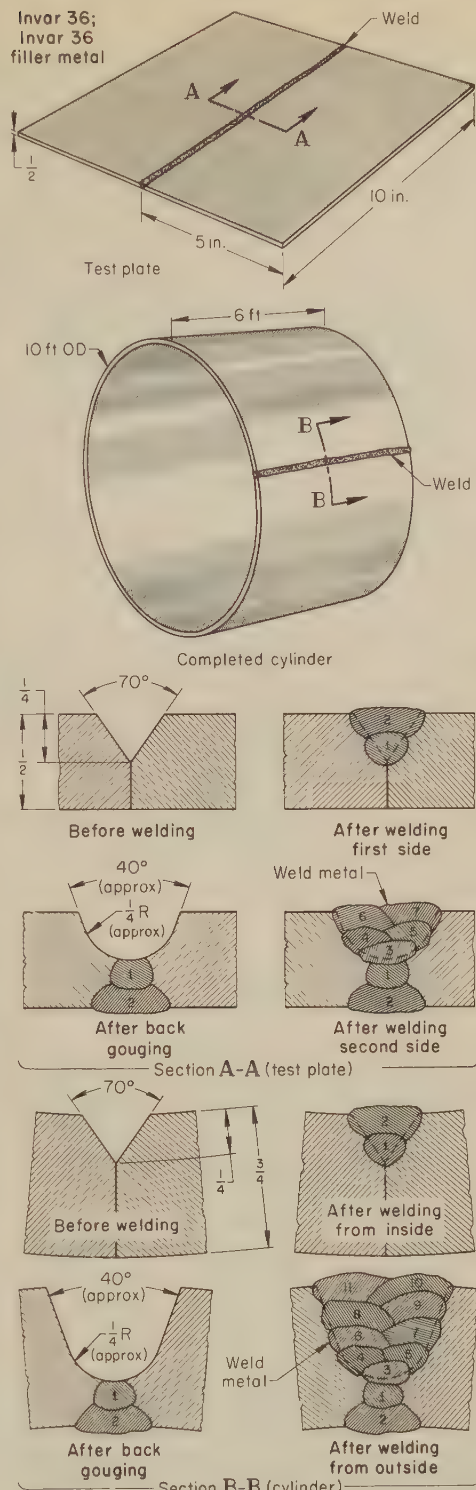
Cracking. Hot shortness of welds can result from contamination by sulfur, lead, phosphorus, or low-melting-point metals such as bismuth, which form intergranular films that cause severe embrittlement at elevated temperature. Hot cracking of the weld metal usually results from such contamination. Cracking in the heat-affected zone is often caused by intergranular penetration of contaminants from the base-metal surface. Sulfur, which is present in most cutting oils used for machining, is a common cause of cracking in nickel alloys. Removal of foreign material from the surfaces of the work metal is imperative, and is described on page 366.

Cracking of the weld metal also can be caused by too high heat input as a result of high welding current and low welding speed (Fig. 5). Cracking can also be caused by undue restraint.

Stress-Corrosion Cracking. Nickel and nickel alloys generally do not undergo any metallurgical changes, either in the weld metal or in the heat-affected zone, that affect normal corrosion resistance, but when the alloys are to be used in contact with substances such as concentrated caustic soda, fluosilicates and some mercury salts, the welds may need to be stress relieved to avoid stress-corrosion cracking. Nickel alloys have good resistance to dilute alkali and chloride solutions. Resistance to stress-corrosion cracking increases with nickel content, and so stress relieving of welds in high-nickel alloys is not usually needed.

Effect of Slag on Weld Metal. The slag formed on the weld surface by covered electrodes is not normally detrimental to the service life of weldments. Slag inclusions between weld beads reduce the strength of the weld. If the service temperature approximates the melting point of the slag, severe corrosion can occur if slag is present on the weld surfaces, particularly in oxygen-containing atmospheres.

Slag also acts as an accumulator of sulfur, particularly in reducing atmospheres, and this can lead to service failure in atmospheres that would be considered adequately low in sulfur. For example, in one instance, although only 0.01% sulfur was present in the atmosphere, the sulfur content of the slag on the weld surface rose from 0.02% to 2 or 3% after a one-month exposure. Sulfur pickup also depresses the melting temperature of the weld slag, and consequently the maximum safe operating temperature of the weldment.



Conditions for Submerged-Arc Welding

Joint type	Butt
Weld type	V-groove and U-groove
Joint preparation	Machining
Electrode	1/16-in.-diam Invar 36 wire
Electrode holder	Semiautomatic, 500 amp
Electrode extension	7/8 ± 1/8 in.
Flux	Proprietary Monel welding flux
Welding position	Flat
Number of passes	11
Interpass temperature	200 F max
Power supply	500-amp constant-voltage welding machine, with wire feeder
Current	280 to 300 amp, dcrp
Voltage	34 v
Welding speed	10 to 15 ipm

Fig. 7. Cylinder made of Invar 36 by submerged-arc welding, as shown (Example 355)

Joining of Dissimilar Metals

Nickel and nickel alloys have been successfully joined to other nickel alloys, to low-carbon steel, stainless steel, and copper alloy 260 (cartridge brass). Filler metal, or consumable electrode, must be selected so as to ensure a compatible metallurgical relationship between the two base metals. Several factors are involved: differences in thermal expansion of the base metals, the possibility of permanent changes in volume after extended service at elevated temperature, and the effect of weld-metal dilution at the interfaces with the base metal. All of these factors influence the choice of filler metal and welding process.

An example of a good metallurgical combination is the welding of nickel to Monel. Because these metals are completely compatible, they can be welded to each other by any welding process, using any compatible filler metal, without difficulty.

Dilution of Weld Metal. The composition of the weld metal can be expected to differ from that of the filler metal or consumable electrode, or the base metals being joined, because some elements are transferred from the base metal to the weld metal during welding. This mixing results in the formation of another alloy. The composition of the weld metal is fairly uniform for a given bead, except in a narrow band at the edge of the joint. The amount of dilution will vary from bead to bead. The welding process, current density, welding speed, work-metal thickness, and welding technique influence the amount of dilution.

The dilution of a nickel-base alloy by a dissimilar metal can be tolerated only to a limited degree. In welding Monel to an austenitic stainless steel, if a stainless steel filler metal is used, any significant amount of copper pickup from the Monel will cause the weld metal to become hot short and to crack. Thus, stainless steel filler metal should not be used when the welding process can cause a considerable amount of dilution. A Monel filler metal cannot be used in this instance because chromium from the stainless steel will dilute the weld metal and cause cracking. A nickel or an Inconel filler metal is best, but either should by used only after the welding procedure has been qualified by tests.

Filler metal must be selected so that the resultant weld will meet the service requirements for strength, corrosion resistance, and soundness, and so that dilution can occur without causing susceptibility to cracking in the weld metal. Crack sensitivity of the weld metal is proportional to the amount of dilution, especially where there is considerable difference in the compositions of a base metal and a filler metal.

Some combinations of base metal and filler metal produce undesirable weld-metal compositions, for example:

1 A ferritic weld-metal deposit diluted by nickel, chromium or copper
2 An 18-8 stainless steel weld-metal de-

4 A high-carbon Monel weld deposit diluted by iron

5 Any Monel weld deposit diluted by more than 6 to 8% chromium.

Manipulation of the welding arc so that it impinges mainly on the base metal nearest in composition to the filler metal, as in Example 356, will help reduce dilution. For most combinations of dissimilar metals, suppliers of filler metal should be consulted before a filler metal is selected.

The coefficients of thermal expansion of the base metals must be considered in selecting filler metal for joining dissimilar-metal combinations. A large difference in expansion can induce stresses of sufficient magnitude to produce cracking in the weld metal. Some of the Inconel (ENiCr, ENiCrFe, ERNiCr and ERNiCrFe) electrodes and filler metals can be used for welding a wide range of base-metal combinations. These electrodes and filler metals can tolerate considerable dilution without loss of strength or ductility.

Filler metal ERNiMo-6 (Hastelloy W) can be used for joining nickel-base alloys, cobalt-base alloys, and stainless steels to themselves and to other metals and alloys.

Welding Processes. Gas tungsten-arc welding can be used to join dissimilar combinations of nickel alloys. When joining dissimilar metals by the gas metal-arc process, the spray or pulsed-arc mode of metal transfer should be used.

Shielded metal-arc welding is widely used for joining nickel alloys to dissimilar metals. The welding current should be maintained near the middle of the recommended range for the electrode, to control dilution. Dilution usually can be kept below 25% by manipulating the electrode so that the arc force is dissipated on weld metal already deposited. When depositing the first bead, the arc should be directed toward the member from which dilution of the weld metal will be least detrimental. Welding procedures that reduce the amount of penetration (which can cause dilution of the weld metal by the base metal) increase the probability of securing a good weld.

In the following example, Monel 400 plates were welded to a low-carbon steel plate. Cracks resulting from excessive dilution were eliminated by modifying the way in which the beads were deposited, and weld crater cracks were prevented by care in ending the weld bead and in breaking the arc.

Example 356. Elimination of Cracking of Welds and Distortion of Base Plate in Joining Monel 400 to Steel (Fig. 8)

Welding of a Monel 400 skirt box to a low-carbon steel (ASTM A285) cover for a fluorine generator resulted in cracking of the weld metal and warping of the cover. The Monel 400 skirt boxes replaced low-carbon steel skirt boxes that had corroded.

The original procedure for removing corroded skirt boxes, making new boxes, and welding the new boxes to the cover plate was as follows:

1 Remove corroded low-carbon steel skirt boxes by air carbon-arc cutting.
2 Clean surfaces of low-carbon steel cover by surface grinding.
3 Clean all joint areas on the Monel 400 plates with trichlorethylene, and remove mill scale with a surface grinder.
4 Assemble Monel 400 skirt box and weld the four corners in one pass each with a 5/32-in.-diam ENiCu-4 (Monel 130) electrode, using a welding current of 130 amp.
5 Weld the Monel 400 skirt box to the low-carbon steel cover with intermittent welds, using the sequence of weld-bead deposition shown in Fig. 8(b). (The box and cover were first tack welded at the starting place for each of the 10-in.-long welds.) Deposit five beads, as shown in Fig. 8(c), with a 5/32-in.-diam ENiCu-1 (Monel 140) electrode, using a welding current of 154 amp.
6 Stress relieve at 1150 ± 25 F for 1 hr in a reducing atmosphere. (The assembly was placed in the furnace when furnace temperature was less than 600 F, and after heating was allowed to cool to 600 F before it was removed.)
7 Test the welds with a helium mass spectrometer under an internal vacuum of 0.025 mm of mercury. Welds that failed the test were rewelded.

During deposition of the first bead, considerable arc blow toward the Monel 400 skirt box was encountered. The ground connection was repositioned several times, but no improvement was obtained. When the welds were tested with a helium mass spectrometer, leakage due to cracks in the weld beads was detected. Investigation revealed that some cracks had resulted from excessive dilution of the weld metal by iron (analysis showed 30% iron in bead 1 in Fig. 8c), a result of the high welding heat, and that cracks in the weld craters had been caused by ending beads too abruptly. In addition to the cracking, there was excessive distortion of the cover, the cover edges being warped upward toward the skirt boxes, 1/8 in. max along the sides and about 1/4 in. across the ends. The distortion was not reduced during stress relieving (step 6).

Experimentation resulted in the adoption of a new welding procedure (step 5) that minimized distortion and eliminated weld-metal cracking. (The remaining steps in the original procedure were retained unchanged.) In this procedure, when welding the box to the cover plate, both parts were securely clamped to a welding surface plate. The sequence of weld-bead deposition was the same as for the original method (Fig. 8b), but only three weld beads were deposited (Fig. 8d). Bead 1 was laid mostly on the Monel 400, which resulted in considerably less dilution by iron (7% compared with 30%). The bead was ended very slowly so as to avoid the danger of subsequent crater cracking. The welds were made with a slightly larger electrode than originally (3/16-in.-diam ENiCu-1 instead of 5/32-in.-diam) and using 145 to 150-amp welding current instead of 154-amp. These modifications reduced the current density and thus the heat input.

When the clamps were released, no significant distortion of the cover plate was observed, and all joints passed the helium leak-detection test. Details of the original and improved methods are given in the table that accompanies Fig. 8.

Arc Welding of Titanium and Titanium Alloys

*By the ASM Committee on Fabrication of Titanium**

TITANIUM and most titanium alloys can be welded by the gas tungsten-arc, plasma-arc, and gas metal-arc processes; procedures and equipment are generally similar to those used for welding austenitic stainless steel or aluminum. However, because titanium and titanium alloys are extremely reactive above 1000 F, more care must be taken to shield the weld and the hot root side of the joint from air than is required during the welding of austenitic stainless steel or aluminum alloys (see comparison of setups in Fig. 1).

Weldability

Unalloyed titanium and all of the alpha titanium alloys are weldable. The alpha-beta alloy Ti-6Al-4V and other weakly beta-stabilized alloys are also weldable, but strongly beta-stabilized alpha-beta alloys are embrittled by welding. Most beta alloys can be successfully welded. However, heat treatment to strengthen the weld by age hardening should be used with caution because aged welds in some beta alloys can be quite brittle.

Unalloyed titanium is generally available in several grades ranging in purity from 98.5 to 99.5% titanium. All grades usually are welded in the annealed condition, rather than in the cold worked condition.

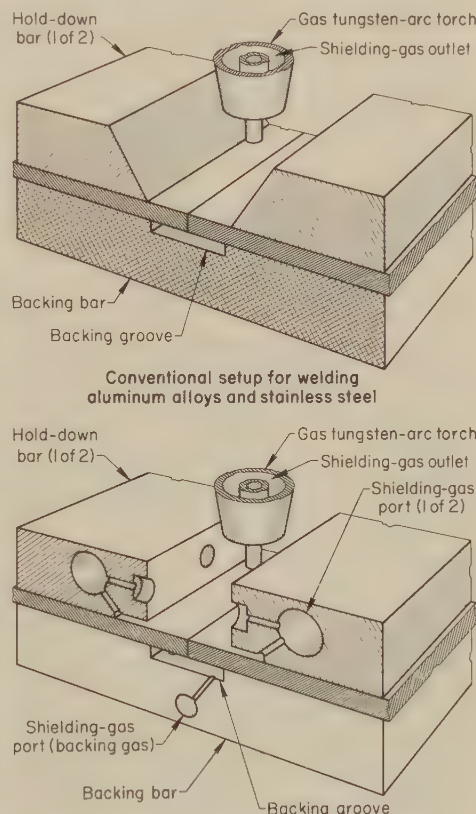
Alpha alloys Ti-5Al-2.5Sn, Ti-5Al-5Sn-5Zr, Ti-7Al-12Zr, Ti-6Al-2Cb-1Ta-1Mo and Ti-8Al-1Mo-1V are always welded in the annealed condition.

Alpha-Beta Alloys. Ti-6Al-4V can be welded in the annealed condition or in the solution-treated and partially aged condition, with aging being completed during postweld stress relieving.

In contrast to unalloyed titanium and the alpha alloys, which can be strengthened only by cold work, the alpha-beta and beta alloys can be strengthened by heat treatment.

The low weld ductility of most alpha-beta alloys is caused by phase transformations in the weld zone or in the heat-affected zone. Alpha-beta alloys have been welded with unalloyed titanium or alpha titanium alloy filler metals to lower the beta content of the fusion zone and improve weld ductility. The use of such filler metals does not prevent embrittlement of the heat-affected zone in susceptible alloys. Low-alloy welds can be embrittled by hydride precipitation.

Beta alloys Ti-3Al-13V-11Cr, Ti-4.5Sn-6Zr-11.5Mo, Ti-8Mo-8V-2Fe-3Al, and Ti-3Al-8V-6Cr-4Zr-4Mo are weldable in the annealed or heat treated condition. Welds are low in strength but ductile in the as-welded condition, and beta-alloy weldments are most often used in this condition. Welds in the Ti-3Al-13V-11Cr alloy embrittle more severely when age hardened. To obtain full strength, the beta alloys can be welded in the annealed condition, the weld cold worked by peening or planishing, and the weldment then solution treated and aged. With this procedure, adequate ductility may be obtained in the weld.



(Upper view) For welding aluminum alloys and stainless steel, gas shielding is from the torch, use of shielding gas in the backing groove being optional. *(Lower view)* For welding titanium and titanium alloys outside a welding chamber, gas shielding is from the torch and through ports in hold-down bars and backing bars.

Fig. 1. Typical setups for inert-gas shielding for gas tungsten-arc welding

Welding Processes

Gas tungsten-arc welding is the process that is most widely used for joining titanium and titanium alloys. Square-groove butt joints can be welded without filler metal in base metal up to 0.10 in. thick. For thicker base metal, the joint should be grooved and filler metal is required.

Plasma-arc welding is applicable to the welding of titanium and titanium alloys (see the article on Plasma-Arc Welding, which begins on page 138). Plasma-arc welding is faster than gas tungsten-arc welding and also can be used on thicker sections. For instance, titanium alloy plate up to ½ in. thick can be welded in one pass, using square-groove butt joints and the keyhole technique.

Gas metal-arc welding is used for joining titanium and titanium alloys more than ⅛ in. thick, and is less costly than gas tungsten-arc welding, especially when base-metal thickness is greater than ½ in. Titanium and titanium alloys are also welded by the electron beam process; this process is described in the article "Electron Beam Welding", which begins on page 519.

Filler Metals

Fourteen titanium and titanium alloy filler-metal (or electrode) classifications are given in AWS A5.16-70. Five of these are essentially unalloyed titanium and the remainder are titanium alloy filler metals.

Maximums are set on carbon, oxygen, hydrogen and nitrogen contents. The compositions of two grades of ERTi-6Al-4V filler metal are as follows:

	ERTi-6Al-4V	ERTi-6Al-4V-1
Carbon	0.05 max	0.04 max
Oxygen	0.15 max	0.10 max
Hydrogen	0.008 max	0.005 max
Nitrogen	0.020 max	0.012 max
Aluminum	5.5-6.75	5.5-6.75
Vanadium	3.5-4.5	3.5-4.5
Iron	0.25 max	0.15 max

For welding titanium thicker than about 0.10 in. by the gas tungsten-arc process, a filler metal must be used. For plasma-arc welding, a filler metal may or may not be used for welding metal less than ½ in. thick.

Filler-metal composition is usually matched to the grade of titanium being welded. For improved joint ductility in welding the higher-strength grades of unalloyed titanium, filler metal of yield strength lower than that of the base metal is sometimes used. For the same reason, unalloyed filler metal has been used to weld Ti-5Al-2.5Sn and Ti-6Al-4V.

The filler metal, as well as the base metal, should be clean at the time of welding. As shown in Fig. 2, wires of the size used for filler metals have a large surface area compared to volume, and therefore if the wire surface is slightly contaminated, the weld may be severely contaminated. Some procedures require that the filler wire be cleaned just before use.

Shielding Gases

Only argon and helium are used for shielding in welding titanium and titanium alloys. Sometimes, a mixture of these two gases is used.

Argon is more widely used than helium because it is more readily available and less costly. Argon was used in each of the four examples presented in this article.

Arc characteristics are affected by the type of shielding gas used. At a given welding current, the arc voltage is much greater with helium than with argon. Because the heat energy liberated in helium is about twice that in argon, higher welding speeds can be obtained, weld penetration is deeper, and thicker sections can be welded more rapidly using helium shielding.

Argon is used in the welding of thin sections, where less heat is required and the arc length can be changed without appreciably changing the heat input. This is a less important factor in automatic welding than in manual welding, because it is easier to control arc length in automatic welding. Helium is often used as the shielding gas at the torch in automatic operations.

Joint Preparation

If welding is done outside a welding chamber, joints must be carefully designed so that both the top and the underside of the weld can be shielded (see the setup in Fig. 1). Dimensions of typical joints are given in Table 1.

For welding titanium alloys, joint fit-up should be better than for welding other metals, because of the possibility of entrapping air in the joint. The joint should be clamped so that no separation occurs during welding.

Cleaning

To obtain a good weld, the joint and the surfaces of the workpieces back at least 1 in. on either side of the joint must be meticulously cleaned. As shown in the flow chart of Fig. 3, the cleaning procedure depends on whether the oxide layer in the joint area is light or heavy.

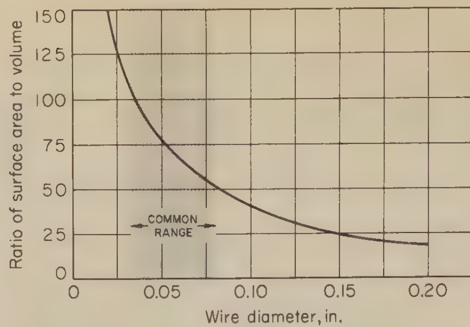

Fig. 2. Ratio of filler-metal (electrode) wire surface area to volume for various wire diameters. Shaded portion indicates range of wire diameters most often used for welding titanium.

(a) Root face, 0.030 in.

Grease and oil accumulated during forming and machining must be removed before welding to avoid weld contamination. Scale-free metal can be degreased only. Metal with an oxide scale is degreased before descaling. Degreasing can be accomplished by steam cleaning, alkaline cleaning, vapor degreasing, or solvent cleaning.

For vapor degreasing, toluene rather than a chlorinated solvent should be used, because residues from chlorinated solvents (and also from silicated solvents) may contribute to cracking of titanium weldments.

Solvent cleaning is frequently used, especially for large components that cannot conveniently be placed in a vapor degreaser or in a washer for alkaline cleaning. Solvents used include methyl ethyl ketone, toluene, acetone, and other chlorine-free solvents. Methyl alcohol is reported to have caused stress corrosion and is, therefore, prohibited for use on aerospace hardware. The joint areas are hand wiped with the solvent just before welding. All wiping should be done with clean, lint-free cloths or a cellulose sponge. Plastic gloves should be worn; rubber gloves are likely to leave traces of plasticizer, which can cause porosity in the weld metal. Handprints are also a source of contamination.

After a lightly oxidized joint area has been degreased, it should be pickled for a short time. A mixture of 4% hydrofluoric acid and 40% nitric acid (by weight) is typical. Pickling should be done cautiously because hydrogen is detrimental to the properties of titanium, causing embrittlement and sometimes contributing to weld porosity. Industrial practice usually is to maintain the acid bath at a high oxidation potential of 30% or more nitric acid by weight. With nitric acid maintained at 30% by weight, the ratio of HNO_3 to HF is then maintained at 15 to 1 strictly as a factor of safety. (For additional discussion, see "Acid Pickling" on page 665 in volume 2 of this Handbook.) If the nitric acid content falls below 30% by weight and the ratio of HNO_3 to HF falls below 10 to 1, excessive hydrogen pickup is possible.

Lightly oxidized joint areas may also be cleaned by brushing with a stainless steel wire brush or by draw filing. However, if such cleaning methods are used, they should be immediately followed by acid pickling when weld corrosion resistance is important. Steel wool or abrasives should never be used, because of the danger of contamination.

If titanium has been exposed to temperatures above 1000 F, the scale formed is thicker than the scale formed below 1000 F. Removal of the heavier scale requires a more complex treatment. Chemical, salt bath, or mechanical treatments, or combinations of these treatments are used. The salt baths are basically sodium hydroxide to which oxidizing agents or hydrogen have been added to form sodium hydride (see the articles on Salt Bath Descaling and Cleaning and Finishing of Titanium Alloys, beginning on pages 356 and 664, respectively, in Volume 2 of this Handbook).

Two alternative procedures for removing heavy scale are shown by the flow chart in Fig. 3. In one, the parts are subjected to liquid abrasive blasting or salt bath descaling after degreasing. These treatments are usually followed by pickling in nitric-hydrofluoric acid, as for the removal of light scale. When salt bath descaling is used, oxide removal can be hastened by removing the workpieces from the bath, scrubbing them with brushes, and then re-immersing them. To prevent hydrogen pickup during salt bath descaling, time cycles must be short (preferably no more than 2 min) and bath temperature must be carefully controlled.

In the alternative method described in Fig. 3, parts are alkaline cleaned after grease removal (unless alkaline cleaning was used for grease removal), and then pickled, rinsed, and dipped in a sodium dichromate solution.

Selection of cleaning method depends largely on the size and shape of the parts and on the cleaning methods available in a particular plant.

Welding in Chambers

For successful arc welding of titanium and titanium alloys it is necessary to have complete shielding of the weld because of the high reactivity of titanium to oxygen and nitrogen at welding temperatures.

Excellent welds can be obtained in titanium and its alloys in a welding chamber, where welding is done in a protective gas atmosphere, thus giving adequate shielding. Welding in a chamber, however, is not always practical. In manual welding, for example, the location of the glove ports and the presence of a chamber wall impose limitations on visibility, movement and accessibility. This is true to some extent even when the wall is transparent, as in plastic chambers.

For large assemblies, welding in a chamber requires unloading of the chamber after each weldment is completed and loss of purging gas. The chamber must be repurged for welding the next assembly. Such procedures are time consuming and expensive.

Various types of modified chambers have been tried, such as clamp-on chambers.

Welding in Metal Chambers. Welding of titanium was first done in metal chambers that could be evacuated and then backfilled with argon or helium. Such chambers are equipped with glove ports, so that the welder can handle the torch, separate filler metal (if used), and the weldment without admitting air to the chamber, and with viewing ports, so that the welder can see what he is doing.

Generally, shielding gas is not supplied to the welding torch when welding titanium in a metal chamber, and excellent welds can be made if the chamber atmosphere is maintained properly. However, in some applications where heavy or long welds are required, gas is supplied to the torch to improve shielding (see Example 357).

Although metal chambers are expensive to use, especially for large weldments, they often are used in aerospace applications.

With flow-purged chambers, the atmosphere is often tested by welding a piece of scrap titanium before making the assembly weld. The color of the solidified weld metal is observed by gradually pulling the torch away from the molten puddle. The weld-metal colors, in increasing order of contamination, are: bright silver, light straw, dark straw, light blue, dark blue, gray-blue, gray, and white loose powder. A light straw color generally is considered acceptable for all but the most stringent requirements.

To monitor the inert atmosphere continuously, a heated tungsten filament may be placed inside the chamber. Any discoloration of the filament indicates that the purity of the atmosphere has become degraded.

Figure 7 in the article on Gas Tungsten-Arc Welding shows the relation of purging time and gas flow rate to the number of volume changes needed for replacing air with argon in a chamber. Example 133 in the same article describes the welding of a zirconium alloy in a chamber.

In the example that follows, a Ti-6Al-4V hydrofoil center strut subassembly was welded in a metal chamber. This subassembly was part of the complete strut assembly shown at the top in Fig. 4. Procedures for welding the leading-edge and trailing-edge strut subassemblies, and for welding them to the center section, are given in Examples 358 and 359, respectively.

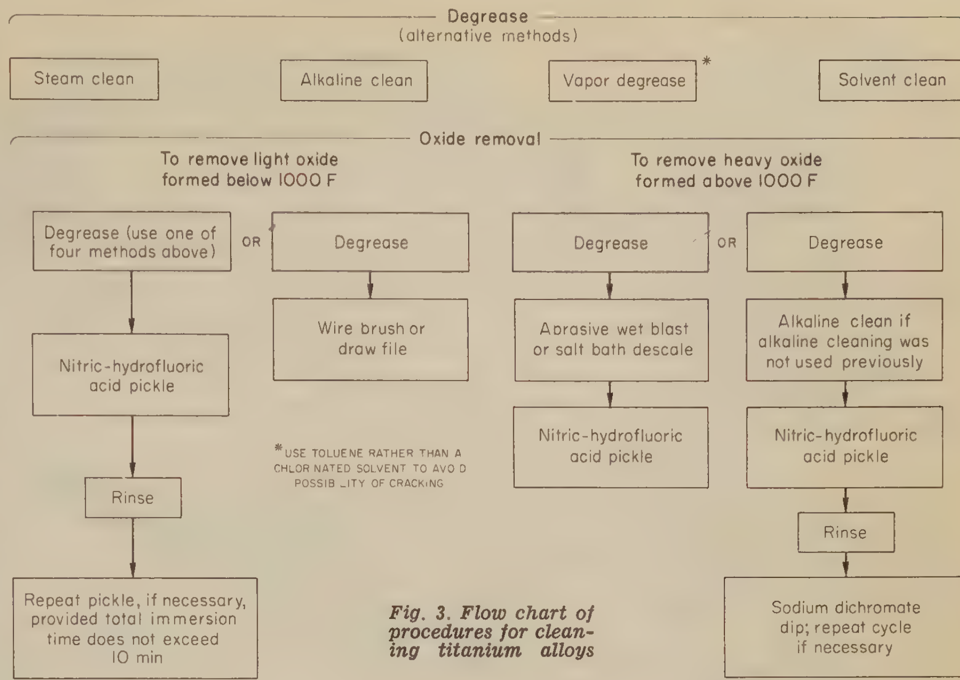

Fig. 3. Flow chart of procedures for cleaning titanium alloys

Example 357. Welding a Hydrofoil Center Strut Subassembly in a Metal Chamber (Fig. 4)

The center strut subassembly of the complete hydrofoil strut assembly shown at the top of Fig. 4 consisted of two machined pieces of Ti-6Al-4V, approximately 112 in. long by 12 in. wide, which were welded by the manual gas tungsten-arc process in a metal chamber 3½ ft in diameter by 24 ft long equipped with four welding ports. The chamber was flow-purged with argon at a slight positive pressure, and was equipped with a fixture-positioner that allowed 360° rotation of the work, if needed, and full conveyance of the workpiece past all of the welding ports. The two components were clamped in a welding fixture, as shown at lower right in Fig. 4, and the fixture was placed in the positioner. The components were clamped at approximately 18-in. intervals along the 112-in. length. Manual welding was used because variations in contour and cross section, limited accessibility, and the small quantity of production weldments that were required ruled out automatic welding.

Before welding, the parts were solution heat treated at about 1750 F, water quenched, and partially aged at 950 F for 4 hr. The joint areas were degreased, alkaline cleaned, and acid pickled in a mixture of concentrated acids (30 volumes of 42° Bé nitric acid and 2 volumes of 70% technical-grade hydrofluoric acid) at room temperature for 5 min. Welding was started within 4 hr after pickling. Workpieces were maintained within the welding chamber until all welds were completed.

The root pass was made without filler metal, to ensure complete root penetration and to minimize burn-through. To obtain the required notch toughness in the joint, the second pass was made with unalloyed titanium filler metal (ERTi-1), although this decreased the strength of the joint slightly. Subsequent passes were made with ERTi-6Al-4V filler metal.

Straight-polarity direct current was supplied from a 300-amp transformer-rectifier with a saturable-core reactor and conventional drooping-voltage characteristic. A foot rheostat controlled the current to the electrode. After welding, the assembly was heat treated at 950 F for 4 hr in argon to complete age hardening, partially relieve welding stresses, and increase weld ductility.

The weld chamber atmosphere was checked periodically by the following tests: weld-bead color, test-coupon weld-bend ductility, dew point, and a heated tungsten filament. All assemblies were examined visually and inspected by dye-penetrant and radiographic methods. Also, representative sample welds were tested mechanically and examined metallographically as a further check on weld quality.

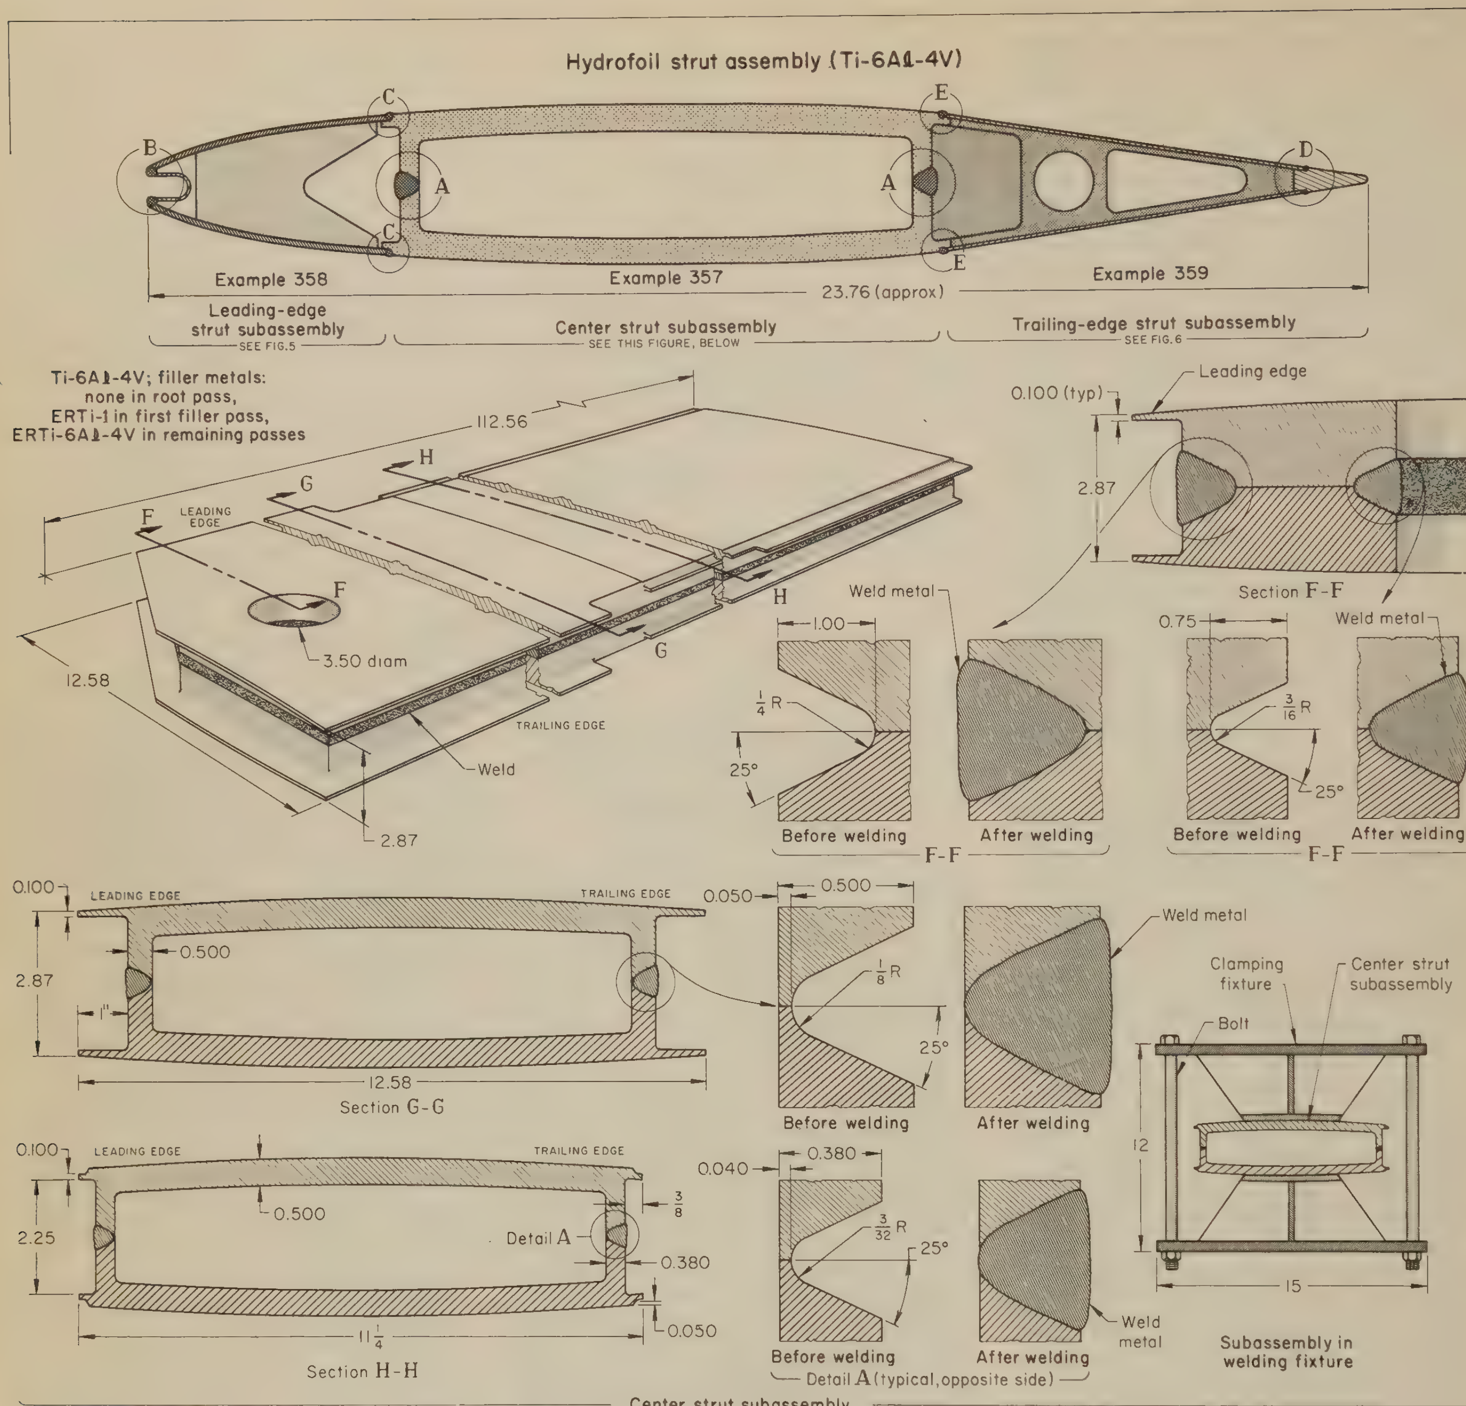
Further details of the welding operation are given in the table with Fig. 4.

Welding in Plastic Chambers. Rigid or collapsible chambers made of transparent plastic can be used where production runs are short, the assembly is large or complicated, and manual welding is required. Rigid plastic chambers are flow-purged with argon or helium, in volumes equal to five to ten times the volume of the chamber, before welding is started. Collapsible plastic chambers are first collapsed and then flow-purged with argon or helium; they require less gas for purging than do rigid chambers.

Advantages of plastic chambers (either rigid or collapsible) are low cost and good visibility of the work. Because there is generally a greater probability of leakage occurring in a plastic chamber than in a metal chamber, the atmosphere must be checked frequently to ensure that it is of proper purity. In addition, torch shielding is usually employed, to make certain that the weld zone is adequately protected. The two examples that follow describe welding in plastic chambers.

Examples 358 and 359. Use of a Plastic Chamber for Welding of Hydrofoil Leading-Edge and Trailing-Edge Strut Subassemblies

A reinforced, collapsible plastic chamber, 3 ft high by 3 ft wide by 20 ft long, having three welding ports, was used for manual gas tungsten-arc welding of hydrofoil leading-edge and trailing-edge strut subassemblies of Ti-6Al-4V alloy and for joining them to a center strut subassembly (see Example 357). The chamber was flow-purged with argon at a slight positive pressure. Purity of the chamber atmosphere was checked by weld-bead color and weld-



Joint type	Butt

bend tests on Ti-6Al-4V test pieces, by a hot tungsten filament in the chamber, and by dew-point measurements.

Manual welding was used because accessibility difficulties and costs precluded automatic welding. All welding was done on components that had been solution treated, water quenched, and partially age hardened (950 F for 4 hr).

Joints were machined smooth, degreased in an alkaline cleaner, and pickled in a mixture of concentrated acids (30 volumes of 42° Bé nitric acid and 2 volumes of 70% technical-grade hydrofluoric acid) at room temperature for 5 min. Welding was started within 4 hr after pickling. Parts remained in the welding chamber until all welds were completed.

Straight-polarity direct current was supplied by a 300-amp transformer-rectifier with a saturable-core reactor and conventional drooping-voltage characteristic. Welding current was controlled with a foot rheostat. Although Ti-6Al-4V has good weldability, copper chill bars were placed adjacent to all welds to increase the cooling rate and improve weld ductility. Chill

Fig. 5. Hydrofoil leading-edge strut subassembly welded by the manual gas tungsten-arc process in a plastic chamber (Example 358)

bars were held in close contact with the joint by simple toggle clamps.

After welding, the parts were heated to 950 F and held for 4 hr to complete age hardening, partially relieve stresses, and increase the ductility of the welds.

Welds were examined visually and inspected by dye-penetrant and radiographic methods on each weldment. In addition, representative samples welded at the same time as the production assemblies were tested for mechanical properties and were examined metallographically.

Mechanical properties of the welds were controlled primarily through filler-metal selection, as shown in the following comparison of minimum weld properties (weld metal only) obtained using two different filler metals:

Filler metal	Tensile strength, psi	Yield strength, psi	Elongation, % in 2 in.
Unalloyed Ti	100,000	90,000	5.0
ERTi-6Al-4V	130,000	120,000	4.0

Example 358 — Leading-Edge Strut Subassembly (Fig. 5). Several welds had to be made in a Ti-6Al-4V hydrofoil leading-edge strut subassembly. First, two curved panels, 83 in. long by 4.62 in. wide and 0.100 in. thick, were joined to a U-shape insert, 83 in. long and 0.050 in. thick, by square-groove edge welding (Fig. 5, section J-J and detail B). Next, truncated triangular ribs, 0.100 in. thick, were welded to the panels at 15-in. intervals, using a 0.100-in. fillet weld on one side of each rib (section K-K in Fig. 5). Finally, the open side of the subassembly was welded to the center subassembly (see Fig. 4), using single-V-groove welds (detail C in Fig. 5).

Copper chill bars were used as shown in Fig. 5. Where greater ductility was required, as in the joint shown in section K-K in Fig. 5, unalloyed titanium filler metal (ERTi-1) was used. Where greater strength was required, as in the joints shown in detail C of Fig. 5, ERTi-6Al-4V filler metal was used. Tack welding was employed as needed. Further details of the welding operation are given in the table that accompanies Fig. 5.

For details of welding the center strut subassembly and for a view of the completed hydrofoil strut assembly, see Example 357 and Fig. 4. Details for welding the trailing-edge strut subassembly and for joining it to the center strut subassembly are given in Example 359 and Fig. 6.

Example 359 — Trailing-Edge Strut Subassembly (Fig. 6). In fabricating a Ti-6Al-4V hydrofoil trailing-edge strut subassembly, two straight panels 63 in. long by approximately 7 in. wide and 0.050 in. thick were welded to a solid triangular piece, as shown in detail D of Fig. 6, using V-groove butt joints. Stiffeners 0.100 in. thick were joined to the panels at 15-in. intervals by fillet welds as shown by section M-M in Fig. 6. The stiffeners were also plug welded to the panels at 1-in. intervals on one side, as shown in section N-N of Fig. 6. The purpose of plug welding was to provide additional stiffener-to-panel attachment in areas where there were no fillet welds because of lack of accessibility. On the side where fillet welds were continuous, no plug welding was needed. Finally, the trailing-edge strut subassembly was welded to the center strut subassembly (detail E, Fig. 6).

Copper chill bars were used adjacent to the butt welds, as shown in Fig. 6. Where good ductility was required, as in the joints shown in detail D and in sections M-M and N-N of Fig. 6, unalloyed titanium filler metal (ERTi-1) was used. Where greater strength was required, as in the joints shown in detail E of Fig. 6, Ti-6Al-4V filler metal was used. Tack welding was employed as required. Further details of the welding operation are given in the table accompanying Fig. 6.

For details of welding the center strut subassembly and for a view of the completed hydrofoil strut assembly, see Example 357 and Fig. 4. Details for welding the leading-edge strut subassembly and for joining it to the center strut subassembly are given in Example 358 and Fig. 5.

Out-of-Chamber Welding

With proper tooling, joints in titanium can be adequately shielded for welding without using a chamber. Both the weld and the heat-affected zones

(a) Occasionally, nozzle was removed for better accessibility to the joint. (b) Flow-purge with slight positive pressure. (c) Fillet welds were made in the horizontal position; plug welds were made in the flat position.

For details of welding the center strut subassembly and for the completed view of the hydrofoil strut assembly, see Example 357 and Fig. 4. For details of welding the leading-edge strut subassembly, see Example 358 and Fig. 5.

Fig. 6. Hydrofoil trailing-edge subassembly welded by the manual gas tungsten-arc process in a plastic chamber (Example 359)

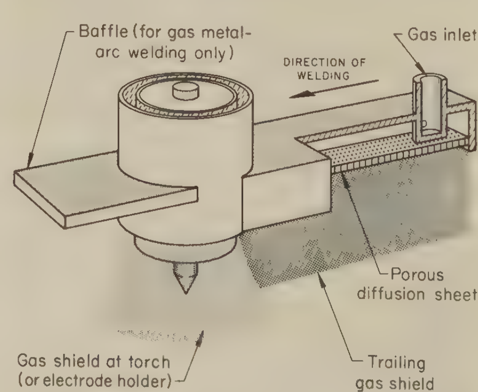
must be shielded during welding and until the temperature of the metal in the area of the weld is below 1000 F. If shielding is inadequate, the welds will be brittle.

The welding torch (or electrode holder) is usually equipped to supply a trailing shield that provides a diffuse, nonturbulent flow of gas to the solidifying weld. A typical trailing shield is shown in Fig. 7. The length of the trailing shield must be adjusted to the speed of welding. Both straight and curvilinear welding can be shielded. The welding station must be shielded by curtains to prevent drafts.

In the following example, titanium alloy straps were welded in air — with adequate shielding — when production in a clamp-on chamber proved clumsy and time consuming.

Example 360. Welding Ti-6Al-4V in Air, Using a Continuous, Enveloping Flow of Argon (Fig. 8)

Because of their length (36 to 42 ft), Ti-6Al-4V fail-safe straps for C-5A transport airplanes were made by welding together two or more pieces, using the manual gas tungsten-arc process. A typical 6-in.-wide joint in a 40-ft-long by 0.188-in.-thick fail-safe strap is shown in Fig. 8 (upper left). Because the straps were too long for the available vacuum welding chamber, a special shielding method had to be developed.



The baffle shown on the leading side of the torch (or electrode holder) is seldom used for gas tungsten-arc welding, but it is used for gas metal-arc welding (see the section in this article on Gas Metal-Arc Welding).

Fig. 7. Arrangement for shielding in automatic welding of titanium alloys in air

The first attempt at providing adequate shielding was to construct a clamp-on displacement chamber, approximately 3 ft long, 2 ft wide and 2 ft high. This chamber contained glove ports, a viewing port, an argon flow control system, a flapper valve for venting excess gas pressure, a feedthrough plate for torch leads, and slots at both ends for the fail-safe straps to pass through. Several straps were manually gas tungsten-arc welded in the chamber, and although weld quality was satisfactory, it was apparent that this method of shielding was too clumsy and time consuming for production use.

A second method, based on flooding the immediate area of the 6-in.-long weld with a continuous flow of argon, proved successful (Fig. 8, left and section B-B), and was simpler to operate. The joint to be welded was centered over the groove of a copper backing bar that was set flush with the surface of a long aluminum support plate (Fig. 8, section B-B). The entire assembly was placed on a long welding table. Next, two copper hold-down bars were bolted tightly in place, ½ in. on either side of the joint. The hold-down bars and the backing bar had been drilled so that shielding gas could be supplied by manifolding arrangements, as shown in Fig. 8 (view at bottom left, and section B-B). This tooling provided a heat sink, good joint alignment, effective gas shielding, and a high degree of

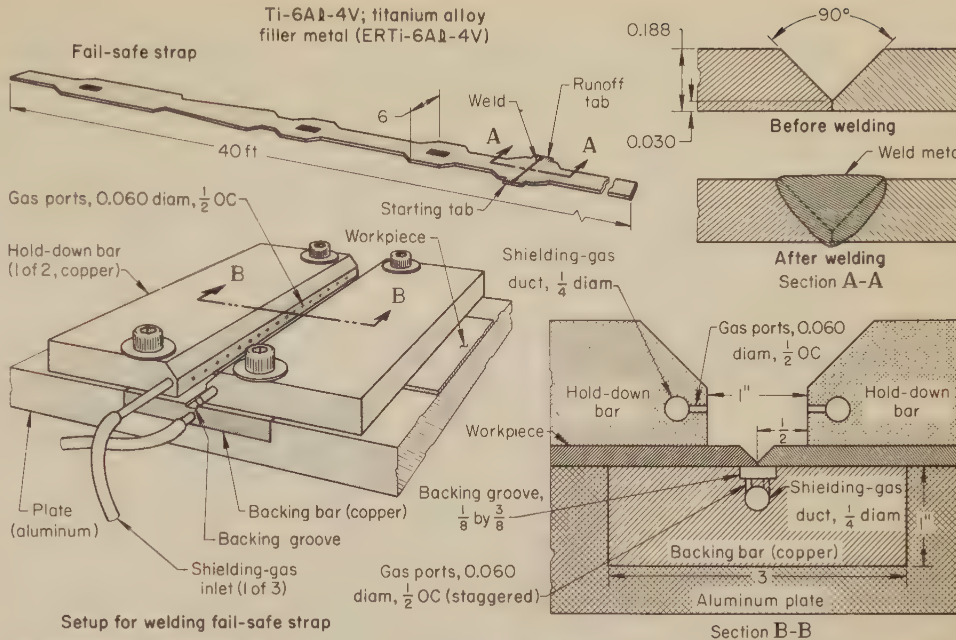
accessibility. Additional argon shielding gas was supplied through the torch.

Joints were provided with integral starting and runoff tabs. A tack weld was placed on the runoff tab, and welding was started at the opposite end and completed in a single pass, using the forehand technique (filler metal preceded the torch in the direction of welding). Details of the cleaning and welding operations are summarized in the table that accompanies Fig. 8.

First results, which were used to qualify the procedure, were quite satisfactory. On both sides, the weld color resembled that of newly minted silver. Radiographic and dye-penetrant examination showed no defects. Specimens bent over a 6*t* (1⅛ in.) radius showed no cracks on the outer surface at a magnification of 10×. All tension-test specimens failed in the base metal at 135,000 psi or more.

Specifications called for testing three preproduction specimens and one postproduction specimen per lot. The first production lot consisted of 16 straps. The test specimens and the 16 production welds were inspected by visual, radiographic and dye-penetrant methods. All welds were acceptable under visual and dye-penetrant examinations, and only two production welds showed slight porosity (which could be repaired) under radiographic examination. Two bend-test specimens and one tension-test specimen were machined from the postproduction weldment. Bend tests showed no cracks at 10× magnification, and the tension-test specimen failed in the base metal at 140,000 psi.

In general, welds made with this shielding technique were comparable in quality to those obtained in a conventional welding chamber, and better than those obtained in the clamp-on displacement chamber. Making a weld in the clamp-on displacement chamber required 60 min and 100 cu ft of argon, compared to 10 min and 15 cu ft of argon for the out-of-chamber technique.



Preweld Cleaning

Degrease	In hot alkaline cleaner, 15 min; brush; rinse in hot tap water
Pickle	In solution of 20% nitric acid – 3% hydrofluoric acid, 30 sec; rinse in hot, then cold, tap water
Final rinse	In deionized water; dry; weld within 4 hr or reclean

Conditions for Gas Tungsten-Arc Welding

Filler metal	⅛-in.-diam ERTi-6Al-4V	Through backing bar	Argon, at 15 cfh
Current	155 to 195 amp, dcsp	Through hold-down bars	Argon, at 40 cfh
Voltage	12 to 16 v	Welding time	About 4.5 min per joint

(a) With 0.030-in. root face

Fig. 8. Tooling setup for supplying shielding gas to the weld area for gas tungsten-arc welding of the military fail-safe strap shown (Example 360)

Equipment for Gas Tungsten-Arc Welding

Transformer-rectifiers are the preferred power supply for welding titanium, because the current can be controlled more closely than with motor-generator sets; slight variations in welding current may cause variations in penetration.

Straight-polarity direct current (dcsp) is always used for gas tungsten-arc welding of titanium because deeper weld penetration and a narrower bead can be obtained than with reverse-polarity direct current (dcrp). Also, in manual welding, straight-polarity current is easier to control.

The power supply should also include accessories for arc initiation because of the danger of tungsten contamination of the weld if the arc is struck by touch starting. If welding is to be done in air, controls for extinguishing the arc without pulling the torch away from the workpiece are needed, so that shielding-gas flow will continue and the hot weld metal will not be contaminated by air. For further details on power supplies and other equipment, see the article on Gas Tungsten-Arc Welding, pages 113 to 137.

Electrodes for welding titanium are of the conventional thoriated tungsten type (EWTh-1 or EWTh-2). The electrode tip is tapered to improve arc initiation and control the spread of the arc.

Shielding. To ensure a diffuse, nonturbulent flow of shielding gas, nozzles of the torches for welding titanium are larger than those used for welding other metals. With a 1/32-in.-diam electrode, a 9/16-in.-ID nozzle is ordinarily used, and with a 1/16-in.-diam electrode, a ¾-in.-ID nozzle. Phenolic or other plastic nozzles should not be used, because there is danger of contaminating the weld with carbon.

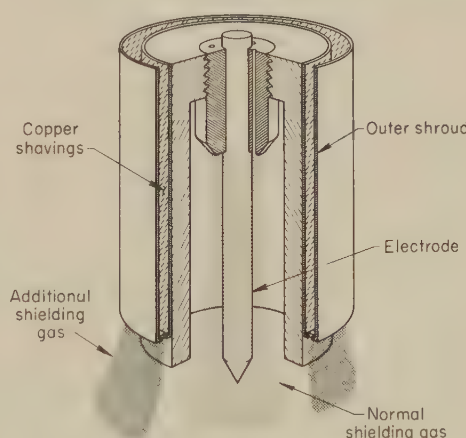

Fig. 9. Sectional view of a torch nozzle equipped with an outer shroud containing copper shavings to provide additional gas shielding for manual inert-gas welding

Because titanium has low thermal conductivity, the area ahead of the arc does not get heated above 1000 F, and therefore leading shields are seldom required when welding is done by the gas tungsten-arc process. For welding operations where a trailing shield such as shown in Fig. 7 is not adaptable, the nozzle of the torch is fitted with a concentric outer shroud through which is fed a supplementary supply of shielding gas. Such a torch is shown in Fig. 9. Here shielding gas is diffused through copper shavings, contained in the outer shroud, which cool the gas substantially, helping to protect the metal near the weld.

Shielding of the underside of a weld is provided by slotted backing bars, usually copper, through which a diffuse flow of argon or helium is maintained (see Fig. 1 and 8). Gas channels in the clamping fixtures also provide diffuse flow of inert gas to the weld area. These fixtures are placed close to the weld so that there is no danger of air contamination (see Fig. 8).

Fixtures. Copper fixtures are usually used. Other metals are sometimes used, but they should be nonmagnetic; otherwise, arc blow is likely to occur. Metal fixtures sometimes are water cooled, although water cooling introduces the possibility of moisture from the air condensing on the fixtures.

Procedures for Gas Tungsten-Arc Welding

Generally, procedures for gas tungsten-arc welding of titanium alloys are similar to those used for austenitic stainless steel.

Preheating. Titanium alloys do not require preheating. Although cracking may occur in titanium alloy weld-

(a) Flat-position welding. (b) A = argon; He = helium.

ments, it is most often related to contamination, and cannot be prevented by preheating. Also, there is no need for maintaining a specific interpass temperature.

Tack welding is used to pre-position parts or subassemblies for final welding operations. Elaborate fixturing often can be eliminated when tack welds are used to their full advantage. Various tack welding procedures can be used, but in any procedure good cleaning practices and adequate shielding must be provided to prevent contamination of the welds. Contamination or cracks developed in tack welds can be transferred to the finish weld. One procedure is to tack weld in such a way that the finish weld never crosses over a previous tack weld. To accomplish this, sufficient filler metal is used in tack welding to completely fill the joint at a particular location. The finish weld beads are blended into the ends of the tack welds.

Arc Length. As with stainless steel and the nickel-base alloys, the maximum arc length for welding without filler metal should be about equal to the electrode diameter. With longer arc length, there is danger of turbulence, which may draw air into the weld puddle. Also, long arc length produces wider weld beads than short arc length.

When filler metal is used, the maximum arc length should be about 1½ times the electrode diameter, depending on the thickness of the base metal.

Welding Conditions. Conditions that have been used for gas tungsten-arc welding of Ti-6Al-4V sheet are given in Table 2.

In welding titanium alloys, it is best to use a heat input just above the minimum required to produce the weld. If a greater heat input is used, the possibility that the weld will become contaminated, distorted or embrittled is increased.

Avoiding porosity in welds is an important consideration in welding titanium alloys. If the joints and filler wire are properly cleaned and the tooling does not chill the weld too rapidly, porosity can be reduced or eliminated by using a slower welding speed, which will retard weld solidification and allow entrained gases to escape.

Gas Metal-Arc Welding

Gas metal-arc welding is normally used for welding titanium and titanium alloys ⅛ in. or more thick. It has been used to a considerable extent for welding ½-in. plate.

Metal transfer through the arc in gas metal-arc welding can lead to difficulty in meeting stringent aerospace quality requirements. For example, weld spatter is often associated with inferior weld quality, and arc instability, which can occur in gas metal-arc welding, is a potential cause of weld contamination and defect formation. Some users of titanium alloys prefer gas tungsten-arc welding over gas metal-arc welding (even for joining thick plate), because with the gas tungsten-arc process more uniform and predictable transverse shrinkage is obtained.

Electrode wires for gas metal-arc welding are available in several grades of unalloyed titanium and in titanium alloys that match the composition of the base metal.

Joint preparation and cleaning procedures are the same as those described earlier in this article.

Typical conditions for gas metal-arc welding of Ti-6Al-4V and Ti-5Al-2.5Sn plate are given in Tables 3 and 4.

Ti-7Al-12Zr	1200	3
	1300	¾

(a) Data apply also to extra-low-interstitial (ELI) modification of the two alloys noted.

Shielding for out-of-chamber welding is provided by inert gas being fed through the nozzle of the electrode holder, through the backing bar or plate, and as a trailing shield, much as in gas tungsten-arc welding (see Fig. 7). The electrode holder is basically the same as the holder used for gas metal-arc welding of steel (see the article on Gas Metal-Arc Welding, which begins on page 78). To avoid contamination and porosity in gas metal-arc welding, it is necessary to have a leading shield as well as a trailing shield, and a suitable baffle added on the leading edge of the electrode holder (see Fig. 7). A leading shield prevents oxidation of spatter before it is melted in the weld metal.

Plasma-Arc Welding

Plasma-arc welding, described in detail in the article on that process, beginning on page 138, has been used successfully for joining titanium alloys. Table 7 and Example 141 in that article present typical operating conditions for plasma-arc welding of Ti-6Al-4V.

Stress Relieving

Most titanium weldments are stress relieved after welding to prevent weld cracking and susceptibility to stress-corrosion cracking in service. Stress relief also improves fatigue strength.

An assembly subjected to a substantial amount of welding and severe fixturing restraint may require intermediate stress relieving of the partially welded structure, which should be done in an inert atmosphere; otherwise, the unwelded joints may have to be recleaned before being welded.

With unalloyed titanium and alpha titanium alloys, time and temperature should be controlled to prevent grain growth. Stress relieving times and temperatures for several weldable titanium alloys are given in Table 5.

For alloys not mentioned in Table 5, tests should be conducted to make certain that stress relieving does not reduce fracture toughness, creep strength, or other property of importance.

Stress relieving of Ti-13V-11Cr-3Al weldments causes aging and subsequent embrittlement of the weld and heat-affected zone, and is not recommended. Re-solution heat treatment (re-annealing) may be used to relieve stresses if the welded assembly is amenable to such treatment. Contaminated surface metal must then be removed from the entire weldment by machining or descaling and pickling to remove 0.001 to 0.002 in. per surface. Mechanical stress relief of Ti-13V-11Cr-3Al weldments is sometimes feasible.

ELECTROSLAG AND ELECTROGAS WELDING

CONTENTS

Electroslag Welding

ELECTROSLAG WELDING is a process in which heat from a layer of molten flux (slag) melts a consumable electrode and the surface of the base metal to produce a weld puddle. Filler metal (the electrode) is fed into a molten flux pool contained in a pocket formed by copper shoes or dams (water-cooled or not) that bridge the gap (joint) between the members being welded. The process utilizes the electrical resistivity of the molten flux to produce continuously the heat needed to melt the filler metal and adjacent base metal. Throughout the progress of welding, the molten flux maintains a protective cover over the joint.

Although the axis of the weld joint is vertical, the process is actually flat-position welding with vertical travel; the consumable electrode is fed downward, through a guide tube, into a cavity formed by the pieces being welded and one or more dams (see Fig. 2).

In its mechanical aspects, electroslag welding resembles electrogas welding (see the article on Electrogas Welding, which begins on page 395), but the electrical characteristics of the two processes differ in two important respects: (*a*) electrogas welding is an arc welding process, whereas in electroslag welding, an arc is used only at the start of welding; when the flux is melted, it chokes the arc, and the filler metal and the surface of the base metal are melted by the heat produced by the electrical resistance of the molten flux; and (*b*) either alternating or direct current is used for electroslag welding, whereas only direct current is used for electrogas welding.

The process described above is generally referred to either as the conventional system of electroslag welding, or simply as electroslag welding.

Electroslag Welding by the Consumable-Guide-Tube System. Consumable-guide-tube electroslag welding, a modification of the conventional system, is a method of electroslag welding in which filler metal is supplied by the electrode and its guiding member (see Fig. 3). The electrode wire (filler metal) is fed to the weld puddle through a tube that is also consumable. The use of a consumable guide tube obviates the need for vertical travel of the welding head, thus simplifying equipment.

The mechanical aspects of the two systems are described in greater detail in the section in this article on Principles of Operation. For the most part, the two systems are capable of producing similar results, although there are applications for which one is better suited than the other (see the section on Conventional System vs Consumable-Guide-Tube System, on page 393).

Applicability

Although most applications of electroslag welding involve the welding of low-carbon steel, the process is also used extensively for welding medium-carbon steels such as 1045 and 1050, and to a lesser extent for welding high-strength structural steels. The electroslag process has also been successfully used for welding high-strength alloy steels such as D-6ac, stainless steels, and nickel alloys.

Thickness Range. Electroslag welding (both systems) is most often used for welding plate from 1¼ to 12 in. thick. In a few applications, the process has proved advantageous for welding plate ⅜ in. thick. No upper thickness limit has been reached; steel sections 36 in. thick have been joined successfully by electroslag welding.

The lower limit of plate thickness depends mainly on costs compared with other processes. Submerged-arc welding and electrogas welding are usually alternative processes for welding plate less than 2 in. thick. In some plants, a 1¼-in. thickness has been established as the economic break point between submerged-arc or electrogas welding on the one hand and electroslag welding on the other, assuming that the joint can be satisfactorily welded by all three processes. In other plants, the break point is considered to be at a thickness of ¾ in. Each application requires careful cost analysis to determine the most economical process.

Length of Joint. The maximum length of joint that can be welded by the conventional system is limited only by the auxiliary equipment available. For the consumable-guide-tube system, there are other limitations (see the section on Conventional System vs Consumable-Guide-Tube System).

Types of Joints Welded. Butt joints between plates of equal thickness are those most readily, and hence most frequently, welded by the electroslag process. When other types or configurations of joints are welded, special dams or special techniques, or both, are usually required. Figure 1 shows several joints that have been successfully welded by the electroslag process.

Circumferential welding can be done by the electroslag process, with the use of special techniques (see the section on Circumferential Welding in this article, page 389).

Specific Applications. Welding of thick steel plate, heavy steel forgings, and large steel castings comprises the principal field of application for electroslag welding. In structural applications, electroslag welding is used to fabricate heavy and massive members in the shop for use in structures such as large buildings.

Cylinders and rings for products such as gear blanks, motor frames, press frames, crusher bodies, pressure vessels, and tires for road rollers comprise another important group of applications for electroslag welding. Such parts are formed from plate and welded along a longitudinal joint. In many applications, electroslag welding has replaced submerged-arc welding (heretofore the method most often used for welding such shapes), with a substantial reduction in fabrication time (see Examples 364 and 365). In one application of welding a cylinder having a 42-in. inside diameter and a 2¼-in.-thick wall, welding time using the electroslag process was one-fourth the time required using the submerged-arc welding process.

In the manufacture of large presses and machine tools, electroslag welding has been used for splicing two or more large, thick plates when it was impossible to purchase single plates that were large enough (see Example 363). One manufacturer spliced plates 8 in. thick by 12 ft wide to make a large press frame. When the joints had been welded by the shielded metal-arc process, welding required 80 hr, and turning the plates took a considerable amount of time. With electroslag welding, the joint was welded in 4.2 hr, and no time was required for handling other than setup.

Because of the high deposition rate and relatively low cost of electroslag welding, weldments are now used where they had been previously considered impractical or too expensive. For example, the demand for large steel castings (200,000 lb or more) is increasing, but castings of this size are beyond the capacity of most foundries to produce. If large, complex castings can be divided into less complex components, there is a reduction in the cost of patterns and molding, and with electroslag welding, they can be joined to produce a weldment that is the structural equivalent of the large casting. Various wrought elements can also be incorporated into the weldment instead of using all castings, thereby simplifying assembly and reducing material costs (see Examples 361 and 362).

Fig. 1. Seven joint-weld combinations made by the electroslag process

Principles of Operation

Electroslag welding is a progressive process of melting and solidification in which heat generated by the passage of current through a layer of molten flux is used to melt the filler metal and the surfaces of the workpieces being welded. The current is conveyed into the flux through the consumable electrode. Welding current flows between the electrode and base metal, maintaining the flux at a temperature determined by the electric power transmitted. Fluxes compounded to provide the desired melting temperatures, viscosity and electrical resistivity are essential for satisfactory operation. The main principle of operation is the same for both methods of electroslag welding — metal transfer is arcless.

Electroslag welding can be started by initiating an arc beneath a layer of granular welding flux, much the same as in submerged-arc welding, or by initiating the arc on steel wool and immediately adding flux. As soon as a sufficiently thick layer of flux is melted, all arc action stops and current passes from the electrode to the metal being joined, through the conductive flux, and the process becomes electroslag welding.

Welding in a vertical direction, using retaining dams to mold the molten metal, results in solidification that is highly directional, and nonmetallics are rejected upward into the flux pool.

In submerged-arc welding, the arc, submerged under powdered granular flux, creates the heat necessary for welding. The voltage across the arc ranges from 25 to 32 volts. Depth of flux is not sufficient to block arc action. In electroslag welding, the flux pool is 1½ to 2 in. deep, and because it offers a conductive path for the flow of electric current between filler-metal wire and base metal, the molten flux can extinguish the arc without breaking the current flow.

To heat the flux sufficiently, higher voltages (about 40 to 55 volts) are used than in submerged-arc welding. High deposition rates, together with constant joint widths, make it possible to join thick sections that were formerly impractical to weld.

Conventional Electroslag Welding. The equipment for welding and a detailed view of a joint being welded by the conventional process are presented in Fig. 2. The sectional view of the joint shows typical depths of molten weld metal and molten flux. In Fig. 2, two guide tubes and two sets of electrode-wire feed rolls are shown. One, two or three guide tubes and sets of feed rolls are commonly used, depending on base-metal thickness, although more may sometimes be required.

The electrode-wire guides are maintained just a short distance (½ to 2 in.) above the molten flux. This distance is controlled by moving the entire welding machine upward at a pre-established rate that is consistent with the deposition rate. Movement can be accomplished by chains lowered from an overhead mechanism, or the welding machine can be moved on a vertical track or rail. The mechanism for providing vertical movement of the welding machine is not shown in Fig. 2.

The rate of vertical travel can be controlled by several means. It can be controlled manually by the welding operator. More often, however, it is controlled by a signal from a photoelectric cell that is focused across the flux pool. As the flux pool rises, the photoelectric cell signals a drive motor that moves the entire unit upward to

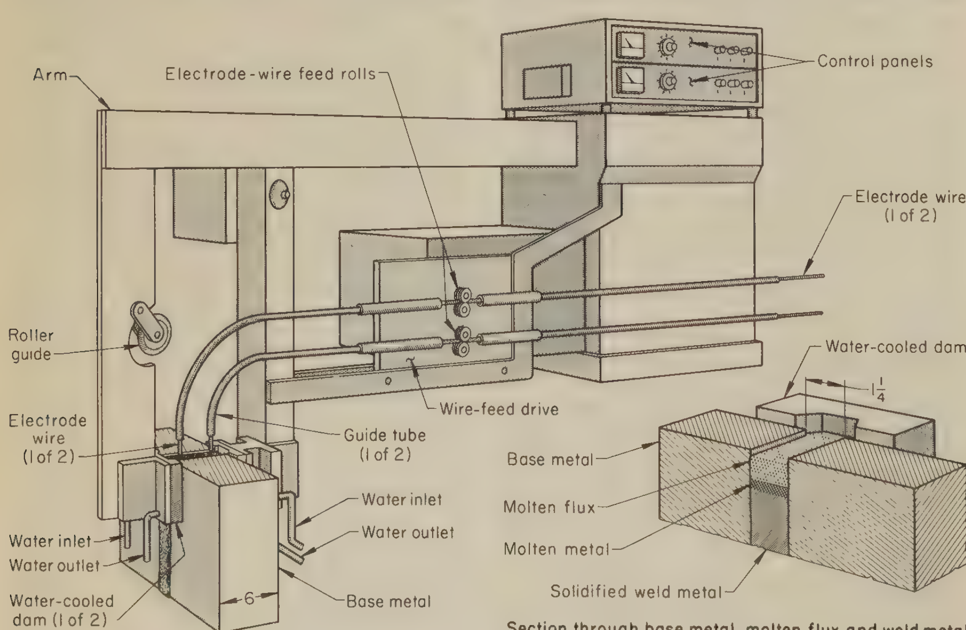

Fig. 2. Principal components and setup of equipment for conventional electroslag welding. The mechanism for providing vertical movement of the welding machine is not shown.

maintain proper relationship of wire guides and flux pool. Irrespective of the mechanism used to control vertical travel, some adjustments are usually required by the welding operator during the early stages of welding, to establish the required travel speed.

As shown in Fig. 2, the electrode wires are fed through the guide tubes by feed rolls. Although electrode feed is automatic, speed must be preset. It may also require adjustment by the welding operator until the operation is established. Current is conducted to the electrode wire by the guide tubes, the guide tubes serving the same purpose as the contact tube in an electrode holder for gas metal-arc welding. The electrode wires (and guide tubes) may or may not be oscillated (moved horizontally back and forth in a direction parallel with the edges of the workpiece) during welding, depending on the thickness of the work metal and the number of electrodes used.

The water-cooled dams (mold shoes) are attached to the welding machine and move vertically as the machine moves. The dams serve three purposes: (*a*) they serve to contain the molten weld metal until it solidifies and to contain the molten flux; (*b*) they accelerate solidification of the weld metal; and (*c*) they mold the outside contours of the joint to give desired reinforcement.

Electroslag Welding by the Consumable-Guide-Tube System. With the consumable-guide-tube system, the mode of metal transfer is also arcless. The principal difference from the conventional system is that none of the welding-machine components moves upward during the welding operation; the only vertical movement is that of the electrode wire through the feed rolls and guide tube (vertical down).

As shown in Fig. 3, the main components are: power supply, control panel, wire-feed drive, consumable guide tube, and water-cooled dams. The wire is fed vertically through the consumable guide tube to the pool of molten flux. At the beginning of welding, the consumable guide tube is lowered to within 1½ in. of the bottom of the joint; it melts off as the level of the weld rises. Welding begins by arcing between the electrode wire and the base metal, or steel wool, as in the conventional system. As soon as the flux pool is established, it extinguishes the arc and welding proceeds in a vertical direction. Most of the filler metal is supplied by the electrode wire, but about 5 to 10% is supplied by the consumable guide tube.

In this system of electroslag welding, the water-cooled dams (mold shoes) are separate from the other equipment. They are held in place by wedges between the dams and strongbacks, as shown in Fig. 3. For welding a short joint, one set of dams may be enough, but more commonly two sets are used, the bottom set being removed from the joint when the weld metal has solidified and being placed above the other set. As welding proceeds, the dams are moved ("hopped") as required.

Although a single wire feed is shown in Fig. 3, multiple wire feeds are often used. Wire can be oscillated if required, as in the conventional system.

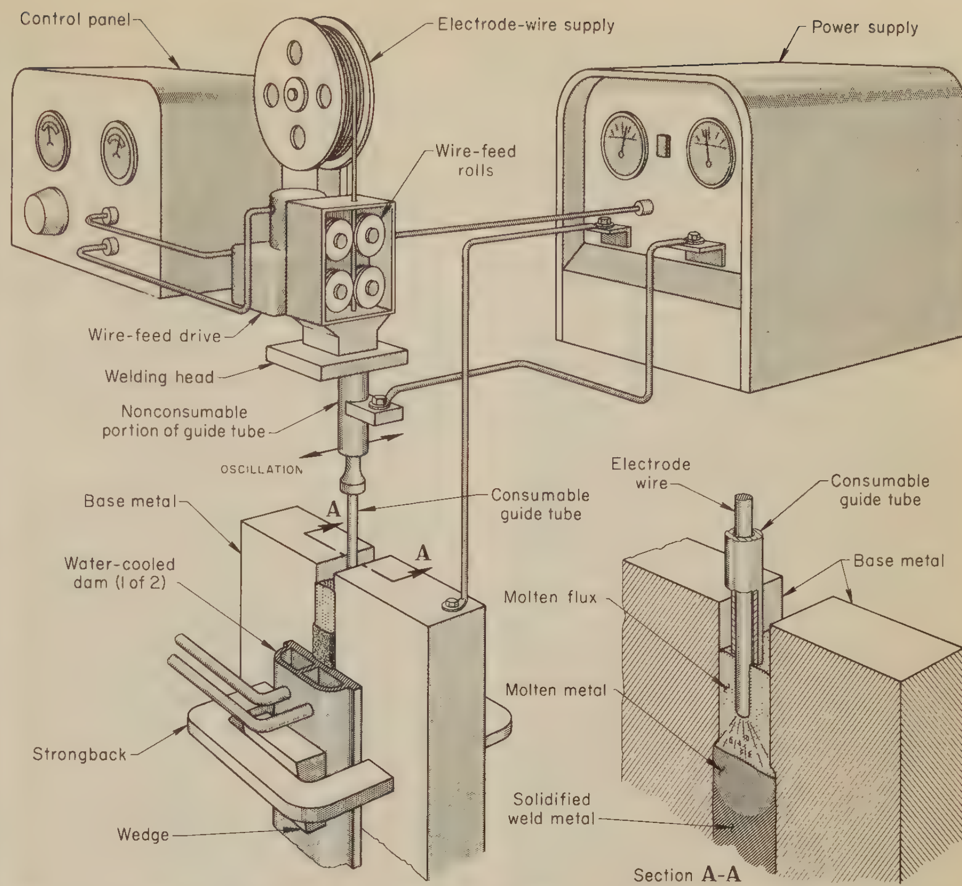

Fig. 3. Principal components and setup of equipment for electroslag welding with the consumable-guide-tube system

Equipment

Constant-voltage transformer-rectifiers are used extensively to supply the power for electroslag welding (both systems), because they are easily controlled and because they are standard in many plants, being used for gas metal-arc and flux-cored arc welding. The power rating of a machine is usually 750 amp, 60 volts at 100% duty cycle. A power supply of this rating is required for each wire fed; thus, total capacity for welding with three electrode wires would be 2250 amp.

Constant-current transformer-rectifiers have been successfully used for electroslag welding, but they are more difficult to control. Their ready availability has usually been the principal reason for their use.

Motor-generators have also proved satisfactory for electroslag welding. However, motor-generator sets having a capacity of 750 amp at 100% duty cycle are far more costly than transformer-rectifiers of this capacity.

Alternating current supplied by transformers has been more extensively used in Europe than in the United States and Canada (see Example 365).

Guide Tubes (Conventional System). The nonconsumable guide tubes shown in Fig. 2 may be identical with the electrode holders used for electrogas welding (see the discussion under the heading "Electrode holders" and Fig. 2 on page 396, and Fig. 3 on page 397). The guide is a beryllium copper tube supported by two narrow rectangular bars brazed to it. The tube and supports are then wrapped with insulating tape. Because the guide tube is positioned close to the molten flux, the end will deteriorate. The end can be cut off and the guide used where a shorter one will suffice (note in Fig. 2 that the curved guide tubes have different lengths).

A guide tube must be narrow enough to clear the plates being welded as it passes vertically between them, and preferably with clearance to spare, especially when the guide is oscillated. Nonconsumable guide tubes are usually less than ½ in. in diameter.

Guide Tubes (Consumable-Guide-Tube System). The nonconsumable portion of the wire guide (where the power is connected, as shown in Fig. 3) is usually made from a copper alloy. Because the consumable portion becomes a part of the weld, it is made from a steel that is compatible with the base metal being welded. The guide tubes are commonly ⅝ in. in outside diameter and ⅛ to 3⁄16 in. in inside diameter, although guide tubes with an outside diameter of less than ⅝ in. are available and are necessary for welding sections thinner than ¾ in. Guide tubes are available in various lengths.

For welds longer than 2 or 3 ft, the guide tubes are usually insulated to prevent them from making electrical contact with the sidewalls of the joint.

There are two methods of insulating consumable guide tubes: (*a*) by coating them with flux, and (*b*) by use of insulator rings (available for this specific purpose) spaced 12 to 18 in. apart and held in place by a small button of weld on the guide tube. The flux cover

insulates the tube above the weld so that, if it touches the sidewalls, no electrical contact is made; also, as the steel guide tube melts, the flux cover helps to replenish the flux pool. Insulator rings melt as the guide tube is consumed and become part of the flux.

Dams (also called mold shoes and retaining shoes) are required to hold the molten metal and flux between the parts being welded.

In conventional single-pass electroslag welding of square-groove butt joints, two dams are ordinarily used. They are attached to the welding machine and move vertically as welding proceeds. When a backing bar is employed on one side, with the conventional process, only one dam is needed. With the conventional process, the front dam (nearest the machine) is always required. However, with the consumable-guide-tube system, it is possible to use two backing bars, under which conditions no dams are needed. Backing bars can be left in place when welding is finished, to become a part of the weld, or they can be cut off, as required by the job. A special type of dam is described in Example 369 in the article on Electrogas Welding.

Dams used with the conventional system are always water cooled and are usually made of copper. The principal features of one type of water-cooled dam are shown in Fig. 4 — designs of dams vary considerably. In the setup shown in Fig. 4, the two plates to be welded are aligned to allow a typical 1¼-in. joint opening. The two copper dams close the ends of the joint opening and form the cavity for molten weld metal and flux.

The dams shown in Fig. 4 are constructed from copper plates and are assembled by brazing or welding. This particular design has a center partition, or baffle, containing one or more openings, to improve circulation of the cooling water.

Dams used with the conventional process require brackets or similar devices for attachment to the welding machine arms, so they will slide upward along the joint as welding proceeds (see Fig. 2). When welding long joints (longer than the distance from the bottom of the dams to the top of the horizontal arm), the horizontal portion of the arm must be narrow enough to move vertically within the joint opening.

Dams used with the consumable-guide-tube system remain stationary until they are manually relocated along the joint. Clamps and similar devices have been used to hold them in place, but the most common method is to use wedges inserted under the strongbacks (see Fig. 3). Water-cooled dams of the type shown in Fig. 4 are also used with the consumable-guide-tube system. They are available in standard lengths of 12, 18 and 24 in.

Dams used with the consumable-guide-tube system need not be water cooled, but if they are to be reused, they must be made from massive copper blocks. Because such blocks are expensive and deteriorate rapidly, water-cooled dams are generally recommended. In Example 366 (see page 392), the copper dam was not water cooled.

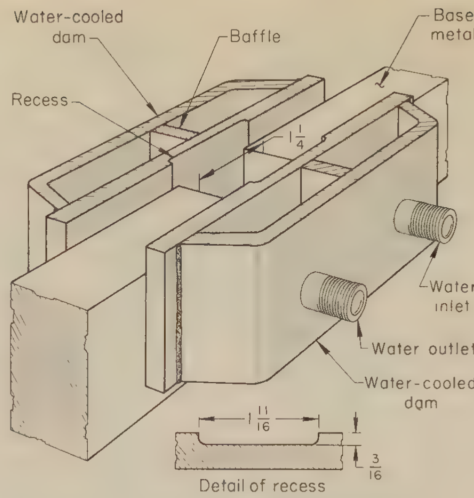

Fig. 4. One type of water-cooled dam

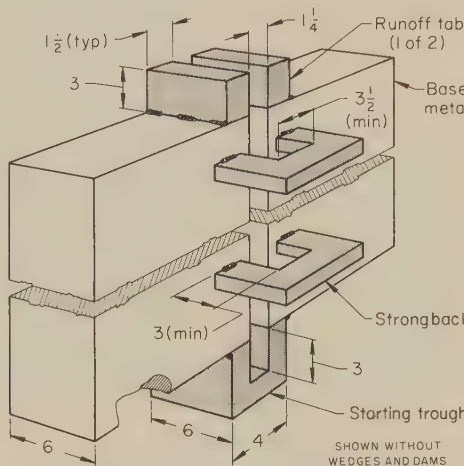

Fig. 5. Two 6-in.-thick plates ready for electroslag welding

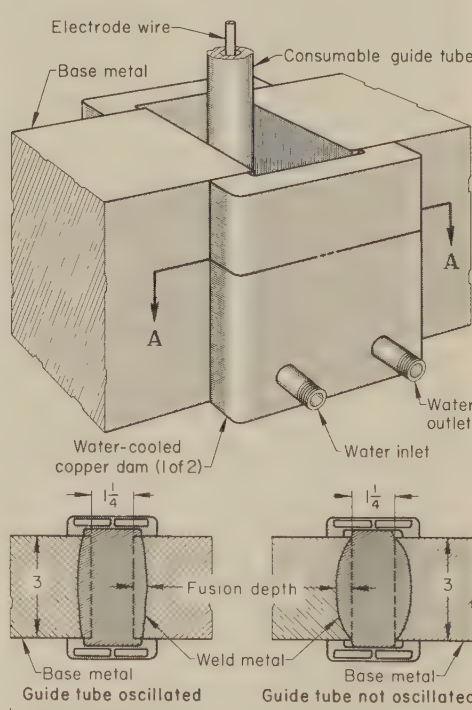

Fig. 6. Setup for consumable-guide-tube electroslag welding of 3-in.-thick plates. Note different depths of fusion obtained with and without guide-tube oscillation.

Wire-Feed Systems. Irrespective of the electroslag system used, the electrode wire must be fed through the wire guide at a pre-established, constant rate. Although wire-feed systems vary in design among manufacturers, they are almost always of the push type. Wire-feed systems are similar to those used for other welding processes that utilize continuously fed consumable electrodes, and are discussed in the articles on Flux-Cored Arc Welding and Gas Metal-Arc Welding, pages 24 and 78, respectively.

Oscillator mechanisms are required when the thickness of the components to be joined exceeds about 2¼ in. per electrode wire. The means of obtaining oscillation varies with the equipment manufacturer. One method utilizes a motor-driven lead screw (see Fig. 1 in the article on Electrogas Welding, page 395). Rack-and-pinion mechanisms also provide oscillation. The mechanism must be capable of being regulated for distance and rate of travel, and also be able to make an adjustable delay at the end of each stroke.

Electrode Wires

Either solid or tubular electrode wires can be used as the filler metal in both systems of electroslag welding.

Solid electrode wires such as are used for gas metal-arc or submerged-arc welding are most often employed. Electrode wires that contain deoxidizers such as those that conform to AWS A5.18-69 are most often used for electroslag welding of low-carbon and medium-carbon steels. For welding alloy steels, it is common practice to choose an electrode wire with alloy content that produces a weld that nearly matches the base metal. The carbon content is usually between 0.07 and 0.19%, irrespective of alloy content.

Tubular electrode wires used for electroslag welding usually contain powdered ferroalloy. The wire is always of low-carbon steel, but the composition of the alloy powder core can be varied to produce a desired composition of weld deposit.

Tubular wire having a core composed entirely, or almost entirely, of flux, such as is used for flux-cored arc welding, is sometimes used for electroslag welding. Flux-cored wires have usually resulted in excessive buildup of flux in the pool (more than 2 in.), and good fusion is impaired.

Size of electrode wire varies from 3/32 to 5/32 in. in diameter. The 3/32-in.-diam size is most often used with the consumable-guide-tube system, because the inside diameter of the guide tubes is often ⅛ in., but consumable guide tubes can be obtained that permit feeding of ⅛-in.-diam wire (see Examples 366 and 367). The same diameter restrictions do not apply in the conventional system, and ⅛-in.-diam wires are most often used. Because they are stiff, wires more than ⅛ in. in diameter sometimes are difficult to feed.

Fluxes

The molten flux is the "slag" that gives the electroslag process its name.

Composition. Fluxes are marketed as proprietary materials; there are no

standard specifications. Fluxes for electroslag welding are usually combinations of oxides of silicon, manganese, aluminum, calcium, magnesium and titanium, with some calcium fluoride always present. The calcium fluoride is added to the basic system to obtain suitable resistivity and fluidity. As the amount of calcium fluoride is increased, viscosity, melting point, and resistivity decrease. Titanium oxide also decreases resistivity; aluminum oxide increases it. Lower resistivity generally results in a lower flux temperature for a given power input.

The ingredients in the various proprietary fluxes vary considerably. The following composition is typical of one that has performed satisfactorily for electroslag welding of low-carbon steel: 35% SiO_2, 40% MnO, 5% Al_2O_3, 7% CaO, 5% CaF_2, 3% FeO, 3% TiO and 1% Na_2O.

Operating Characteristics. A flux for electroslag welding must meet several requirements:

1. It must be sufficiently conductive when molten to carry the welding current from the electrode to the molten weld puddle and to the surfaces of the solid base metal without arcing. With a constant-voltage power supply, the electrode melts off on penetrating only part way through the flux pool. Because the current drawn from a short length of wire has to maintain the temperature of a 2-in.-deep flux pool, a flux of the correct resistivity must be chosen. A flux of high resistance will draw too little current, allowing the pool to cool and the wire to drive too deeply into the molten flux. A flux of low resistance will draw excessive current, raising the temperature of the pool until the process stabilizes with a shorter length of wire immersed. A flux with too little resistance may lead to arcing above the flux pool.
2. Flux viscosity must be in the range between the high viscosity that results in sluggishness and prevents settling of small droplets of molten metal (and also leads to slag inclusions in the weld) and the low viscosity that causes the flux to leak through small crevices between the dams and the work. Viscosity must be low enough to permit a good stirring action in the flux pool, so that heat will be distributed uniformly to all surfaces of the joint. This is especially important in a small flux pool, as in welding relatively thin plates.
3. The flux must have a melting range lower than that of the weld metal. All ingredients in the flux should volatilize slowly. Preferential loss of one ingredient will alter the pool composition and lead to varying results in long welds.
4. The flux must be metallurgically compatible with the alloy being welded. For carbon steel, low-alloy steel, and stainless steel, a basic flux is usually recommended. The same flux and a simple flux composed principally of fluorspar and lime have been used for nickel alloys.
5. The flux should solidify to a slag that is easily removed from the surface of the weld. The commercially available fluxes differ in this characteristic, some being rather difficult to remove. This is seldom a major consideration.

Starting Flux. Specially compounded fluxes that have lower-than-normal resistivity and that are used with higher-than-normal voltage and current can be used for startup, to develop the flux pool and the weld-metal puddle. After startup, welding is done with the regular welding flux. Some fabricators do not use a special startup flux.

Table 1. Typical Conditions for Electroslag Welding With the Consumable-Guide-Tube System

Plate thickness, in.	Number of electrodes	Root opening, in.	Total current, amp	Voltage, v	Oscillation distance, in.	Oscillation speed, ipm
½	One	1	500	34 to 36	0	0
1	One	1	600	37 to 39	0	0
2	One	1	725	38 to 40	0	0
2⅜	One	1¼	750	39 to 41	1¾	20
3	One	1¼	750	39 to 41	2⅜	25
5	One	1¼	750	45 to 47	4⅜	50
5	Two	1¼	1500	40 to 42	1⅛	10
6	Two	1¼	1500	41 to 43	2⅛	25
8	Two	1¼	1500	44 to 46	4⅛	45
10	Two	1¼	1500	47 to 49	6⅛	65
12	Two	1¼	1500	50 to 52	8⅛	85

Workpiece Preparation

Preparation of the joint edges is often much simpler than for other welding processes (see Examples 365 and 367). Plates are usually cut to size by gas cutting and then are ready to weld without further edge preparation. This simple procedure saves considerable time and money compared with preparation by beveling.

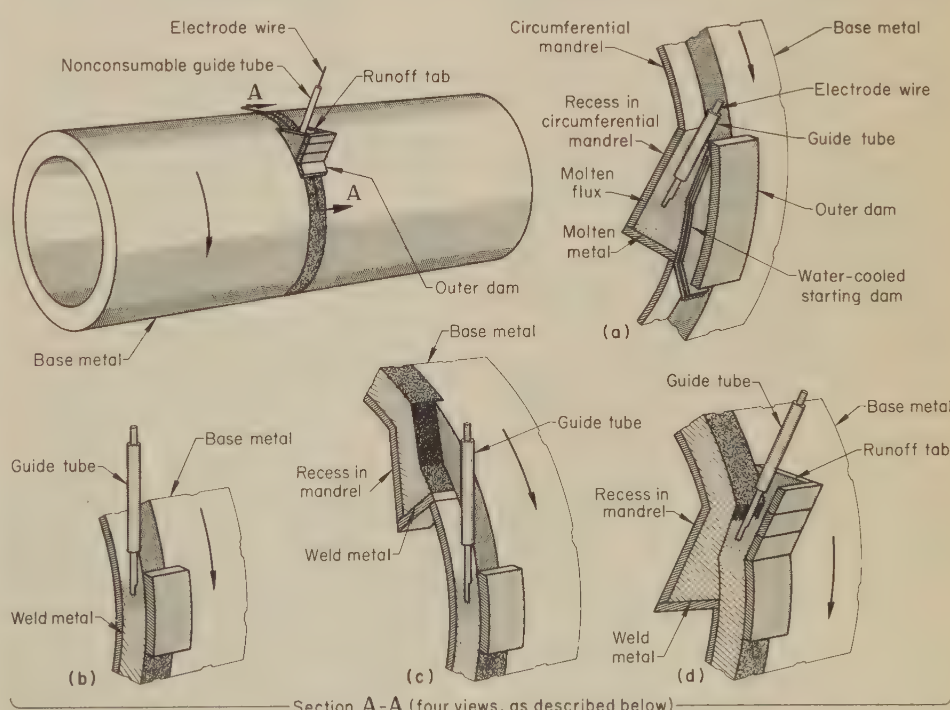
Joint components to be welded are assembled in a vertical position, supported over a starting trough of full plate thickness and about 3 in. deep (see Fig. 5). The starting trough can be made by tack welding together three pieces of scrap steel plate, or it can be a clamp-on starting sump made from copper, which type can be reused many times. The faces of the starting trough must be flush with the outside surfaces of the plates, for proper fit of the dams. The runoff tabs (Fig. 5) are also full plate thickness and about 3 in. deep, so as to bring the weld crater beyond the top of the plates.

Strongbacks. Spacing of the joint opening (usually 1⅛ to 1¼ in.) and alignment of the plates must be maintained. The most common means of accomplishing this is by the use of U-shape restraining plates (strongbacks) welded across the outer face of the joint, as shown in Fig. 5.

For welding by the conventional system, the openings of the strongbacks must be large enough to permit the water-cooled dams to move through them. A space of 3½ by 3 in., as shown in Fig. 5, is usually sufficient.

With the consumable-guide-tube system, dimensions of the strongback are not critical. In this system, the strongbacks serve the additional function of helping to hold the stationary dams in place (see Fig. 3).

The number of strongbacks along a joint depends mostly on the workpieces and the degree of difficulty encountered in maintaining them in position. The ease or difficulty of fit-up will also determine whether strongbacks are needed on both sides of the joint. Strongbacks are commonly located 12 to 18 in. apart, starting about 6 in. from the bottom of the joint and ending not much nearer the top than 6 in.



(a) Setup for beginning the weld, showing recessed internal mandrel, starting dam, and outer dam. (b) Welding the major portion of the circumference, using a mandrel and a contoured outer dam. (c) Approaching the finish of the weld. (d) Completing the weld with the help of runoff tabs and additions to the outer dam.

Fig. 7. Circumferential electroslag welding

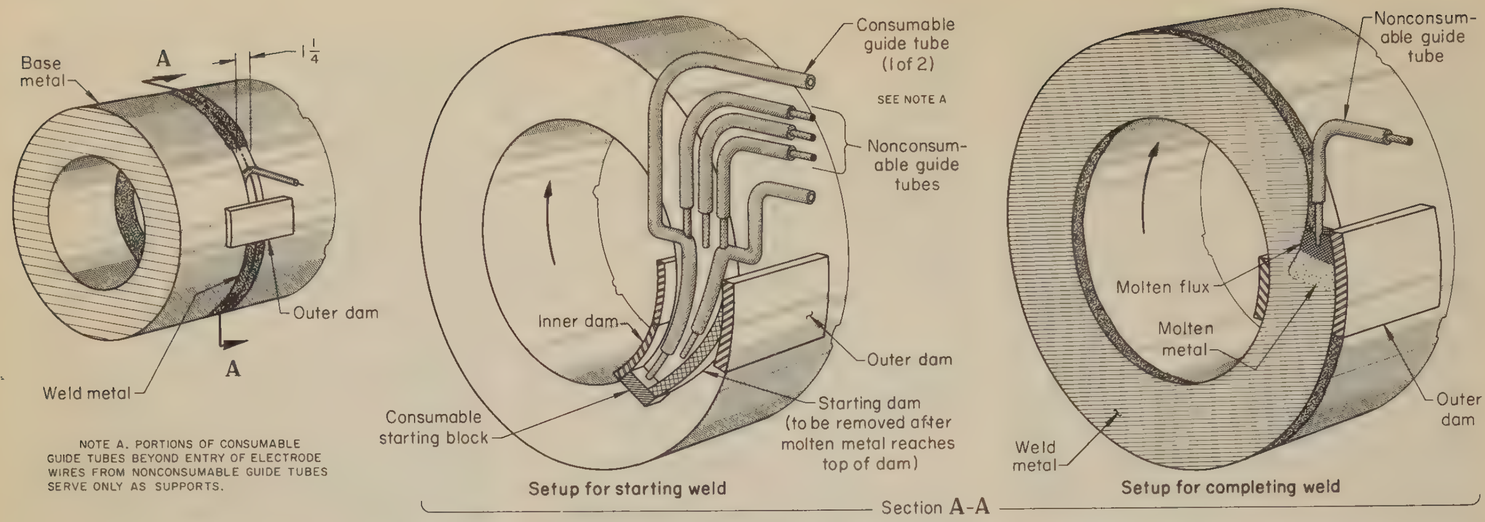


Fig. 8. Electroslag welding of cylindrical sections, using a combination of the conventional and consumable-guide-tube systems. Note setups for starting the weld, obtaining initial contour, and completing the weld.

In some setups, the workpieces are easily positioned and fewer than the normal number of strongbacks are adequate. In other setups, fit-up is difficult and extreme force (applied by power jacks or a crane) may be required to get the workpieces into position, and additional strongbacks must be used. Sometimes, when welding with the consumable-guide-tube system, the placement of the water-cooled dams influences the number and location of strongbacks, because the water-cooled dams depend on the strongbacks to hold them in position.

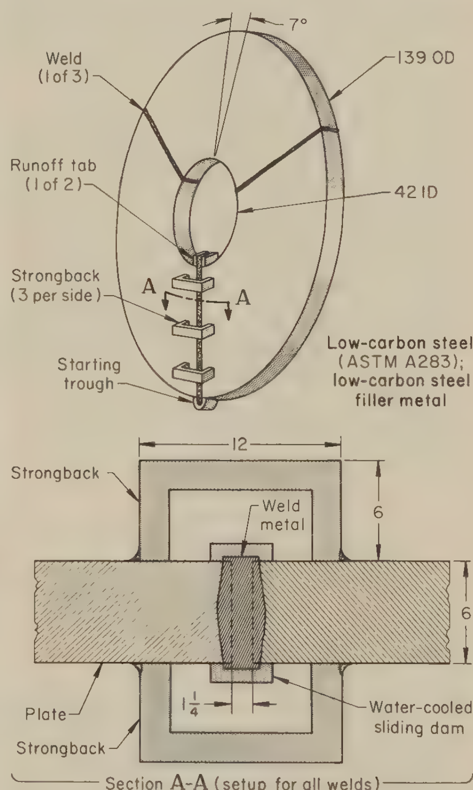
In the conventional system, it is highly desirable to use strongbacks only on the side opposite that from which the electrode wires are fed. If strongbacks are used on both sides, they must be successively removed on the wire-feed side as the welding machine travels up the joint.

Strongbacks are removed after the joint is welded, unless the operation makes it necessary to remove them sooner, as mentioned above. If they have been securely welded, they can be removed by gas cutting at about ¼ in. from the face of the finished joint. If service requirements make it necessary to remove all evidence of the strongback, the remaining ¼ in. should be chipped and ground away. However, strongbacks often are only tack welded along one side and can be broken off with a few sledgehammer blows.

Preheating. Because of the thermal cycle that characterizes electroslag welding, preheating is seldom used. Sometimes, the joints are warmed with a torch to drive off moisture before welding begins. Also, if high-strength steels are welded, preheating may be required. (See the section in this article on Preheating and Postheating, page 390.)

Operating Procedure

In setting up for electroslag welding, the entire welding machine is positioned over or beside the gap between the two workpieces. For welding by the conventional system, the machine is lowered and raised to make certain that the guide tube (or tubes) enters and leaves the joint opening smoothly



Process	Conventional electroslag welding
Joint and weld types	Butt; square groove
Joint preparation	Gas-cut edges
Power supply	Two 750-amp transformer-rectifiers(a)
Electrode wires	Two ⅛-in.-diam low-carbon steel
Number of passes	One
Current, amp (dcrp)	750 per wire; 1500 total
Voltage	50 v
Electrode consumption	25.2 lb per foot
Flux consumption	50 gr per hour
Oscillation	2⅛-in. length of travel at 60 ipm
Preheat	100 F (by gas torch)
Stress relief	1150 ± 25 F, 7 hr
Deposition rate	90 lb per hr (total, two wires)
Setup time (total, 3 joints)(b)	5.2 hr
Welding time per joint	1.15 hr
Postweld trimming time(c)	0.25 hr

(a) Constant-voltage type, 100% duty cycle. (b) Includes positioning welding machine, aligning, and attaching strongbacks. (c) Total, for cutoff of starting troughs, runoff tabs, and strongbacks from all three joints.

Fig. 9. Grinding-mill head that was fabricated by joining three plate sections by electroslag welding (Example 361)

and remains centered in it. The roller guide shown in Fig. 2 provides a means of keeping the machine aligned after the initial adjustments are made. The dams are checked to make sure that they will slide freely. Wire-feed rate, reference voltage, and current are adjusted. Electrode-wire size and required deposition rate must be considered in making the initial settings. If experience with similar applications is not available, the best procedure is to use the data supplied with the particular machine as a starting guide. However, sample welds should be made and tested to ensure that the welding procedure will provide joints having the required properties.

Setup for the consumable-guide-tube system is similar to the above. When the machine is made ready, the guide tube is adjusted so that it extends nearly to the bottom of the joint and does not touch the sidewalls of the workpieces (unless it is well insulated). The dams are then wedged in place.

Startup is almost always done with the aid of a piece of steel wool placed in the starting trough. The electrode is lowered into the starting trough (both systems), and as it touches the steel wool, violent arcing takes place. Flux is added immediately. A large handful is usually sufficient, although the quantity depends on the thickness of the joint. The flux can be a special starting flux. In some plants, the initial flux is placed on top of the steel wool before the current is switched on.

As soon as the flux melts and the violent arcing dies down, more flux is added. The arc is soon extinguished and welding begins. The objective is to have welding proceeding smoothly by the time the flux level rises to the bottom of the joint. To obtain a smoother start, especially if a special starting flux is used, the voltage can be increased and the amperage decreased during startup.

After the arc has been extinguished, welding proceeds continuously until the joint is completed. During welding, some adjustments in current or wire feed may be needed. Welding-current variations of about 30 amp caused by variations in line voltage can be tolerated for periods of not more than about

half a minute, after which the current should be readjusted to correct value.

Flux is added manually as needed to maintain a molten-flux depth of about 1½ to 2 in. Attempts to automate the addition of granulated flux have not been successful, largely because only a small amount is consumed. On the average, about 1 lb of flux is used per 20 lb of weld metal deposited. The amount of flux consumed depends largely on the amount that is lost by leaking out between the dams and the workpiece. Very little is consumed by the process. When welding with the consumable-guide-tube system, some welding engineers prefer flux-covered guide tubes, which automatically help to replenish the flux pool as welding proceeds. Although depth of the pool is not critical, for best welding efficiency, the depth should be kept reasonably uniform and generally should not exceed 2 in. If the flux starts to bubble vigorously, the flux pool is too shallow and flux should be added, and if the surface of the flux pool is entirely quiet, it is too deep.

Although the welding operation for both the conventional and consumable-guide-tube systems is largely automatic, additions of flux, minor adjustments of the machine, and changing of dams, in the consumable-guide-tube system, demand fairly close surveillance.

Typical operating conditions for electroslag welding of plates ranging in thickness from ½ to 12 in., using the consumable-guide-tube system, are presented in Table 1.

Oscillation. Thickness of the work metal is the major factor in determining whether or not the guide tubes (and electrodes) should be oscillated during welding. When work-metal thickness is less than about 2¼ in., oscillation is not usually required, although it is sometimes used for work metal as thin as 1½ in. Better uniformity of heat penetration is obtained when the electrode is oscillated, even in welding thin plates. Because the water-cooled copper dams are efficient heat sinks, when the electrode remains stationary in the center of the joint opening and midway between the two sides, heat penetration is considerably greater at the center of the joint than at the edges. Oscillation will greatly lessen this nonuniform distribution of heat; a dwell time of 1 sec or more at each end of the stroke will compensate for the heat loss due to the water-cooled dams. Figure 6 shows the effect of oscillation on depth of fusion in welding 3-in.-thick plates. A base-metal thickness of 3 in. generally is considered excessive for welding with one electrode wire, and without oscillation. As shown at the lower right in Fig. 6, there is little depth of fusion at the four corners adjacent to the dams if oscillation is not used.

Sometimes the fusion is deep on one side of the joint and very shallow on the opposite side. This may be caused by an excessive amount of flux or by the electrode not being centered between the joint walls, thereby providing a shorter path for the current flow to a joint sidewall instead of down to the molten weld metal. Also, when current flow is to one sidewall, the flux pool near the opposite sidewall will cool, which can result in slag inclusions in the weld metal. Oscillation will decrease this effect and promote more even depth of fusion.

The oscillator mechanism moves the guide tube back and forth within the joint opening. The length of travel can be varied, but is usually set so that the guide tube stops at each side, about ⅜ to ½ in. from the dam. The oscillation distance depends on the thickness of the plates and the number of electrode wires. For a particular plate thickness, oscillation distance is considerably less for two wires than for one (compare the values for 5-in.-thick plate in Table 1). Usually, delay (dwell time) is 1 to 7 sec before the direction of travel is reversed. This delay helps to keep the flux pool at a uniform temperature. Oscillation speed varies with oscillation distance, as shown in Table 1.

Number of Electrode Wires. One wire with no oscillation is recommended for work-metal thicknesses of ½ to 2⅜ in., one wire with oscillation for thicknesses of 2⅜ to 5 in., and two wires with oscillation for thicknesses of 5 to 12 in. Some welding engineers regard the 2⅜-in. thickness as too great for welding without oscillation. Also, it is sometimes preferable to use three electrode wires with oscillation as work-metal thickness approaches 12 in. In some applications, particularly for the consumable-guide-tube system, the use of more electrode wires can replace oscillation (see Example 367). In one application, 22-in.-thick plates were welded using six wires not oscillated.

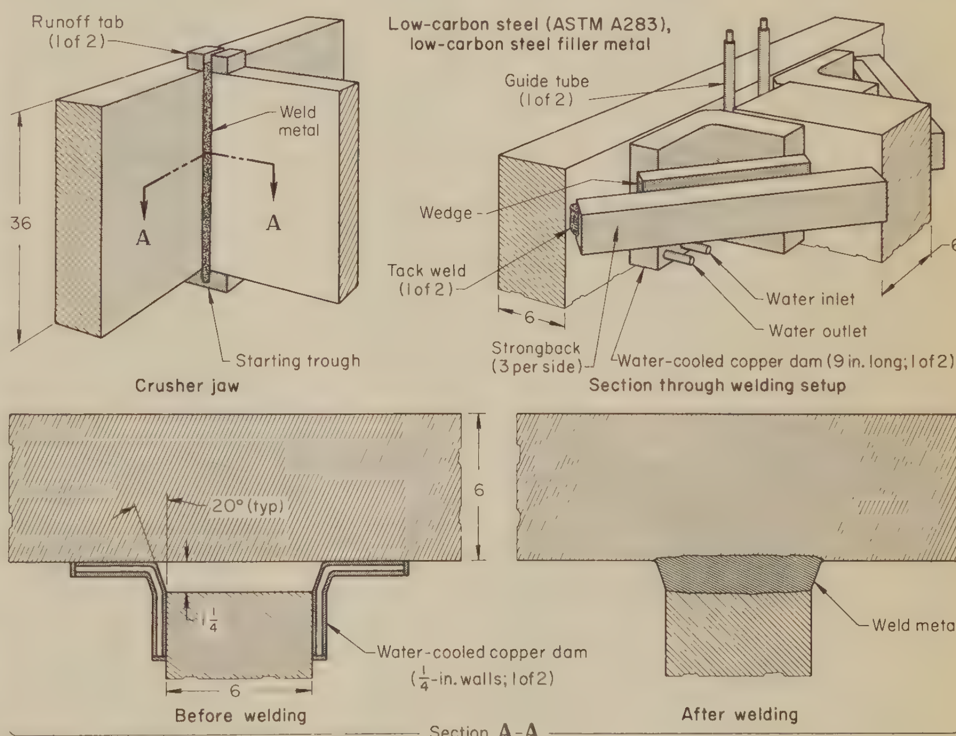
Control of Vertical Travel. Best results are obtained by maintaining close control of vertical travel, when the conventional electroslag system is used, so as to keep the length of wire in the flux pool constant. Even though the equipment may provide for automatic control of vertical travel, the rate of travel requires periodic adjustment during welding, particularly when long welds are being made.

With the consumable-guide-tube system there is no vertical travel, but electrode-feed rate (which controls current) must be closely controlled.

Circumferential Welding

Circumferential welds for joining sections of thick-wall pipe or pressure vessels can be made efficiently by the electroslag process. The methods used differ considerably from those used in welding straight vertical joints.

One method is essentially the same as that described in the article on Electrogas Welding, page 395 (see also Fig. 7 in that article). In this method,



Joint type	T, with square-groove weld	Number of passes	One
Joint preparation	Gas-cut edges	Current (dcrp)	750 amp per wire; 1500 amp total
Fixtures	Strongbacks; wedges	Voltage	41 to 43 v
Power supply	Two 750-amp transformer-rectifiers(a)	Preheat	150 F
Electrode wires	Two; 3/32-in.-diam low-carbon steel(b)	Stress relief	1150 ± 25 F, 6 hr
Guide tubes	Two; ⅝-in. OD, ⅛-in. ID(c)	Welding speed	0.72 ipm

(a) Constant-voltage type, 100% duty cycle. (b) Wires supplied from 750-lb reels. (c) Low-carbon steel.

The two-piece weldment shown replaced a single-piece cast jaw, at a cost saving. Joint configuration was better suited to electroslag welding by the consumable-guide-tube system than by the conventional system.

Fig. 10. T-section of a rock-crusher jaw that was electroslag welded, using a starting trough, runoff tabs, strongback fixtures, and specially shaped water-cooled dams, as shown (Example 362)

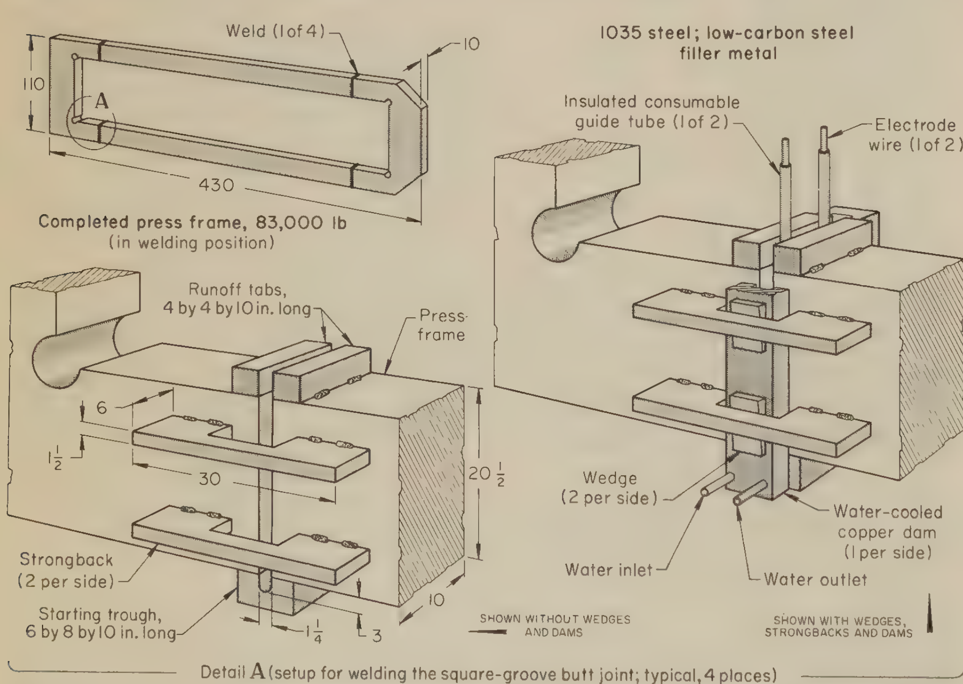
the dams fit the curvature of the workpiece, and they, as well as the other welding equipment, remain stationary as the workpiece is rotated. A major disadvantage of this method is that the weld cannot be completed by electroslag welding. After all but about 18 in. of the circumference has been welded, the electroslag equipment is removed and the weld is completed by another process, such as shielded metal-arc welding.

Other methods involve rotating the work past a stationary welding head, using special techniques for starting and finishing the joint. A dam within the cylinder must be used. This dam may be a single mandrel or several separate dams tacked or bolted in position in "leapfrog" progression as the weld advances.

One method for starting and closing a circumferential weld is as follows. Welding is started on a simple dam that is tacked in place on the inside of the cylinder. Preparation for closing is made when welding is half completed, by cutting away the starting dam and gouging out the first weld metal deposited along a predetermined surface that is tangent to the inside diameter. Tapered finishing tabs are tacked in place outside the joint at this location, so that the weld puddle can be brought to the surface of the cylinder as the joint is completed.

A method and apparatus covered by U. S. Patent 3,433,926 is sometimes used to provide the same kind of contoured start and finish as described above. The weld is started by use of a mandrel having a recess contoured as shown in Fig. 7(a) (which serves as the inner dam), a specially shaped water-cooled starting dam, and another dam shaped to the outer contour of the workpiece. Welding begins by positioning the guide tube as shown in Fig. 7(a) and filling the recessed area in the mandrel with weld metal. The shape of the water-cooled starting dam causes the weld to have a taper at the bottom. After the recessed area is filled and has solidified, the water-cooled dam is removed, as welding continues. As the workpiece rotates in the direction shown in Fig. 7(b), the flux and weld metal are retained by the mandrel and the contoured outer dam. As the weld nears completion, runoff tabs are attached, and these, with the aid of the taper at the beginning of the weld and additions to the outer dam, permit completion of the weld as shown in Fig. 7(d). The mandrel is then removed, and the excess metal at the start and finish is cut off. This method is not efficient for wall thicknesses of more than about 4 in.

A more elaborate method for circumferential welding is shown in Fig. 8. A starting dam is used to mold the initial weld into the contour needed to complete the weld. Inner and outer dams are also used. The inner dam can be a mandrel, or short dam segments can be used by "leapfrogging". The outer dam is usually fastened to the welding machine and remains stationary as the workpiece rotates.



Joint type	Butt	Current (dcrp)	700 amp per wire; 1400 amp total
Weld type	Square groove	Voltage	52 v
Joint preparation	Gas-cut edges	Oscillation:	
Fixtures	Strongbacks; wedges	Speed	122 ipm
Power supply	Two 750-amp transformer-rectifiers	Travel	6 in.
Electrode wires	Two 3/32-in.-diam(a)	Dwell time	2 sec(c)
Guide tubes	Two 5/8-in.-diam(b)	Frequency	20 cycles per minute
Flux depth	1½ in.	Postheat	Stress relief

(a) Composition: 0.11 C, 1.20 Mn, 0.45 Si, 0.020 S, 0.020 P. (b) Insulated with ceramic ferrules or glass fiber. (c) Within ½ in. from each dam.

Fig. 11. Setup for consumable-guide-tube electroslag welding of four sections of 10-in.-thick plate for fabrication of a press frame (Example 363)

The significant feature of this method is the guide-tube arrangement. As shown in Fig. 8 (center), at the time welding starts, there are five guide tubes, three nonconsumable and two consumable, but no more than three electrode wires are fed at any one time. The two consumable guide tubes serve as extensions of the corresponding nonconsumable guide tubes, so as to lead the electrode wires in the latter down into the pocket provided by the starting dam. The consumable guide tubes gradually melt off, until they are consumed, and then welding continues from the three electrode wires as they emerge from the nonconsumable guide tubes. The supports for the consumable guide tubes are then removed. At this point, rotation of the workpiece begins and the starting dam is removed. Welding continues in a normal manner, electrode wire being supplied through the three nonconsumable guide tubes, until the starting point is approached. Then, the two innermost guide tubes are removed successively, as the depth of the joint tapers down (Fig. 8, right). The joint is finished with only one electrode wire being fed. A small crater that can usually be blended in without runoff tabs is left.

Preheating and Postheating

The thermal cycle developed by electroslag welding is different from that resulting from arc welding. The temperature of the flux pool, normally from 3000 to 3500 F, is much lower than the temperature of a welding arc, but the total amount of heat for electroslag welding is much greater than for arc welding. As a result, a larger area is heated, but more slowly. Thus, in effect, the process incorporates a preheating operation.

Because a great amount of heat is imparted to the entire area around the weld, cooling is relatively slow and postheating is usually not required. However, postweld heat treating is often used to obtain specific properties.

Production Examples

Of the seven examples that follow, two describe electroslag welding by the conventional system; the others deal with electroslag welding by the consumable-guide-tube system.

Because electroslag welding is capable of extremely high deposition rates, it is generally less costly than other welding processes for joints in massive parts in which hundreds of pounds of filler metal must be deposited. In some of the applications that follow, weldments were comprised of several castings, or of various combinations of castings, wrought shapes, and forgings, that would have been impractical to fabricate by any process other than electroslag welding. The first three examples describe applications in which a large weldment was used instead of a single casting.

Example 361. Use of a Three-Piece Weldment To Reduce Cost and Lead Time (Fig. 9)

As originally designed, the 139-in.-diam 34-ton grinding-mill head shown in Fig. 9 was a single ductile iron casting. Changing

to a weldment comprised of three sections of 6-in.-thick low-carbon steel plate, joined by electroslag welding, reduced production cost by 50% and lead time by 17 weeks.

The three plate sections were held in alignment by strongbacks as shown in Fig. 9. The strongbacks were removed in succession as required by vertical movement of the equipment. The assembly was rotated so that each joint was in the vertical position during welding.

Welding was initiated by placing granulated flux in the well that was formed by the starting trough and two 9-in.-long water-cooled copper dams, and advancing two ⅛-in.-diam electrode wires (from a welding head) into the flux, melting the flux and forming the puddle of molten weld metal. Welding was done in a single pass with the welding head oscillating the electrodes across the length of the gap between the plates, to within ½ in. of the dam on each side of the joint. A dwell of 1 sec at each side was included in the oscillation cycle.

Under the welding conditions given in the table with Fig. 9, void-free welds, with minimum shrinkage, were obtained. Joint shrinkage was about 1⁄16 in., compared with the ⅜-in. shrinkage normally obtained when using submerged-arc welding. Filler-metal deposition rate was 90 lb per hour, from two wires, at a vertical-travel rate of 0.72 in. per minute. After welding, all weld reinforcements were ground flush and welds were subjected to 100% radiographic and ultrasonic inspection.

The same process was used for making other grinding-mill heads from plates up to 12 in. thick.

Example 362. Replacement of a Casting by a Weldment To Reduce Cost and Lead Time (Fig. 10)

Jaws for rock crushers were originally made as ductile iron castings, but to reduce cost and lead time, the castings were replaced by weldments comprised of two 6-in.-thick plates of ASTM A283 low-carbon steel. Electroslag welding, using the consumable-guide-tube system and the conditions listed in the table with Fig. 10, was employed. The welded T-section of a crusher jaw is shown at upper left in Fig. 10.

The joint edges were prepared by gas cutting, and plates were aligned and fastened in position by tack welded strongbacks and wedges, as shown at upper right in Fig. 10. The assembly was preheated to approximately 150 F with torches to ensure that the joint was dry. At first, because of the joint configuration, solid copper dams were used (no water cooling), but these dams became overheated and shaped water-cooled dams were therefore substituted. The water-cooled dams were 9 in. long, and were made by brazing together ¼-in. formed copper plates. A plan view of a cross section of the joint area and dams is shown at the lower left in Fig. 10.

Two consumable guide tubes, inserted at the top of the joint (Fig. 10, upper right) and extending down its entire length, carried the electrode wires into the starting trough. The water-cooled dams were "leap-frogged" as required during welding. A cross section of the welded joint is shown at the lower right in Fig. 10.

After welding, the strongbacks, starting trough, and runoff tabs were removed and the weldment was stress relieved at 1125 to 1175 F for 6 hr. After stress relief, the weldment was inspected ultrasonically.

Conditions for welding the joint are given in the table with Fig. 10. This joint is typical of those that are better suited to welding by the consumable-guide-tube system than by the conventional system.

Example 363. Electroslag Welding an 83,000-Lb Press Frame From Four Plate Sections (Fig. 11)

Because the press frame shown in Fig. 11 (upper left) was too large for production as a single piece by casting or by cutting from a large plate, it was fabricated by joining four sections of 10-in.-thick medium-carbon steel (1035) plate by consumable-guide-tube electroslag welding.

The components of the frame were prepared by gas cutting, and each joint was aligned (leaving a root opening of 1¼ in.) and held in position by means of strongbacks tack welded to both sides of the joint. Starting troughs and runoff tabs were welded to the bottoms and tops of the four joints. A typical setup is shown at the lower left in Fig. 11. The workpiece was then turned on edge, as shown in Fig. 11, and water-cooled copper dams (about 28 in. long) were wedged in position at the two joints on the lower side (as made ready for welding) of the frame. Starting flux was placed in the starting trough, and two consumable guide tubes were inserted into the 1¼-in. gap between the frame sections (Fig. 11, right). The guide tubes were insulated with ceramic ferrules or glass fiber to prevent electrical contact with the sidewalls of the joint. During welding, the guide tubes were oscillated along the width of the joint to within about ½ in. of the copper dams. The dwell time at each end was 2 sec. After the first joint had been completed, the guide tubes were replaced and the welding head was moved to the second joint, which was welded in the same manner. Welding conditions are given with Fig. 11.

After completion of the first two welds, the workpiece was turned 180° and the remaining two welds were made by the same procedure. The completed weldment was stress relieved. Quality was verified by ultrasonic inspection.

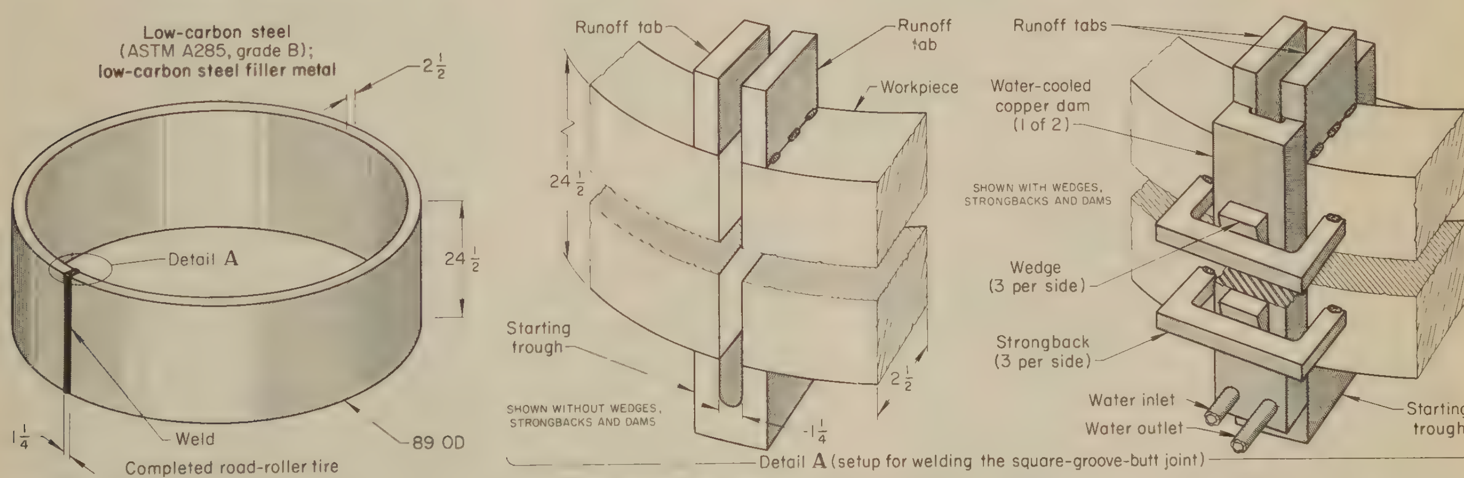
Five press frames were made by the procedure described.

Electroslag Welding vs Other Welding Processes

Deposition rates are higher for electroslag welding than for any other welding process — at least 25 to 50% higher than for submerged-arc welding, which is usually the closest to electroslag welding in deposition rate.

In some applications, electroslag welding is closely competitive with electrogas welding. Equipment used and principles of operation are similar. The range of work-metal thickness is much narrower for electrogas welding (⅜ to 4 in.) than for electroslag welding, and deposition rates are much lower. Consequently, heat input is less and cooling rate is higher in electrogas welding. Sometimes, these characteristics are advantageous (see Example 369 on page 400, in "Electrogas Welding").

Electroslag welding is not suitable for welding complex structures in which the joints are short or interrupted, or in which the time required to align the joint for welding in the vertical direction would be too great. In the next example, electroslag welding was chosen because it eliminated a rerolling operation; in Examples 365, 366 and 367, it replaced a slower process.



Conditions for Welding 2½-In.-Thick Tire Shown

Fixtures	Strongbacks; wedges
Power supply	750-amp transformer-rectifier(a)
Electrode wire	3⁄32-in.-diam low-carbon steel
Guide tube	⅝-in.-OD, ⅛-in.-ID 1010 steel
Current and voltage	750 amp, dcrp; 39 to 41 v
Arc time	0.32 hr
Filler-metal consumption	10.55 lb per foot(b)
Welding speed	0.79 ipm

(a) Constant-voltage type, 100% duty cycle. (b) Including guide tube.

Plate thickness, in.	Number of wires	Root opening, in.	Current, amp	Voltage, v	Vertical travel Speed, ipm	Vertical travel Time, min/ft
Conditions for Welding Tires ½ to 6 In. Thick						
½	1	1	500	34 to 36	1.6	10
1	1	1	600	37 to 39	1.2	10
1½	1	1	650	37 to 39	1.1	11
2	1	1	725	38 to 40	0.99	12
2½	1	1¼	750	39 to 41	0.79	15
6	2	1¼	1500	41 to 43	0.72	17

Fig. 12. Road-roller tire, three-roll formed from steel plate of various thicknesses, with a longitudinal square-groove butt joint that was welded by the consumable-guide-tube electroslag process using the setup shown, and under the conditions given in table (Example 364)

Example 364. Use of Electroslag Welding To Eliminate Rerolling of an 89-In.-Diam Road-Roller Tire (Fig. 12)

Road-roller tires (Fig. 12, left) that had been three-roll formed from 2½-in.-thick ASTM A285, grade B, plate were originally welded by the submerged-arc process and rerolled to shape after welding. By changing to the consumable-guide-tube system of electroslag welding, rerolling was eliminated, because the low weld shrinkage (1/16 in. to 5/64 in.) obtained with this process resulted in less work-metal distortion. As a result, the over-all cost of fabrication was reduced, despite the higher cost of welding.

Before welding, the steel plate, gas cut to a width of 24½ in. and approximately 272 in. long, was rolled to an 89-in.-OD cylinder, leaving a root opening of 1¼ in. (Fig. 12, center), which was maintained by strongbacks tack welded to the plates on both sides of the joint at intervals of 8 in. Water-cooled copper dams, extending from the sump of the starting trough to the runoff tabs, were wedged in position against the joint (Fig. 12, right). The guide tube and electrode wire were inserted through the top of the joint. Welding was done with a single electrode wire, without oscillation, under the conditions given in the left half of the table with Fig. 12. No preheating or postweld heat treatment was required. After welding, the outside diameter of the tire was machined to a surface finish of 125 micro-in.

The same procedure was used for welding tires 32 to 84 in. in inside diameter and ½ to 6 in. in wall thickness. Typical welding conditions for this range of plate thicknesses are given in the right half of the table with Fig. 12.

Example 365. Change From Submerged-Arc to Electroslag Welding for Fabricating 7-In.-Wall Pressure Vessels (Fig. 13)

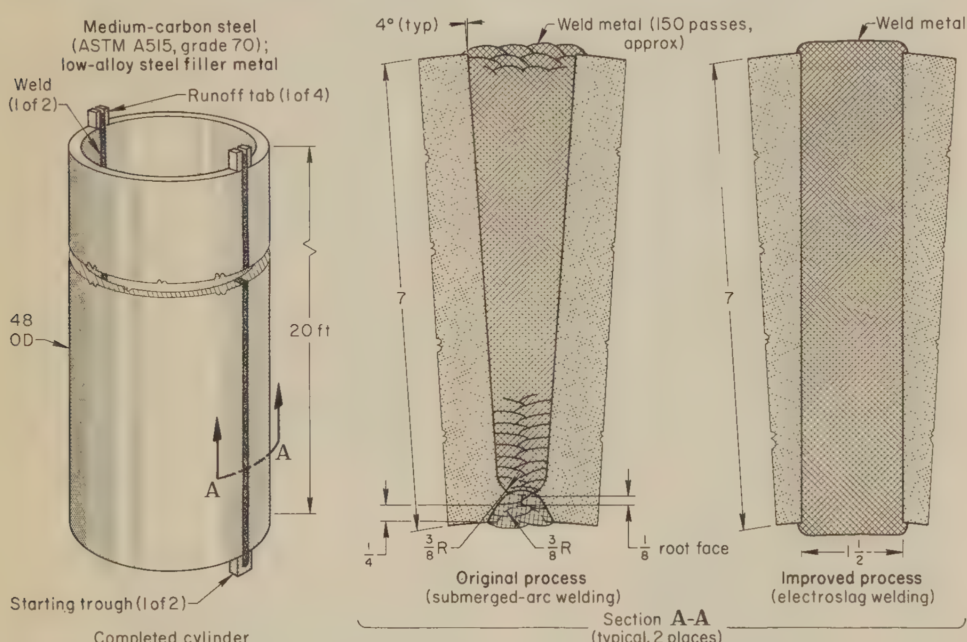
The 48-in.-OD pressure vessel shown in Fig. 13 was fabricated by welding two halves of cylinders rolled from 20-ft-long, 7-in.-thick ASTM A515, grade 70, plate. Originally, the two longitudinal seams of the vessel were welded by the submerged-arc process; later, the conventional electroslag process was adopted, with considerable saving in welding time and improvement in the quality of the weld. Welding conditions for both processes are given in the table with Fig. 13.

For submerged-arc welding, the joints were machined to the double-U-groove shape shown in the middle view in Fig. 13. The large outside groove was welded first and then the inside of the joint was back gouged to sound metal and welded. Using two 5/32-in.-diam electrodes in tandem, about 150 beads were deposited at a rate of 25 to 30 lb per hour. The average welding time per seam was 44 hr.

For the conventional system of electroslag welding, joints were prepared by gas cutting the plate edges to form a square groove with a root opening of 1½ in. (Fig. 13, right), which was maintained by strongbacks tack welded to the walls of the vessel on both sides of the joints. Starting troughs and runoff tabs were attached to the joints, and the vessel was mounted vertically on a positioner table and leveled. Welding was done in a single pass with two 1/8-in.-diam electrode wires, which were oscillated across the joint between two sliding water-cooled copper dams. The copper dams, welding head and controls were mounted on an elevator platform that moved upward along the joint as welding progressed. The strongbacks were progressively removed during welding to allow the dams to move vertically with the level of the rising weld and flux puddle. Welding time per joint was 6½ hr, at a deposition rate of 70 lb per hour. An additional saving in time resulted from there being no need for interpass cleaning, which was required in submerged-arc welding.

The electroslag process produced welds that, under radiographic inspection, were nearly free of voids and slag inclusions, and required no grinding or repair. In contrast, the submerged-arc welded joints had many voids and slag inclusions that necessitated rework. For submerged-arc welded vessels, the rework rate was generally 4 to 6% and occasionally as high as 10 to 15%, whereas for the electroslag welded vessels it never exceeded 2%.

The electroslag welding procedure described above was also applied successfully to similar pressure vessels made from alloy steel (ASTM A387, grades C and D).



Item	Submerged-arc welding	Electroslag welding
Joint type	Butt	Butt
Weld type	Double-U groove	Square groove
Joint preparation	Machined edges	Gas-cut edges
Fixtures	None(a)	Strongbacks; wedges
Power supply	750-amp motor-generator	Two 1000-amp transformers(b)
Electrode wire	Two 5/32-in.-diam EH14	Two 1/8-in.-diam low-carbon steel (Mn-Mo)
Flux	F61(c)	Proprietary(d)
Welding position	Flat (work axis horizontal)	Flat (work axis vertical)
Number of passes	About 150	One
Current, amp	600 to 700, dcrp	650 to 700, ac, per wire
Voltage, v	30 to 31	45 to 48
Deposition rate, lb per hour	25 to 30	70

Electrode separation, in.	...	2 to 2¾
Oscillation speed, ips	...	½
Dwell time, sec	...	5 to 7
Preheat	250 F min	None
Postheat	...	(e)
Welding speed, ipm	16 to 18	...
Welding time (per seam), hr	44	6½

(a) Joints tack welded initially. (b) Variable output; drooping to constant voltage characteristics. (c) Neutral, fused; mesh size 20×200. (d) Composed of SiO_2, MnO, CaO, CaF_2; quantity used was one twentieth of the weight of metal deposited. (e) Normalized at 1650 F, 1 hr per inch of cross section, for grain refinement; stress relieved at 1150 F, 1 hr per inch of cross section.

Fig. 13. Cylindrical pressure vessel that was fabricated by roll forming two halves and welding them by the submerged-arc (original) and conventional electroslag (improved) processes, using two different joint designs, as shown (Example 365)

Example 366. Change From Flux-Cored Arc to Electroslag Welding for Trunnion Shoes (Fig. 14)

The dam-gate trunnion shoe shown at the upper left in Fig. 14 was fabricated by joining two 2⅝-in.-thick pin plates to a 5-in.-thick base plate. Originally, the plates were welded by the flux-cored arc process, which was later replaced by the consumable-guide-tube system of electroslag welding. Conditions for both processes are given in the table accompanying Fig. 14.

For welding by the flux-cored arc process, a double-bevel corner joint was used, as shown at the lower left in Fig. 14. The plates, which were preheated to a minimum temperature of 225 F, were welded in about 96 passes (48 per joint) using carbon dioxide for shielding. The change to the consumable-guide-tube system of electroslag welding simplified joint design (Fig. 14, lower right) and reduced the time for joint preparation. Preheating was eliminated and welding time per weldment (two joints) was reduced by about half. In addition, weld shrinkage was low and this improved dimensional control, which in turn permitted the pin plates to be surface ground to final size prior to assembly and also helped to hold the spacing between these plates to within 1/32 in. during welding and stress relieving. As a result, machining time per weldment was reduced by 20 hr. Changing to electroslag welding resulted in a total time saving of approximately 32 hr per weldment, or a cost saving of about $23,000 for 90 weldments.

The sequence of operations for welding by the electroslag process was as follows:

1 Fit and tack weld pin plates to the base plate using braces (Fig. 14, upper right).
2 Fit and tack weld starting troughs and runoff tabs.
3 Position the welding head over the joint and center the guide tubes in the joint opening.
4 Position and clamp inner and outer solid copper dams (see Fig. 14, upper right).
5 Add starting flux and weld one joint.
6 Weld the second joint immediately.
7 Remove copper dams and cut off starting troughs and runoff tabs.

8 Stress relieve weldment.
9 Remove braces.
10 Machine.

The first two weldments (four joints) were inspected by radiographic and ultrasonic methods. This inspection served to qualify the process and the operator, and to correlate the two inspection methods. Subsequently, weldments were inspected by ultrasonic testing only.

Slag inclusions occurred in the weld metal of the first two weldments. The two joints of each weldment had been welded simultaneously, which is not an unusual practice. However, when the other weldments were welded one joint at a time, no slag inclusions were encountered. The cause of the slag inclusions was never definitely determined.

Example 367. Electroslag Welding Instead of Gas Metal-Arc Welding for a 7⅜-In.-Wall Cylinder (Fig. 15)

The 37½-in.-diam cylindrical shell shown at the upper left in Fig. 15 was fabricated by welding the gas-cut ends of a formed low-carbon steel (ASTM A113) plate that was approximately 140 in. long, 48 in. wide and 7⅜ in. thick. Originally, the seam was welded by the gas metal-arc process, but later the consumable-guide-tube electroslag process was adopted, at a considerable saving in fabrication time. Welding conditions for both processes are included in the table accompanying Fig. 15.

With the gas metal-arc process, a double-V-groove butt joint (Fig. 15, lower left) was welded in the flat position, using 148 to 175 passes. The sequence of operations was as follows:

1 Manually gas cut plate to size, with the edges for the joint beveled as shown at the lower left in Fig. 15.
2 Clean joint areas.
3 Heat plate and roll form into a cylinder.
4 Reroll cylinder to roundness, and tack weld internal braces to hold it in shape.
5 Preheat cylinder to 250 to 350 F.
6 Weld inside of longitudinal seam in 72 to 85 passes, depending on fit-up.
7 Back gouge the weld to sound metal.
8 Weld outer surface of longitudinal seam in 76 to 90 passes.

The change to electroslag welding permitted a square-groove butt joint (Fig. 15, lower right) to be used. Plate preparation was therefore simplified. In addition, the method of gas cutting was changed from manual to automatic, to reduce the cost of production still further.

The sequence of operations for plate preparation and electroslag welding was as follows:

1 Gas cut plate with an automatic cutting torch.
2 Clean joint area.
3 Heat plate and roll form into a cylinder.
4 Reroll cylinder to roundness, and tack weld strongbacks to maintain root opening of 1⅛ to 1¼.
5 Position cylinder vertically and attach starting trough and runoff tabs.
6 Wedge solid copper dams (2 by 4 by 60 in. long) behind the strongbacks.
7 Position three consumable guide tubes between the edges of the joint (Fig. 15, upper right).
8 Weld in a single, continuous pass.
9 Remove dams, starting trough and runoff tabs.

The joint after electroslag welding is shown in Fig. 15 (lower right). In addition to the time saved in joint preparation, the change to the electroslag process reduced welding time by 32.4 hr (more than 80%) and eliminated preheating.

Welds were examined radiographically in developing the welding procedure. Once the procedure was established, magnetic-particle inspection was used.

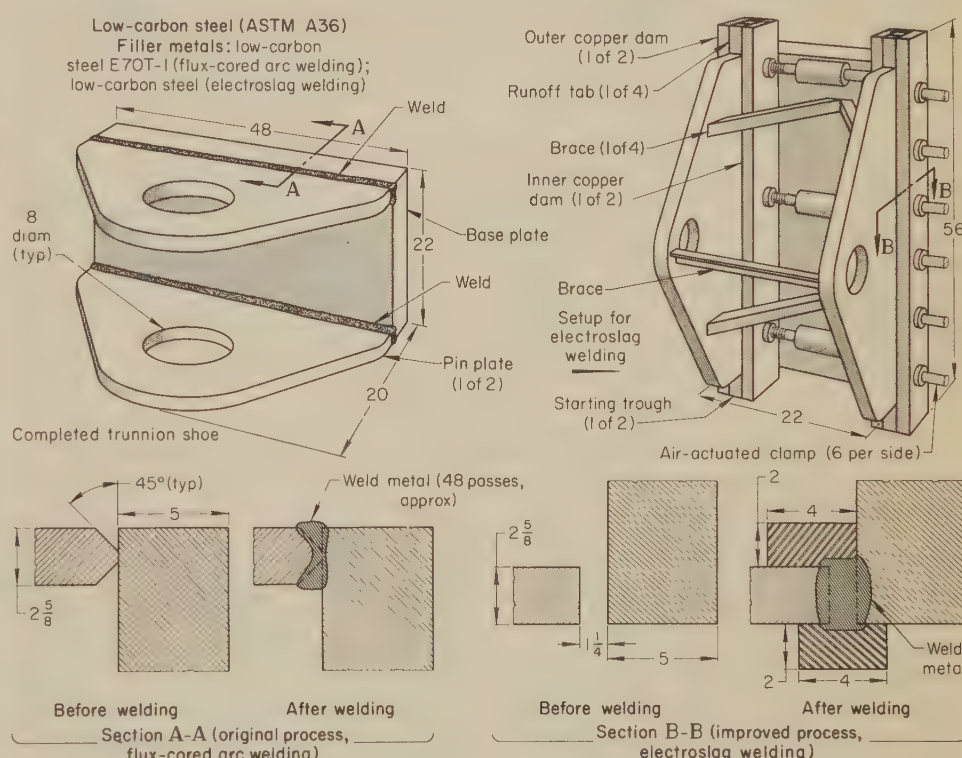
Conventional System vs Consumable-Guide-Tube System

Under most conditions, conventional and consumable-guide-tube electroslag welding give equal results at about the same speed. Factors that influence the choice of system are generally related to the length of joint to be welded, the shape of the joint, the number of pieces to be welded, and the cost of capital equipment.

Length of Joint. Joints up to 20 ft long are welded regularly by the conventional system of electroslag welding. The only limitation on length of joint is the scaffolding or other auxiliary equipment required for controlled vertical travel of the welding machine.

Joints up to 20 ft long have also been successfully welded by the consumable-guide-tube system. Maximum length depends in part on work-metal thickness. If the thickness is no more than about 2⅜ in., longer joints can be welded, with acceptable results, using one electrode wire and one guide tube without oscillation. In general, for welding long joints in thick sections, more than one electrode wire, or oscillation, or both, are required, but it is better to increase the number of electrode wires than to use fewer electrode wires and oscillation. (In Example 367, three wires were used to weld joints 7⅜ in. wide by 48 in. long.) When multiple electrode wires and oscillation are used, guide tubes must be bridged together by welding (not brazing). Maintaining alignment of the guide tubes in the joint opening becomes more difficult as their length increases. Control difficulties become even greater when oscillation is used.

Joint Configuration. For welding square-groove butt joints (the most common type), the two electroslag welding systems are equally suitable. For other types of joints, however, one system is often preferred. For example, if the joint to be welded is curved in the vertical plane, or if it contains some other type of irregularity that prevents a straight guide tube from extending the full length of the joint, electroslag welding may be restricted to the conventional system, although consumable guide tubes can be bent to conform to some configurations. Welding of a T-joint such as described in Example 362 would be difficult, if not impossible, by the conventional system.



Item	Flux-cored arc welding	Electroslag welding
Joint type	Corner	Corner
Weld type	Double-bevel groove	Square groove
Power supply	...	Two 1200-amp transformer-rectifiers(a)

Production Requirements. Both systems are adaptable to repetitive and one-of-a-kind jobs, but the conventional system of electroslag welding is better suited to repetitive work and the consumable-guide-tube system to a variety of short-run work.

Equipment utilization is an important consideration in choosing between the two systems, because the cost of conventional-system equipment cannot be justified for part-time utilization.

Equipment Cost. Equipment required for the conventional system costs from four to five times as much as that needed to do the same job by the consumable-guide-tube system. To a great extent, this difference accounts for the more extensive use of the consumable-guide-tube system. Use of the conventional system is restricted mainly to applications in which the practical limits of the consumable-guide-tube system are exceeded.

APPENDIX

Electroslag Welding of Ship Plate

Neither the conventional system nor the consumable-guide-tube system of electroslag welding as described in the main portion of this article is well adapted to the welding of ship plate in the vertical position, principally because the thickness of ship plate is generally less than is practical for welding by either system of electroslag welding. Except for the well-known manual and semiautomatic arc welding methods, electrogas welding has been the most widely used process for this application.

There is, however, electroslag welding equipment available that is practical for welding plates within the thickness range of ½ to 2 in. and for the long joints normally required in ship construction. Welding with this equipment is fundamentally the same as conventional electroslag welding, as described in this article. However, the details of equipment and operation of the equipment vary considerably.

Equipment designed especially for welding ship plate (but usable also for similar other applications) differs in several respects from equipment used for conventional electroslag welding. The major differences are in the arrangement of equipment components and the method of moving the welding head. Minor differences include many design features that permit a unitized head.

The equipment consists primarily of a mobile unit, often referred to as the crawler assembly because it moves vertically up the plates. In addition, a power supply, electrode-wire supply and water supply, all remotely located, are required.

The crawler assembly consists of two structural frames that ride on the front and back of the workpiece and are connected through the gap, above the welding area, by a ball-lock pivot pin for rapid setup and removal. The front frame carries the drive motor and gear-reducer/transmission unit, a flux dispenser, a tensioning device, a wire-guide assembly, and an articulated welding dam (shoe). The rear frame of the crawler consists of a set of leading rollers, a guide fin, and a second articulated welding dam. The crawler assembly is designed to pass through strongbacks that have a minimum opening 4 in. wide by 2½ in. deep.

Vertical movement is achieved by means of a 60°-V-shape knurled roller that rides on the corner edges of the plates, in the gap, above the welding area. The knurled roller is driven by the motor mounted on the unit. Thus, no overhead suspension or vertical track is required as in most conventional electroslag welding (see the section on Principles of Operation, on page 384 in this article).

The crawler type of welding machine requires a constant-voltage power supply capable of providing 38 volts at 325-amp output and 47 to 48 volts at 550-amp output. Because of the long cables normally needed for this type of application, the voltage drop is usually high. The power supply must incorporate a motorized voltage adjustment.

This welding equipment utilizes a completely enclosed wire-feed system mounted in the control cabinet. The cabinet also houses two electronic governors, a 65-lb-capacity wire reel, and all electrical circuitry for operation and control of the crawler unit. Access to all components is provided through hinged doors located on the cabinet. Four lifting rings are provided to permit suspension of the control unit to follow the plate crawler during welding. This part of the equipment is often suspended on a chainfall so that it can be relatively close to the welding area.

Electrode wire is supplied by a heavy-duty, two-speed wire feeder incorporating an external gearshift that allows selection of either a 29-to-1 or a 95-to-1 gear ratio. The unit, in conjunction with its electronic governor control, feeds electrode wire through an interconnecting conduit to the weld zone at a controlled rate.

For welding in areas where a plant water supply is not available, a specially built water cooler can be used. Such a unit provides cooling water at a rate of 3 gal per minute at 100 psi. The circulating system includes an adjustable pressure-relief valve, a water filter, a visible water-flow indicator, a water-pressure gage and control valve, and an air-pressure-release valve for reverse air flushing. This unit also can be suspended on a chainfall if desired, so as to lessen the distance between the water-cooling unit and the welding unit. A junction box, which is supplied as one component of the equipment, provides a convenient terminal for connecting the water lines to the dams. This box contains bulkhead fittings, and safety switches that automatically shut off the welding current in the event of a water-flow failure.

Operation. The crawler unit is installed in the plate gap and adjusted to the proper tension. Wire feed is preset. An initial starting charge of iron powder and flux is placed in the joint gap, where welding is initiated by an arc as in other electroslag welding operations. As the electrode wire is fed into the joint, a flux depth of ⅝ to 1⅛ in. is maintained. The welding unit (crawler) can be adjusted to move at a rate of ½ to 2½ in. per minute.

Once started, the operation is essentially automatic, although it must be monitored by an operator. Periodic adjustments are required to ensure uniform results.

Electrogas Welding

ELECTROGAS WELDING is an automatic method of gas metal-arc or flux-cored arc butt welding (depending on whether the consumable electrode is a solid wire or a flux-cored tubular wire) in which external shielding gas is supplied and two water-cooled dams (molding shoes) confine the molten weld metal. Although the axis of the weld is vertical, the process is actually flat-position welding with vertical travel, because the consumable electrode is fed downward into a cavity formed by the opposing faces of the components to be welded and the two water-cooled dams (see Fig. 1).

In its mechanical aspects, and its application to welding practice, electrogas welding resembles conventional electroslag welding, from which it was developed (see the article on Electroslag Welding, which begins on page 383). Electrically, electrogas welding differs from electroslag welding in two ways: (*a*) the heat is produced by an electric arc and not by electrical resistance of a slag; and (*b*) only direct current can be used, whereas either alternating or direct current can be used for electroslag welding.

Applicability

Electrogas welding is most often used for joining relatively thick plates, such as those required in the construction of ships, bridges and large tanks (see the section in this article on Welding of Tanks, and Example 368). Large-diameter thick-wall pipes and circular pressure vessels also can be butt welded by the electrogas process, provided that the work can be positioned to permit vertical feeding of the electrode (see the section in this article on Circumferential Welding).

Metals Welded. The electrogas process has been generally restricted to the welding of low-carbon and medium-carbon steels, although it has been successfully used for the welding of alloy steels and the austenitic grades of stainless steel.

Base-Metal Thickness. Electrogas welding is most suitable for the joining of plates within the thickness range of ½ to 3 in., although plates ⅜ in. thick and 4 in. thick have been welded successfully by the process. For the welding of plates thinner than ½ in., shielded metal-arc, gas metal-arc, flux-cored arc, and submerged-arc welding usually are more economical. For plates thicker than 3 in., electroslag welding is usually more practical, because of the difficulty in obtaining adequate shielding-gas coverage (inadequate coverage results in weld defects).

With the use of specially shaped dams it is possible to weld together two plates that differ in thickness by as much as 50%, provided that both plates are within the thickness range of ⅜ to 4 in. prescribed for electrogas welding.

Length of Joint. There is no established limit on the length of joint that can be welded by the electrogas process. In shipyards, joints 80 ft long have been welded in one pass, with the joint in the vertical position. Single-pass welding is the method most frequently employed, but a two-pass method can also be used (see Example 369 and Fig. 8).

Equipment

The essential components of equipment for electrogas welding are a power supply, an electrode holder, water-cooled dams, a system for feeding the electrode wire, a mechanism for oscillating the electrode holder, and devices for supplying shielding gas to the area immediately above the weld puddle. Except for the power supply, the major components of the equipment are incorporated in an assembly that moves as an integral unit as welding proceeds.

A typical unit for electrogas welding is shown in Fig. 1. This unit is suspended on two chains that raise and lower it, as required, by means of a motor-driven hoisting mechanism (not shown in Fig. 1). (Other units are suspended by a single chain or by cables, or a track may be employed.) In addition to the components shown in Fig. 1, the unit incorporates control devices

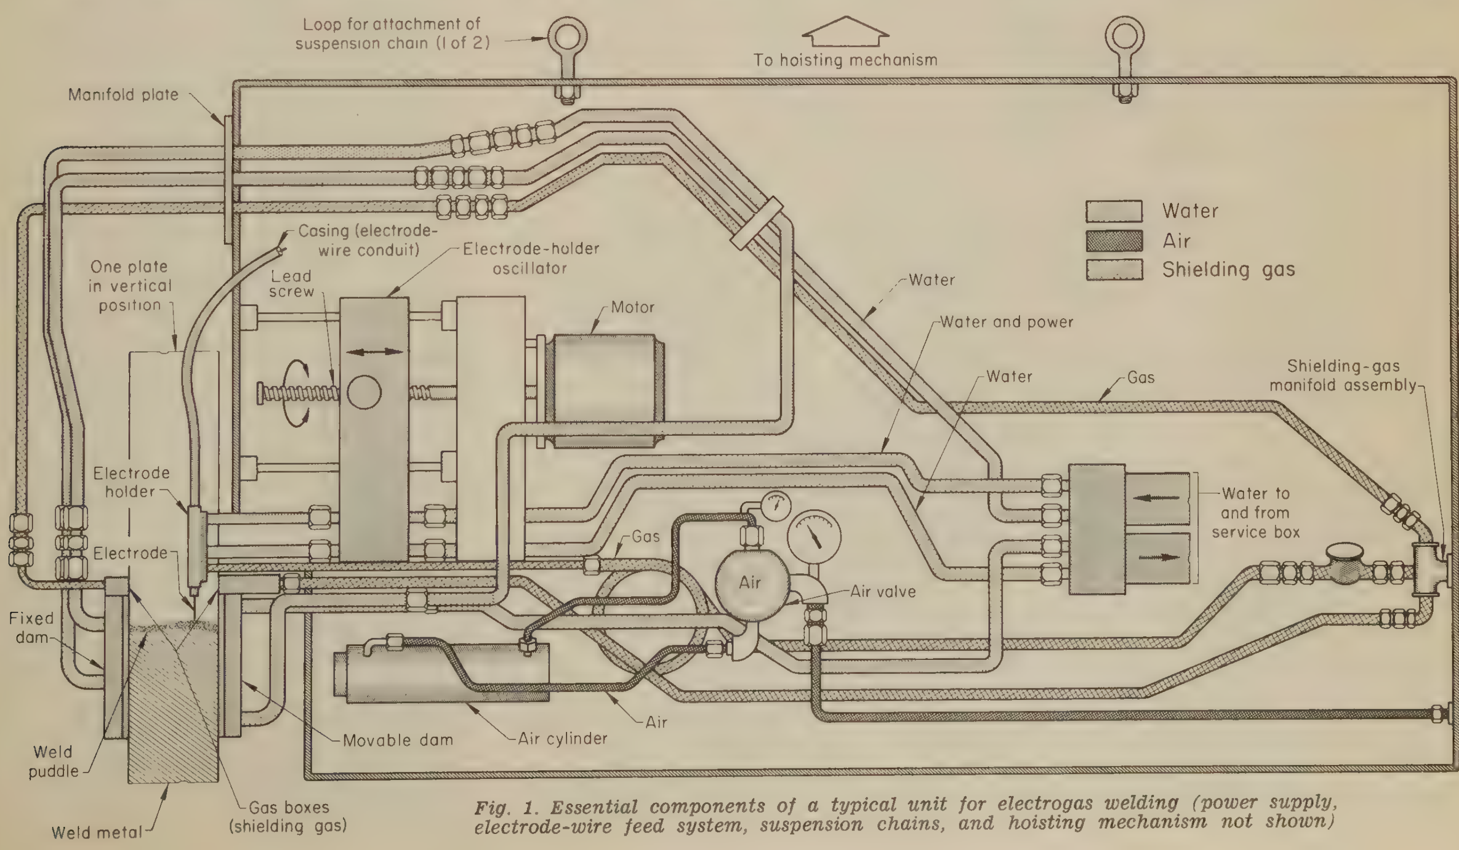

Fig. 1. Essential components of a typical unit for electrogas welding (power supply, electrode-wire feed system, suspension chains, and hoisting mechanism not shown)

for maintaining the required welding voltage and current, electrode-wire feed rate, shielding-gas flow rate, welding speed, and cooling-water flow rate.

The arrangement of the joint assembly (plates in a vertical position), water-cooled dams, gas boxes, and the electrode holder for one system of electrogas welding is shown in Fig. 2(a). Details of the electrode holder, a gas box, and the fixed dam (so called because it cannot move in the horizontal plane) are shown in Fig. 2(b), (c) and (d). The workpieces are held in position during welding by conventional strongbacks. Shielding gas is supplied through ports of two separate gas boxes (Fig. 2c), one on each side of the joint being welded. In this system, the electrode holder (also called the contact-tube guide or the wire guide) has a duct through which a part of the shielding gas is supplied.

Figure 3 shows the arrangement and details of essential components for another system of electrogas welding. In this system, shielding gas is supplied through ports incorporated in the water-cooled dams (see Fig. 3c); therefore, no separate gas boxes are needed.

Power Supplies. Electrogas welding is done with reverse-polarity direct current, normally supplied by a transformer-rectifier. Motor-driven and engine-driven generators are also used, but to a lesser extent. The power supply may be of either the constant-current or constant-voltage type; the constant-current type is used for a welding unit in which vertical travel is controlled by changes in arc voltage (see the discussion under "Control of Vertical Travel", on page 399).

Because current demands are usually heavy and duty cycles are often long, the power-supply unit must be rugged. Power supplies having capacities that exceed the maximum anticipated current demand are recommended. Most power supplies used have capacities of 750 amp or more at 100% duty cycle.

(For a more detailed discussion of power supplies used in welding, see page 3 in the article on Shielded Metal-Arc Welding and page 80 in the article on Gas Metal-Arc Welding.)

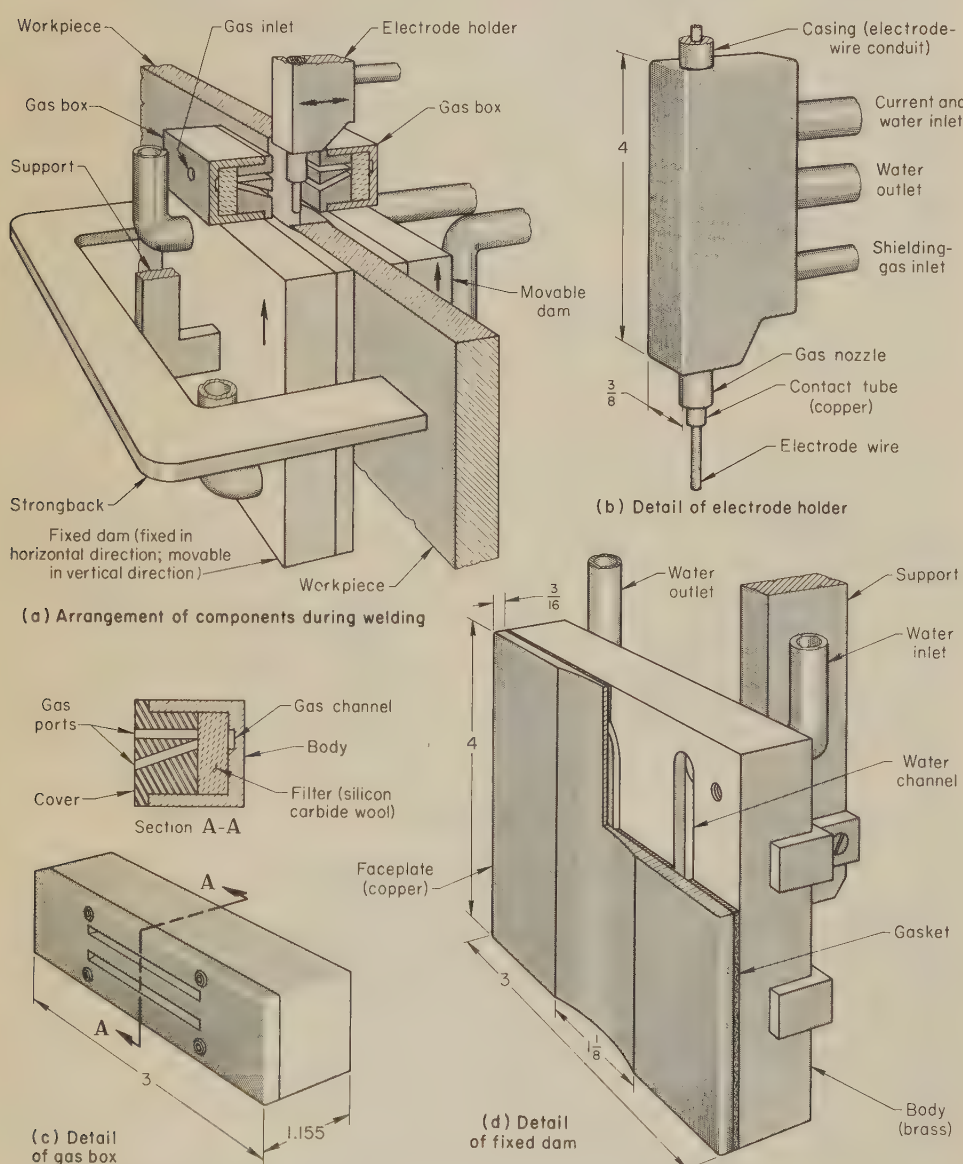

Fig. 2. Arrangement and details of essential components of an electrogas welding system employing a water-cooled electrode holder and separate gas boxes

Electrode holders for electrogas welding serve essentially the same purpose as those used in automatic gas metal-arc and flux-cored arc welding. However, they differ considerably in design for different electrogas systems (compare Fig. 2b and 3b). Regardless of the system used, the electrode holder must be narrow enough to clear the two plates being welded as it moves vertically within the gap between them. For this reason, the width of an electrode holder usually is limited to about 3/8 in.

A typical water-cooled electrode holder is shown in Fig. 2(b). The body of this holder contains cooling-water ducts and a duct for carrying shielding gas. The power supply is connected to the contact tube, which is made of copper and transmits the current to the electrode wire as it passes through, as in gas metal-arc welding. Water-cooled electrode holders are more complex, and therefore cost more, than holders that are not water cooled; water cooling, though, provides longer service life.

A typical non-water-cooled electrode holder is shown in Fig. 3(b). This holder serves only to guide the electrode wire and to carry the current; it has no duct for carrying shielding gas. It consists essentially of a curved contact tube of heat treated beryllium copper, held between and brazed to a pair of copper supports, and a copper bracket for mounting the assembly to the welding unit. The electrode holder is wrapped with insulating tape to protect it from the heat and from accidental arcing if it touches the sidewalls of the joint. Even so, the end nearest the weld puddle becomes extremely hot and gradually deteriorates. The deteriorated end can be cut off, and the electrode holder can be used for an application where a shorter electrode holder is acceptable.

Water-Cooled Dams. In most electrogas welding, two water-cooled dams (also called molding shoes) are used to form the cavity for the molten weld metal, to retain the weld metal until it solidifies (in most applications, the dams form two sides of the cavity), and to provide shape to the weld reinforcement. The dams move vertically with the welding unit. Water cooling prevents the molten metal from welding to the dam, and hastens solidification.

In one system, one dam is called the fixed dam, and the other, the movable dam (Fig. 2a). (The terms fixed and movable refer only to horizontal movement; both dams move vertically.) The fixed dam is held by a rigid support to prevent it from moving horizontally. The movable dam is actuated by an air cylinder and is moved horizontally to accommodate plates of different thicknesses. The pressure from the air cylinder also ensures that the dams are always held securely against the work.

In the system shown in Fig. 3(a), the two dams are pressed against the work by vise action through a cantilever arm that is spring loaded to relieve excessive pressure when the dams ride over minor obstructions.

The design of the dams varies considerably, depending on whether or not shielding-gas ducts are incorporated in them. A fixed dam without ducts for shielding gas is shown in Fig. 2(d). (The movable dam is essentially the same

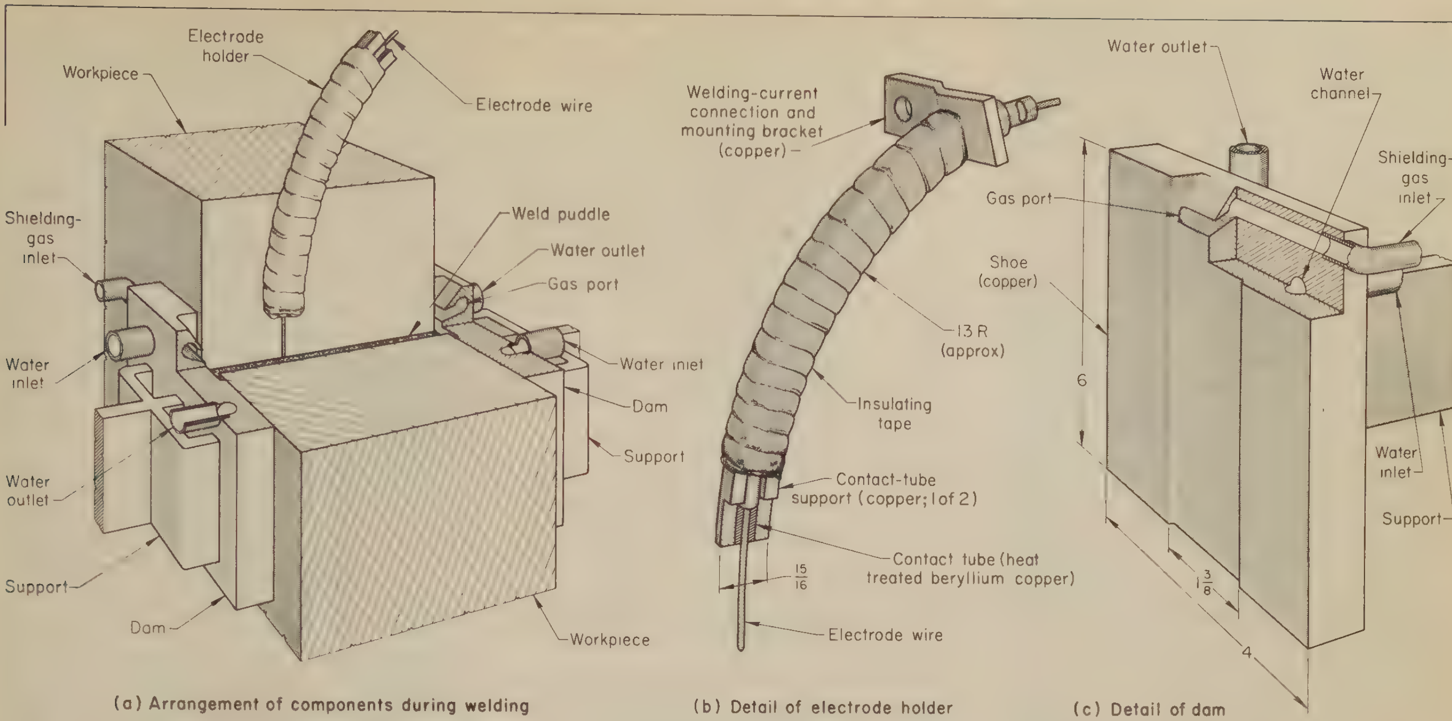

Fig. 3. Arrangement and details of essential components of an electrogas welding system employing an insulated electrode holder and dams that incorporate ports for supplying all shielding gas

except for the method of mounting.) This dam has a brass body that contains channels for circulation of cooling water. A copper faceplate is secured to the brass body, with an intervening gasket to act as a water seal. Faceplates are made of copper because of its high thermal conductivity; they are subject to damage in handling. The two-piece construction of the dam permits replacement of the faceplate without replacing the entire dam, and also makes it simpler to machine the water channels in the brass body.

The concave section in the middle of the faceplate on the dam shown in Fig. 2(d) straddles the joint as the dam moves vertically during welding. The width of this concave section is fairly critical; for example, the 1⅛-in. width shown in Fig. 2(d) is intended for welding plates separated by an 11⁄16-in. gap, using a solid electrode wire. It is not customary to leave a gap between the dam and the work, but should such a gap exist, the extra width of concave section that extends beyond each side of the joint allows any molten metal that starts to flow between the work and the dam to solidify before reaching the outer edges of the concave section. If flux-cored electrode wire is used, the width of the concave section should be increased to about 1¼ in., and the depth of the concave section should be increased correspondingly, to allow room for slag accumulation with the required weld reinforcement.

A dam that incorporates channels for both cooling water and shielding gas is shown in Fig. 3(c). The use of this dam (covered by U. S. Patent 3,281,570) eliminates the need to supply additional shielding gas through the electrode holder. The dam is of one-piece construction in solid copper and its gas port is designed to provide uniform shielding of the weld area without turbulence. The recessed area on the face of the dam differs slightly in dimensions and shape from the concave section shown in Fig. 2(d), but it serves the same purpose.

Electrode-wire feed systems are of the push type, and are similar to those used for gas metal-arc welding. (See the section on Wire-Feed Systems on page 82 in the article on Gas Metal-Arc Welding.) In addition to the reel of electrode wire, the feed rolls, and the casing (wire conduit) through which the electrode wire is pushed, the system may include a wire straightener, located between the reel and the feed rolls.

Electrode-Holder Oscillators. Most units for electrogas welding incorporate an oscillator mechanism for the electrode holder. Oscillation is generally required when welding sections thicker than 1 in., but it is sometimes used for thinner sections. There are several types of mechanism for achieving oscillation of the electrode holder. One common type, shown schematically in Fig. 1, consists of a motor-driven lead screw that moves an oscillator plate connected to the electrode holder.

Gas Ports. Shielding gas must be supplied, uniformly and without turbulence, above the weld puddle. In one system, part of the shielding gas is supplied through two separate components, called gas boxes, and supplementary shielding gas is supplied through the electrode holder. One gas box is mounted on the top of each dam, as shown in Fig. 2(a). Each gas box is constructed with a gas inlet (Fig. 2a), a gas channel, and slot-shape gas ports (Fig. 2c). Common practice is to drill the inlet hole to a diameter that will permit an adequate supply of shielding gas to be fed into the box under some preselected line pressure.

In another system, all of the shielding gas is supplied through ports in the dams (see Fig. 3c), and no supplementary shielding is required.

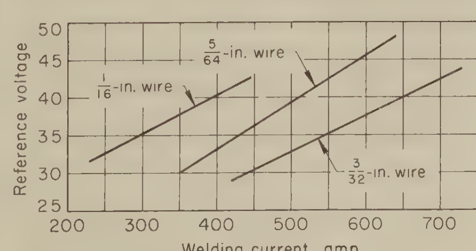

Fig. 4. Relations between reference voltage and welding current for three sizes of solid electrode wire in electrogas welding

Electrode Wires

Either solid or flux-cored electrode wire (filler metal) can be used in electrogas welding. Regardless of the type, preferred practice of one equipment manufacturer is to process the wire through a straightener before it enters the feed rolls.

Solid electrode wires are the same as those used for gas metal-arc welding (see Table 1 in the article on Gas Metal-Arc Welding for AWS classifications and compositions). Sizes most commonly used are 1⁄16, 5⁄64 and 3⁄32-in. diameter. Typical relations between reference voltage and welding current for these three sizes of electrode wire are shown in Fig. 4.

Flux-cored electrode wires used for electrogas welding are often of special composition and do not necessarily conform to AWS specifications (see Table 1 in the article on Flux-Cored Arc Welding). The tubular portion of the electrode is made of low-carbon steel, and the core is composed of flux and alloying elements as needed to meet the mechanical-property requirements of the welded joint. The most commonly

used sizes of flux-cored electrode wire are 1/16, 5/64 and 3/32-in. diameter.

Flux-cored electrode wires for electrogas welding normally have a lower flux-to-metal ratio than those for flux-cored arc welding. One flux-cored wire used in electrogas welding contains only about 6% flux by volume. Some electrode wires designed for flux-cored arc welding are likely to provide an excess of flux and result in choking of the arc when used for electrogas welding of long joints. With low-flux electrodes, joints 48 ft long have been electrogas welded in one pass with no arc choking.

For welding of low-carbon steel, the unit cost of flux-cored electrode wire is more than that of solid electrode wire. In one application, for example, 1/16-in. flux-cored wire cost $0.575 per pound and 1/16-in. solid wire cost $0.345 per pound, quantity and other conditions being the same. For alloy steel electrodes, solid wire often costs more than flux-cored wire, because alloy steel wire is subject to alloy extras, whereas alloying elements are added in powder form to the core of a flux-cored wire.

In welding of low-carbon steel, the higher cost of flux-cored wire is often justified because flux-cored electrode wire has about 20% greater deposition rate than solid electrode wire. Deposition rates typical of two sizes of solid and flux-cored electrode wire are:

Diam, in.	Solid	Flux-cored
1/16	18 lb per hr	22 lb per hr
5/64	24	29

Stickout. In most electrogas welding, electrode stickout of about 1½ in. is used. This relatively long stickout increases electrode melting efficiency by providing preheating of the wire.

Shielding Gases

A mixture of approximately 80% argon and 20% carbon dioxide is widely used, and is generally preferred, as a shielding gas for most electrogas welding applications. This mixture is well suited for use with both solid and flux-cored electrode wire.

Carbon dioxide alone is also used and is particularly satisfactory when employed with flux-cored wire.

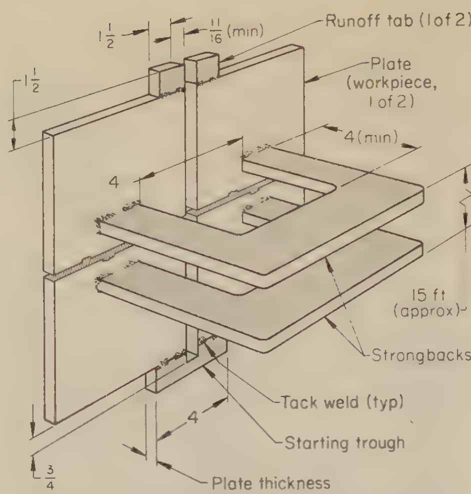

Fig. 5. Two plates with starting trough, runoff tabs, and strongbacks, in position for electrogas welding

Workpiece Assembly

Figure 5 shows two steel plates that have been assembled in a typical joint for electrogas welding. Both a starting trough and runoff tabs are used, to permit deposition of weld metal beyond the ends of the joint. The need for starting troughs and runoff tabs depends mainly on plate thickness and on the extent to which repair welding (usually by the shielded metal-arc process) can be tolerated. Plates less than about 1 in. thick can usually be welded satisfactorily without the use of runoff tabs and by using only a starting block instead of a starting trough. Plates thicker than 1 in. can be welded in the same way, but as plate thickness increases, the amount of repair welding required will be greater if a starting trough and runoff tabs are not used.

As Fig. 5 shows, the starting trough and runoff tabs have the same thickness and width of gap as the plates to be welded, and are tack welded in place. The depth of the starting trough and the height of the weld metal deposited in the runoff tabs vary, depending on the specific equipment and the application requirements. Ordinarily, a ½-in. starting-trough depth and runoff-tab height are sufficient, but these may be increased to as much as 1½ in. for thicker sections. In one plant, 2 in. is the standard depth of starting troughs and height of runoff tabs.

When many identical joints are to be welded, the starting trough and the runoff tabs are often made of copper and are usually air cooled. Instead of being tack welded, they are clamped in place, thereby shortening setup time, and can be reused many times.

Usually, the plates to be welded are temporarily held in position by as many strongbacks as are needed to obtain rigidity. The cut-out portion of strongbacks must accommodate the fixed dam and usually must not be smaller than 4 by 4 in., as shown in Fig. 5, so that the dam can pass through as it travels up the joint.

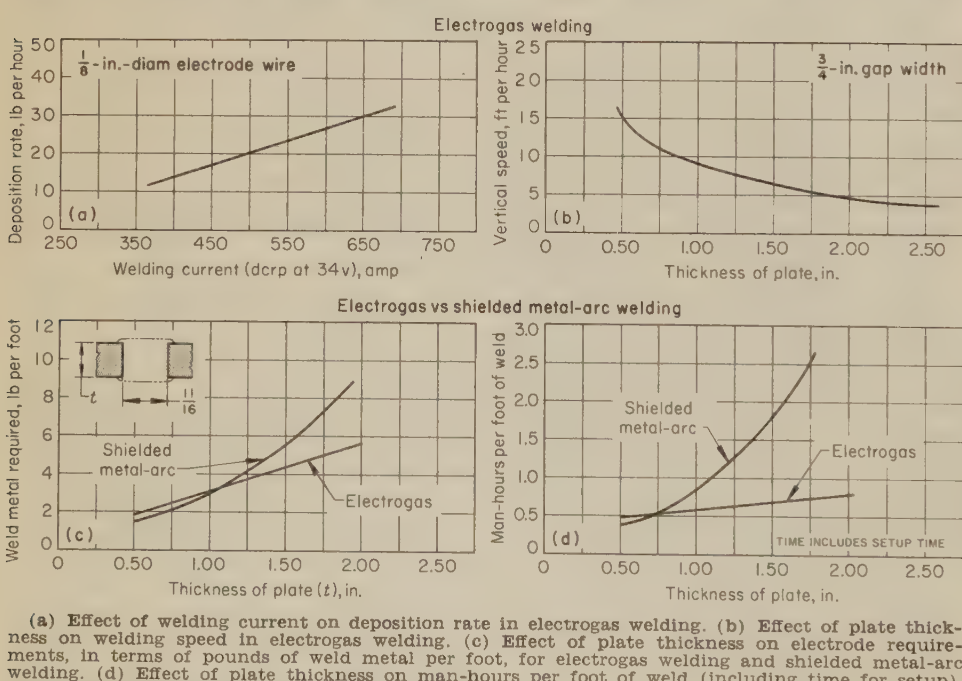
The gap between the plates does not vary with plate thickness. A minimum gap of 11/16 in. (Fig. 5) is commonly used.

Operating Procedure

In setting up for electrogas welding, the entire welding unit is installed over or beside the joint between the two plates. Travel is checked by lowering and raising the unit, making certain that the electrode holder enters and leaves the gap smoothly and remains centered in the gap. During setup, other adjustments, including feed rate of the electrode wire, reference voltage, and current, are made. Electrode-wire size and required deposition rate must be considered in making the initial settings. If experience with similar applications is not available, the best procedure is to use the data supplied with the particular machine as a starting guide. However, sample welds should be made and tested to ensure that the welding procedure will provide joints having the required properties.

After the preliminary adjustments have been made, a button is pushed to start the automatic welding operation. First, the weld area is purged with gas, then the electrode wire is fed, the arc is struck, and welding begins. After the arc is established and becomes steady, correction of the current control may be required. Current variations of about ±25 amp caused by fluctuations in line voltage can be tolerated for short periods of time, but if the welding current stays off the pre-established value for more than about half a minute, it should be adjusted to bring it to the pre-established value.

Oscillation. Thickness of the work metal determines whether or not the electrode holder will be oscillated during welding. When the work metal is



(a) Effect of welding current on deposition rate in electrogas welding. (b) Effect of plate thickness on welding speed in electrogas welding. (c) Effect of plate thickness on electrode requirements, in terms of pounds of weld metal per foot, for electrogas welding and shielded metal-arc welding. (d) Effect of plate thickness on man-hours per foot of weld (including time for setup), for electrogas welding and shielded metal-arc welding.

Fig. 6. Relation of welding variables and welding-process efficiency (Example 368)

less than 1 in. thick, oscillation usually is not required, although it may be used in certain applications. If oscillation is used, it is necessary to make the adjustments during setup.

The oscillator mechanism moves the electrode holder back and forth within the gap. This is commonly accomplished with a lead screw, as shown in Fig. 1. The length of travel can be varied, but is usually set so that the electrode holder stops at a distance of ⅜ in. from each dam. The speed of traverse during oscillation is commonly 16 to 18 in. per minute. The oscillation cycle is normally set to incorporate a dwell time of up to 3 sec at each side before the direction is reversed. Dwell time near each water-cooled dam is used to achieve satisfactory penetration into the workpiece sidewall near the outer face that abuts the dam. If the dwell time is insufficient, the cooling effect of the copper dam causes lack of fusion of the base-metal surface.

Control of Vertical Travel. Close control of vertical travel is necessary, to maintain constant arc length and uniform arc voltage.

The method used for control of vertical travel depends mainly on the type of power supply used. A constant-current (drooping voltage) power supply enables travel to be controlled by a change in arc voltage. If, for example, the reference voltage (set on the machine) is 35 volts, there will be no movement until the arc voltage drops below 35. When this occurs, the travel mechanism is automatically actuated and the unit moves upward until the arc voltage is restored to its former value. The equipment is sensitive to a reduction as small as ¼ volt.

When a constant-voltage power supply is used, another means of controlling vertical travel must be sought. One system employs a photoelectric cell that controls the rate of travel by observing the height of the rising weld puddle.

To obtain the required control of travel speed, some minor adjustments by the operator are commonly required at the beginning of welding and, occasionally, from time to time during an extended welding cycle.

Welding of Tanks*

The electrogas process has been used successfully for making the vertical welds on field tanks built to various code specifications. A major reason is that thickness of plates used in construction of these tanks is usually within the range where the electrogas process can be applied most efficiently.

Because such tanks are large, duty cycles are long and the amount of welding done at one site is large. These conditions favor rapid amortization of electrogas equipment, which is considerably more costly than equipment for shielded metal-arc or other arc welding processes.

In one plant a development program was carried out to evaluate the relationships of some of the common welding variables and to compare efficiencies of electrogas welding and of shielded metal-arc welding for use in joining plates of the thickness range most widely used for tank construction (approximately ½ to 2 in.). Results of this investigation are given in the example that follows.

*This section, including Example 368 and Fig. 6, is based on information presented in the article Automatic Vertical Welding and Its Industrial Applications, by R. J. Franz and W. H. Wooding, *Welding Journal*, June 1963.

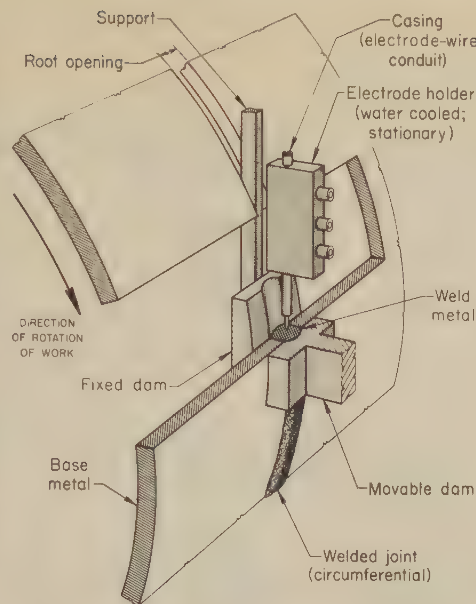


Fig. 7. Typical setup for circumferential (girth) welding by the electrogas process

Example 368. Development Program To Determine the Interrelation of Welding Variables and Efficiency of the Electrogas Process for Welding of Tanks (Fig. 6)

With the exception of Fig. 6(a), wherein amperage is one of the variables, a welding current of 650 amp dcrp at 34 volts was used to develop the data on electrogas welding shown in Fig. 6. As seen in Fig. 6(a), deposition rate has a straight-line relation to current in electrogas welding. With a current of 650 amp and a ⅛-in.-diam low-carbon steel electrode wire, a deposition rate of 30 lb per hour was obtained as shown in Fig. 6(a). The deposition efficiency was approximately 95%. Figure 6(b) shows the speed of electrogas welding, in feet per hour for 100% arc time, as a function of plate thickness, using a ¾-in. gap.

Figure 6(c) shows the electrode requirements in pounds of weld metal per foot for electrogas welding versus shielded metal-arc welding as a function of plate thickness, using an ¹¹⁄₁₆-in. gap. It should be noted that the electrode requirements plotted for electrogas welding form a straight line, whereas the shielded metal-arc requirements are on a curve of continually increasing slope. This is because of the square-cut joint edges used for the electrogas process, in contrast to the V-groove joint used for shielded metal-arc welding. Figure 6(d) compares the total time requirements for electrogas welding and shielded metal-arc welding. From these curves it can be seen that electrogas welding can be used for welding plates as thin as ½ in., but that it is less efficient than the shielded metal-arc process as plate thickness decreases to slightly below ¾ in. This is due in part to the initial setup time required, but mostly because a two-man crew was required to operate the electrogas machine.

The electrogas process thus proved to be economical, not only because of its ability to make acceptable welds at high deposition rates, but also because base-metal preparation was simple. For electrogas welding, edge preparation was simply a square-cut surface obtained by shearing or gas cutting. It was necessary only that the surfaces to be welded form a rectangular opening. Although fit-up and surface alignment should be held to reasonable tolerances, it was found that such tolerances may be exceeded to a considerable extent without any adverse effect on weld quality or finished appearance of the joint. The minimum gap between the surfaces to be welded was held to ¹¹⁄₁₆ in., because this minimum opening was needed to accept the electrode holder without difficulty of arcing on the surfaces of the joint. However, it was found that the gap could vary from ¹¹⁄₁₆ to ⅞ in. in any joint without causing difficulty other than that of adjusting the vertical travel speed to accommodate the differences in quantity of weld metal required.

Typical Applications. Four applications involving the use of electrogas welding for vertical joints in large outdoor tanks are briefly described below.

Surge Tanks. Fourteen tanks 70 ft in diameter and 145 ft high were constructed for use as surge tanks and were located between the penstocks and the powerhouse near a large dam. These tanks were fabricated from ASTM A515 or A516 carbon steel plates ranging in thickness from 1¾ in. for the bottom course to ⅜ in. for the top course. The tanks were built in accordance with Section VIII of the ASME Boiler and Pressure Vessel Code, and in accordance with the Corps of Engineers specifications. Welded seams were subjected to x-ray examination.

Cement slurry tanks 150 ft in diameter by 37 ft high were constructed from ASTM 515 or 516 steel to conform with API-12C specifications. Plate thickness in these tanks ranged from 1³⁄₁₆ in. for the bottom course to ⅜ in. for the top course.

Storage Tanks. A group of three storage tanks was built from ASTM A285 steel in accordance with Section VIII of the ASME Boiler and Pressure Vessel Code. The two bottom courses were 1½ in. thick and the remaining 13 courses were made of plates 1³⁄₁₆ in. thick.

Water Reservoirs. Three tanks for water reservoirs were constructed in accordance with AWWA D-100 and AWS D5.2 specifications. Each of these tanks was 338 ft in diameter and 16 ft high and was constructed with two courses. Plates for the lower course were 1⅛ in. thick, and for the upper course were ⁹⁄₁₆ in. thick.

Circumferential Welding

Circumferential (girth) welding of large-diameter pipes or pressure vessels can be done efficiently by the electrogas process. The method used differs from welding straight vertical sections of similar thickness in two respects: (*a*) the dams must be made to fit the curvature of the joint to be welded, and (*b*) the welding equipment remains stationary and the workpiece is rotated.

Circumferential welding can be done by more than one procedure. In one common method, shown in Fig. 7, the equipment components, with the exception of the curved dams, are the same as those used for vertical welding of plates. Welding proceeds as the workpiece rotates in a clockwise direction. The water-cooled electrode holder remains stationary, although it could be oscillated if required. The fixed dam is curved to fit the inside contour of the workpiece, and does not move in either the vertical or horizontal plane. The movable dam is curved to fit the outside contour of the workpiece and can be moved horizontally only, to accommodate variations in wall thickness.

A disadvantage of using the method shown in Fig. 7 is that when all but

approximately 18 in. of the circle has been welded, the electrogas equipment must be removed and the weld must be completed by another welding process, such as shielded metal-arc, gas metal-arc, or flux-cored arc welding. The seriousness of this disadvantage depends mainly on the wall thickness and the circumference of the sections to be joined. If the wall thickness were less than 1 in. and the circumference 30 ft, the amount of welding to be completed (in proportion to the total amount of welding) would be relatively small. On the other hand, if the wall thickness were 2 in. and the circumference only 10 ft, the amount of welding required for completion might be considered great enough to warrant the use of another process for the entire weld, or at least an alternative method of electrogas welding.

Alternative methods of circumferential welding, developed primarily for electroslag welding, and described in the article that begins on page 383, have also been applied successfully to electrogas welding. In one of these methods, circumferential welding begins on a starting block inserted between the two sections to be welded. The fixed dam is fastened on the inside of the joint area. Preparation for the closing sequence is made when the weld is half completed, by cutting away the starting block and gouging out the initial weld along a predetermined surface and tangential to it until the inner surface is reached. Tapered finishing tabs are tacked in place outside the joint at this location, so that the weld crater can finally be brought to the surface of the cylinder as the joint is finished. The weld is completed with the cylinder stationary and the electrode holder rising, as in a vertical weld.

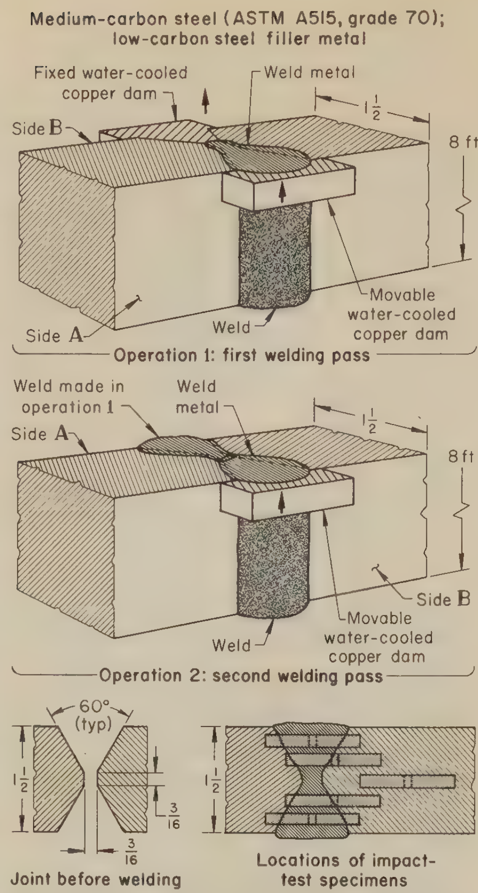
Two-Pass Welding

Most electrogas welding is done in a single pass, using square-groove butt joints, as shown in Fig. 5, but a type of joint that requires two-pass welding, such as a double-V-groove joint, may be needed (see Example 369 and Fig. 8). For two-pass welding, specially shaped dams are required. For instance, in welding a double-V-groove joint, the fixed dam must be contoured to fit the V for the first pass (see Fig. 8). After the workpiece is turned 180° (or the welding unit is moved), the second pass is made with only the movable dam; the first-pass weld performs the function of a fixed dam. Back gouging or grinding of the root of the first pass is required before the second pass can be deposited.

Two-pass welding has two metallurgical advantages over single-pass welding: (*a*) the shallower weld deposit requires lower heat input, and thus grain growth is minimized; and (*b*) the second pass generates enough heat to provide a grain-refining heat treatment for the weld made on the first side.

Electrogas vs Electroslag Welding

The equipment for electrogas welding closely resembles that for conventional electroslag welding. Therefore, a change from one process to the other entails



Location of impact-test specimen (see view at bottom right, above)	Testing temperature, F	Energy absorbed, ft-lb
Charpy V-Notch Impact Strength		
Plate as received	70	17
	50	7
Weld metal, side A	70	80
	30	60
Weld metal, side B	70	65
	30	45
Heat-affected zone:		
Side A	70	24
Side B	70	18
One-pass electroslag weld	70	10

Conditions for Electrogas Welding

Joint type .... Butt
Weld type .... Double-V-groove
Electrode wire .... ⁷⁄₆₄-in.-diam, flux-cored
Current (both passes) .... 475 amp, dcrp
Voltage ....34 v, first pass; 36 v, second pass
Arc length .... ¼ in., approx
Shielding gas .... Carbon dioxide, at 30 cfh
Welding position ...... Flat (vertical-axis weld)
Welding speed, both passes .... 3 ipm
Preheat .... None
Postheat .. Stress relief (if required for service)

Fig. 8. Section of an 8-ft-high vessel erected in the field, showing details of a two-pass electrogas weld that had greater notch toughness than a one-pass electroslag weld (Example 369)

simply a change from shielding gas to flux, or from flux to shielding gas. Thus, selection between processes is based on cost and application requirements, not on capital expenditure.

For work metals ¾ to 3 in. thick, the electrogas and conventional electroslag processes are often closely competitive. Some advantages of the electrogas process over electroslag welding are:

1 Restarting the weld is much easier.
2 The weld is much more visible to the operator.
3 As-welded impact properties are better. Thus, electrogas welding often is chosen if no heat treatment follows welding.

Offsetting these advantages is the fact that the electroslag process usually produces welds that are cleaner and more nearly crack-free. Also, when electrogas welding and shielding gas are used, porosity generally increases as base-metal thickness increases, because shielding becomes less effective.

The choice between the two processes for work metal ¾ to 3 in. thick is sometimes influenced by the properties obtainable in the completed weld. This was the case in Example 369, where electrogas welding produced tougher welds.

For sections more than 3 in. thick, electroslag welding is usually more practical. When applicable, the electroslag process that uses a consumable guide tube may cost less than electrogas welding, because the capital investment for the consumable-guide-tube electroslag process is only about 20% of that for the electrogas process. For welding low-carbon steels such as ASTM A36 in applications for which impact requirements are not stringent, the electroslag process is more often chosen because of its higher deposition rate.

Weld Properties. In welding large steel vessels, it is rarely possible to provide postweld heat treatment to improve the mechanical properties of the weld metal and of the heat-affected zone, and so the welding process used must be one that will ensure adequate toughness in the as-welded condition. In some applications, the low heat input and fast cooling of the weld metal in electrogas welding have made it possible to obtain specified mechanical properties that could not be obtained by electroslag welding. One such application is described in the next example.

Example 369. Two-Pass Electrogas Welding That Produced Tougher Welds Than One-Pass Electroslag Welding (Fig. 8)

A vertical weld 8 ft high was made by the electrogas process in the field erection of a vessel fabricated from 1½-in.-thick ASTM A515, grade 70, steel plate. Welding was done in two passes, one on each side of the plate, as shown in Fig. 8. A water-cooled copper dam with a shaped nose was used as a fixed dam for the first pass; the weld metal of the first pass served as the fixed dam for the second pass. For start-up, a starting trough was used at the bottom of the joint (not shown in Fig. 8). Joint preparation consisted of beveling the plates as shown in the view at bottom left in Fig. 8. Welding conditions are given with Fig. 8.

Impact tests were made using full-size Charpy V-notch specimens cut from the weld metal and heat-affected zone for each weld pass, and on a specimen taken from the as-received plate for comparison; the approximate locations of the specimens are shown in Fig. 8, bottom right. A further comparison was made by impact testing the heat-affected zone of a one-pass weld made by the electroslag process. As shown in the table with Fig. 8, the notch toughness of all specimens from the electrogas welded joint exceeded that of the as-received plate, whereas the notch toughness of the specimen from the heat-affected zone of the electroslag weld was considerably less.

Four side-bend tests and two tension tests of specimens from the electrogas welded vessel were conducted in accordance with Section IX (Welding Qualifications) of the ASME Boiler and Pressure Vessel Code. Code requirements were met in all tests. In the first tension test, tensile strength was 82,500 psi, and elongation in 2 in. was 24%; in the second test, tensile strength was 81,900 psi, and elongation 30%.

RESISTANCE WELDING

CONTENTS

Resistance Spot Welding

*By the ASM Committee on Resistance Welding of Steel**

RESISTANCE SPOT WELDING is a process in which faying surfaces are joined in one or more spots by the heat generated by resistance to the flow of electric current through workpieces that are held together under force by electrodes. The contacting surfaces in the region of current concentration are heated by a short-time pulse of low-voltage, high-amperage current to form a fused nugget of weld metal. When the flow of current ceases, the electrode force is maintained while the weld metal rapidly cools and solidifies. The electrodes are retracted after each weld, which usually is completed in a fraction of a second.

The size and shape of the individually formed welds are limited primarily by the size and contour of the electrode faces. The weld nugget forms at the faying surfaces, as shown in Fig. 1, but does not extend completely to the outer surfaces. In section, the nugget in a properly formed spot weld is obround or oval in shape; in plan view, it has the same shape as the electrode face (which usually is round), and approximately the same size. The spots should be at a sufficient distance from the edge of the workpiece ("edge distance") so that there is enough base metal to withstand the electrode force and to ensure that the local distortion during welding does not allow expulsion of metal from the weld. Also, spacing between adjacent spot welds or rows of spot welds must be enough to prevent shunting or to limit it to an acceptable amount.

Applications. Spot welded lap joints are widely used in joining sheet steel up to about ⅛ in. thick, and are used occasionally in joining steel ¼ in. or more in thickness. Thicknesses of 1 in. or more have been joined by spot welding, but this requires special equipment and would not ordinarily be economical. Many assemblies of two or more sheet-metal stampings that do not require gas-tight or liquid-tight joints can be more economically joined by high-speed resistance spot welding than by mechanical methods. Containers such as receptacles and tote boxes frequently are spot welded. The attachment of braces, brackets, pads or clips to formed sheet-metal parts such as cases, covers, bases or trays is another common application of spot welding.

Major advantages of resistance spot welding are high speed and suitability for automation and inclusion in high-production assembly lines with other fabricating operations. With automatic control of current, timing and electrode force, sound spot welds can be produced consistently at high production rates and low unit labor costs by unskilled operators.

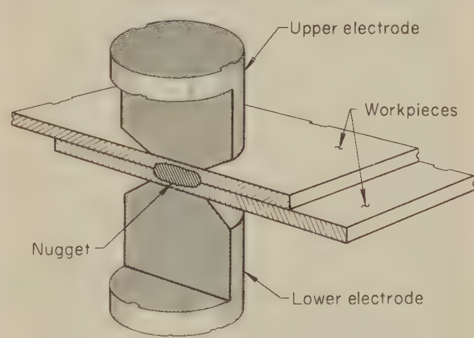


Fig. 1. Arrangement of electrodes and workpieces in resistance spot welding, sectioned to show shape of nugget and position of nugget relative to inner and outer surfaces of workpieces

However, a resistance spot weld in steels, which typically draws a current of about 5000 to 20,000 amperes at about 5 to 20 volts, imposes a heavy kilovolt-ampere (kva) demand. (The kva demand is even higher for resistance spot welding more conductive metals, such as many aluminum alloys and copper alloys.) Even though the duration of current flow for a single weld is only a few cycles, the corresponding power demand may be an undesirable load, especially if power is drawn from only one phase of a three-phase supply. Also, the initial cost of equipment is generally much higher for resistance welding than for most arc welding processes.

Although the most common application of resistance spot welding is the joining of two sheets of metal having the same composition and thickness, the process is also used to join more than two sheets of metal, to join metals that are dissimilar in thickness or composition (or both), and to join steel coated with another metal. The 13 examples of practice presented in this article illustrate the range of application of resistance spot welding to low-carbon steel.

For information on the spot welding of metals other than low-carbon steel, see the articles in this volume on resistance welding of stainless steel (page 456), aluminum alloys (page 466), and copper and copper alloys (page 475).

SILVERBERG, Welding Engineer, Maytag Co.

Most of the examples in this article were contributed by members of other Metals Handbook welding committees. Additional examples on resistance spot welding that appear in other articles in this volume are listed in Table 8, page 424.

Equipment. Nearly all resistance spot welding of low-carbon steel is direct-energy welding, in which single-phase or three-phase 60-cycle* alternating current, drawn ordinarily from 220-volt or 440-volt in-plant power lines and stepped down to about 2 to 20 volts, is fed directly to the electrodes as each weld is made.

The equipment needed for resistance spot welding may be simple and inexpensive, or complex and costly, depending on the degree of automation. Machines for direct-energy welding generally are composed of the following three principal elements:

1. **Electrical Circuit.** This consists of a welding transformer, a tap switch and a secondary circuit. The secondary circuit includes the electrodes that conduct the welding current to the workpieces.
2. **Control Equipment.** This initiates and times the duration of current flow, and may also be used instead of (or in addition to) the transformer tap switch to regulate the welding current. Controls may also sequence, time and regulate the over-all operation of the machine, including initiation, automatic adjustment, and termination of welding force and current.
3. **Mechanical System.** This consists of the frame, fixtures and other devices that hold and clamp the workpieces and apply the welding force.

Specifications for resistance welding equipment have been standardized by the Resistance Welder Manufacturers' Association (RWMA); and, for controls, by the National Electrical Manufacturers' Association (NEMA).

Single-Phase and Three-Phase Direct-Energy Welding Machines

The choice between single-phase and three-phase direct-energy machines for resistance spot welding is based mainly on machine capability and on initial, operating and maintenance costs. Power factor and load balance among the three phases of the power supply should also be considered, particularly when a high-capacity machine is needed in a plant where the supply of electric power is limited.

Single-phase machines are more widely used than three-phase machines. Single-phase machines are simpler than three-phase machines, and they cost less to buy, install and maintain. When equipped with suitable controls, however, a single-phase machine has the same performance capabilities as a three-phase machine of the same size and rating.

The two disadvantages of single-phase machines are low power factor (about 40 to 50%) and high kva demand (about double that for three-phase machines of the same capacity). Since the demand time for a resistance weld is very short, the amount of electric power consumed in welding may be insignificant. Nevertheless, if the welding-machine load is an appreciable part of the total electrical load in a plant, fixed charges for standby service, connected load, and power factor may be quite high when single-phase machines are used, even though they draw power from only one phase of the three-phase supply. If the welding-machine load is a small part of the total plant electrical load, or is used in industrial areas where ample electric power is available, these fixed charges usually are minor.

The low power factor and high kva demand of single-phase machines are outweighed in most situations by their cost advantages. In plants where many single-phase machines are in use, they can be connected so that the welding-current load is distributed among the three phases of the power supply to reduce the kva demand.

Three-phase machines, which take electric power from all three phases of the power-supply line, are of two general types — frequency-converter and rectifier. They differ from single-phase machines only in electrical construction. The transformer of a single-phase machine has only one primary winding. The frequency-converter three-phase machine has a transformer with three primary windings. The rectifier type has a three-phase-to-three-phase transformer, the secondary circuit of which supplies current to low-voltage rectifiers, which in turn deliver high-amperage, low-voltage direct current to the electrodes.

Three-phase machines have advantages over single-phase machines in relation to power factor and maximum kva demand. Power factor is about 40 to 50% for single-phase machines, but because of decreased frequency of the secondary current, is 85% or more for three-phase machines. The kva demand for a three-phase machine is about 50% less than that for a single-phase machine of the same capacity. This demand is distributed over all three phases of the power supply and therefore is further reduced in the ratio of 1.73 to 1, for an over-all reduction of 3½ to 1 — a marked advantage where electric power is limited.

The additional cost of three-phase machines may not be justified where power supply is adequate, or where a large number of machines is involved. Also, a three-phase machine is not generally suitable for welding of thin metal or where weld times of three cycles or less (with 60-cycle current) are required. Three-phase transformers generally have not been applied to multiple-electrode or multiple-transformer machines, because the necessary phase balance can be attained through distribution of single-phase welding transformers over the three phases of the power supply.

Controls for Direct-Energy Machines

Electrical controls for direct-energy resistance welding machines perform three principal functions: (*a*) initiating and terminating the flow of current to the welding transformer, (*b*) controlling the magnitude of the current, and (*c*) timing and controlling the mechanical operations of the welding machine. The controls fall into three groups: welding contactors, timing and sequencing controls, and other current controls and regulators.

Welding contactors are devices for making and breaking an electric power circuit. On resistance welding machines, contactors and other controls are applied to the primary circuit of the welding transformer. A welding contactor should be large enough to handle the maximum input from the electric-power line to the machine with the tap switch at the highest position. Three types of contactors are used on resistance welding machines — mechanical, magnetic and electronic.

Mechanical contactors are of either the single-pole or the double-pole type, and are operated by a foot pedal or a motor-driven cam. In foot-pedal operation, movement of the pedal first applies the squeeze pressure and then closes the electrical contacts. Further movement of the pedal opens the contacts and at the same time increases the welding force.

A magnetic contactor uses an electromagnet for closing the electrical contacts. When the magnet is de-energized, the contacts are opened by gravity and spring pressure. Single-pole, double-pole and synchronously interrupting types of magnetic contactors are available. The synchronously interrupting type opens the power circuit when the alternating-current wave approaches zero, and thus reduces arcing, for longer electrode-tip life and less marking on the work.

Electronic contactors use ignitron tubes, thyratron tubes, or silicon-controlled rectifiers to control the flow of current to the primary winding of the welding transformer. Ignitron tubes are used for applications requiring an extremely high welding-machine current, or a very large number of welding operations per minute. Thyratron tubes or silicon-controlled rectifiers are used to control currents that are too low for ignitron tubes to handle (less than 40 amp).

Electronic contactors, either synchronous or nonsynchronous, always open the circuit when the current wave passes through zero.

An ignitron contactor consists of two ignitron tubes connected in inverse parallel so that one tube carries the positive half-cycle of the welding current and the other tube carries the negative half-cycle.

A schematic diagram of the power-supply circuit and control circuit of an electronic contactor with two ignitron tubes is shown in Fig. 2. Semiconductor-type rectifiers are used to allow current flow from the ignitor to the mercury-pool cathode only. A control-circuit fuse provides protection of the ignitrons and isolation of the control circuit from the power circuit. In machines that are provided with electronic heat control, these rectifiers are replaced by thyratron tubes or by silicon-controlled rectifiers.

An ignitron tube is a rectifier because current flows only from the graphite anode to the mercury-pool cathode. Therefore, two tubes are needed to conduct alternating current. Together, the two tubes act as a single-pole electronic switch to control

*Throughout this article, "per second" has generally been omitted in reference to frequency, and the more familiar "cycle" or "cycles" is used in preference to Hertz (or Hz).

the flow of current to the primary winding of the welding transformer.

Most ignitron tubes are water cooled and have a stainless steel water jacket to prevent corrosion. A thermostatic switch (not shown in Fig. 2) is mounted on one of the tubes to stop operation if the temperature of the tube becomes too high. The other ignitron tube has a thermostatic switch that controls a solenoid-operated water valve, which conserves cooling water.

The contactor energizes the welding circuit when the control circuit is closed. The voltage for the control circuit is obtained from the power-supply circuit. Each ignitron tube is fired for each conducting half-cycle by an ignitor that is energized through the control circuit whenever the control circuit is closed by the timer.

When the duty cycle required of an electronic contactor exceeds the rating of the ignitron tubes, two contactors may be used with an auxiliary control to switch the load alternately from one to the other. When two contactors are operating in this manner, the permissible duty cycle and the averaging time are both doubled. However, the peak load cannot be exceeded, because the entire load at any instant is carried by one contactor only.

Time and Sequence Controls. The duration of current flow to the welding machine is controlled by a welding timer. The over-all operating cycle of the welding machine is timed and controlled by a sequence control or timer. Timing elements are of two types: nonsynchronous and synchronous.

A nonsynchronous timer, by NEMA standards, may start and stop the flow of welding current at random points with respect to the line-current wave form. Variations of timing and of current input to the machine result from closing and opening the welding contactor at random points on the wave form. The time variable is at least plus or minus one half-cycle, and sometimes more. Ordinarily, nonsynchronous timing is sufficiently accurate for weld times of 20 cycles or longer, because the percentage variation is low and can usually be neglected. The nature and quality of the work being done determine the type of timing required for weld times of 10 to 20 cycles. Nonsynchronous timing is not recommended for weld times that are shorter than 10 cycles.

A synchronous timer provides an accurate timing period, and closes the primary circuit of the welding transformer at the same point (electrical angle) with respect to the power-circuit voltage in making each weld. Thus the current wave form is consistent, and the energy delivered to the welding transformer is the same for consecutive operations.

Besides providing accuracy and reproducibility in these respects, a synchronous timer also eliminates variation in initial current caused by load transients. Load transients result from failure to initiate the flow of current at the power-factor angle in the highly inductive secondary circuit of the welding transformer.

A synchronous timer can be used in any application for which a nonsynchronous timer is suitable, but it is more expensive and, to be effective, must be accompanied by heat control.

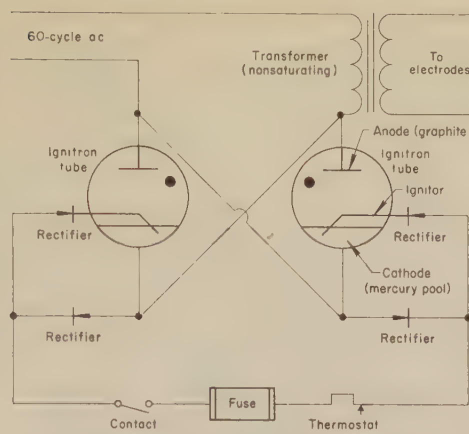

Fig. 2. Diagram of the power-supply circuit and the control circuit of an electronic contactor employing ignitron tubes

Sequence timers are used to control the four basic steps needed for most spot welding cycles. These steps are:

1 Close electrodes and apply force
2 Initiate and maintain welding current
3 Turn off welding current and maintain electrode force until weld nugget solidifies
4 Open electrodes.

The duration of step 1 is referred to as *squeeze time*; of step 2, *weld time*; of step 3, *hold time*; and of step 4, *off time*. Off time is provided by means of a two-position selector switch. One position of the selector switch permits the machine to continue cycling as long as the initiating switch is closed; the other position permits one complete sequence only, after which the machine cannot be restarted until the initiating switch is opened and reclosed.

Heat Control. The tap switch on the primary circuit of the welding transformer is used to change the ratio of transformer turns for major adjustment of the welding current. When an intermediate setting is needed, or for fine adjustment of the welding current, electronic heat control is used. Electronic heat control is standard equipment when synchronous timing controls are employed, and it can be added to nonsynchronous controls.

For electronic heat control, the semiconductor-type rectifiers in an ignitron contactor (see Fig. 2) are replaced as firing devices by thyratrons or silicon-controlled rectifiers. These tubes or rectifiers control firing of the ignitrons during each half-cycle of the welding current. Firing of the ignitron can be delayed by delaying application of a firing signal to the thyratron grid. This delay is usually controlled by a heat-adjustment dial. As the firing of the applied voltage wave is retarded, the root-mean-square (rms) current is reduced. The reduction in heat or energy varies as the square of the applied current, in amperes.

Because ignitron contactors require a certain minimum voltage and current to fire properly, complete control from 100% to zero is not feasible. It is necessary to limit the minimum value to 40% rms current for 220-volt equipment, and to 20% rms current for equipment operating on 440 volts or more. Heat-control switches are calibrated as a percentage of the increment in primary voltage between tap settings.

Automatically controlled phase-shift heat-control circuitry forms the basis of all accessories that change the level of welding current during a welding sequence. Therefore, use of current and voltage regulators, upslope and downslope controls, and quench and temper controls requires that the basic welding-machine control be equipped with a heat-control unit.

To minimize variations in welding current, heat control should be operated as near full heat as possible. Where a welding current of 30% of the maximum rms current is being used, only a few degrees of delay angle will produce a 10% change in welding current. Variations in line voltage can distort the sinusoidal line voltage sufficiently to produce another 10% change at such a low value. Therefore, a tap switch should be used to change the ratio of transformer turns for major changes in current magnitude, and heat control should be used only for fine adjustment of current magnitude.

Power demand is always greater when heat control is used to adjust the magnitude of the welding current. If heat control is used, the kva demand, in relation to maximum, generally follows a linear relationship with current. If the ratio of transformer turns is changed by a tap switch, the kva demand varies as the square of the secondary-current value. For example, if the welding current is adjusted to 80% of maximum by heat control, the kva demand is also 80% of maximum. If the secondary voltage is reduced to 80% of maximum by changing the ratio of transformer turns through a tap switch, the kva demand is about 64% of maximum, or 20% less than when using heat control.

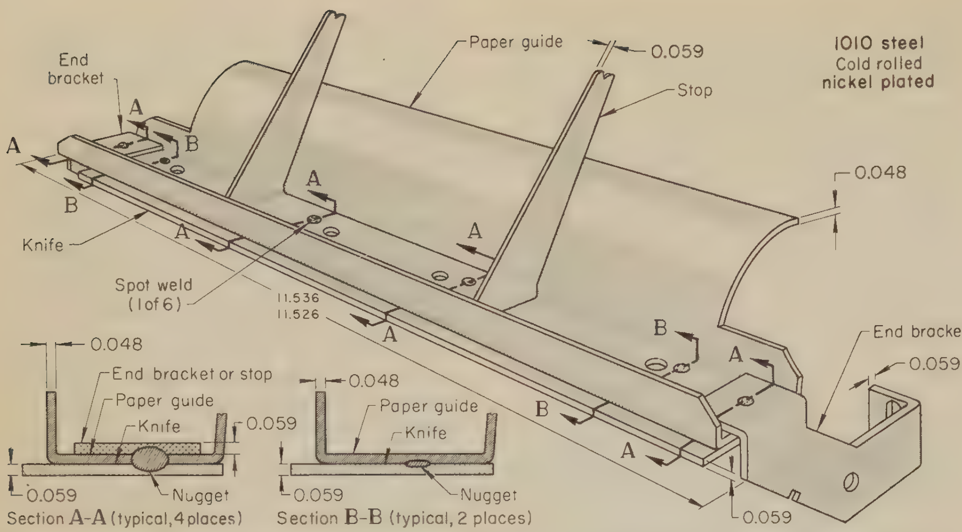
In the following example, in which the welding machine had both a transformer tap switch and phase-shift heat control, two and three thicknesses of metal were spot welded using the same weld-cycle timing but different heat-control settings.

Example 370. Use of Different Heat-Control Settings for Spot Welding Through Two and Three Thicknesses (Fig. 3)

Figure 3 shows a paper-stop assembly consisting of five pieces of nickel-plated cold rolled 1010 steel, which were joined by six spot welds, made one at a time. The over-all length of the assembly was held within ±0.005 in.

As shown in sections A-A and B-B in Fig. 3, four of the spot welds were made through three pieces of metal (total thickness, 0.166 in.), and two were made through two pieces (0.107-in. total thickness). For the three-thickness welds, a heat-control setting of 76% was used, and for the two-thickness welds, 70%. The welding machine was equipped with a phase-shift heat control that was changed manually for the two different heat requirements. The same transformer tap setting was used for both heat-control settings. Indentation at each weld spot was pronounced, but uniform in appearance and smooth. Additional equipment details and welding conditions are given in the table with Fig. 3.

The components were plated (bright nickel, 0.0003 to 0.0005 in. thick) before



Equipment Details	
Power supply	220-v, single-phase ac
Welding machine	Press type
Rating at 50% duty cycle	50 kva
Rating of secondary circuit	1.8 to 6.6 v
Transformer taps	Eight
Electrodes	3⁄16-in. diam, type A (pointed) tip, No. 4 taper, RWMA class 2
Heat control	Phase shift

Welding Conditions	
Welding voltage (est)	4 v
Transformer tap setting	No. 4
Heat-control setting	76% for three thicknesses, 70% for two thicknesses
Electrode pressure	50 psi on 3½-in.-diam air cylinder
Squeeze time	20 cycles
Weld and hold times	10 cycles each
Production per hour	276 welds (46 assemblies)

For the weld through three thicknesses (section A-A), the nugget was typically 0.185 in. in diameter and penetrated about 0.041 in., or 69%, into each of the outer workpieces. For the weld through two thicknesses (section B-B), the nugget was typically 0.130 in. in diameter and penetrated about 0.015 in., or about 31% (based on the thinner material), into each of the workpieces.

Fig. 3. Paper-stop assembly made by joining preplated components with four spot welds through three thicknesses and two spot welds through two thicknesses, using two heat-control settings and the same timing (Example 370)

being spot welded, because when assemblies had been plated after spot welding, chemical solutions were trapped that later bled out and made unsightly stains. All five components were loaded into a fixture, using the edge of the knife as the reference for alignment. Loading and unloading the fixture took 80% of the production time. Although the fixturing was time-consuming, limited demand for this part precluded revision of the design of the part to simplify fixturing and permit more efficient handling.

Upslope control is used for starting the welding current at a low value and controlling its rate of buildup to full welding current. The use of upslope control in resistance spot welding is discussed under the heading "The welding cycle" on page 414, and its application to the single-impulse welding cycle is shown schematically in Fig. 16(b).

Downslope control is used for decreasing the value of the welding current at the end of the welding cycle from the maximum value to a lower value. The use of downslope control in resistance spot welding is discussed under the heading "The welding cycle" on page 414, and its application to the single-impulse welding cycle is shown schematically in Fig. 16(b).

Current and Voltage Regulators. Electronic current regulators are used to maintain a constant welding current under severe conditions by compensating for line-voltage variation or impedance changes resulting from insertion of magnetic materials into the throat of the welding machine. Current regulators provide feedback control of the phase-shift network, based on the primary current.

Voltage regulators designed for use in ordinary welding operations can maintain the welding current within ±2% of its preset operating value for any combination of load-circuit changes that would normally cause unregulated current to change ±20%. The response time of these devices is about 3 cycles at best, and it is recommended that the weld time be a minimum of 6 cycles to allow time for regulation of heat.

Voltage across the welding electrodes can be maintained at a constant preset value by a device that compares the actual electrode voltage with a preset reference voltage and makes automatic corrections in the phase-shift heat control.

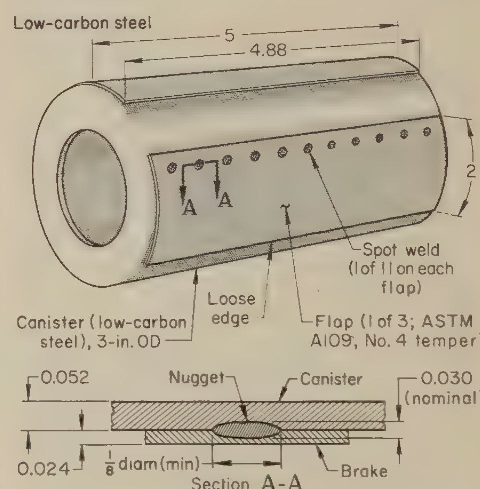
Shunting decreases the current passing through the metal between the electrodes by introducing another path for the welding current, which causes a drop in the welding voltage. A voltage regulator automatically increases the welding voltage when shunting occurs, and thus maintains the correct current level at the weld.

Very large changes in the secondary-current requirements cannot be compensated for by voltage or current regulators, and controls must be reset to provide and maintain suitable welding current at the workpieces. Special in-process feedback control units that automatically adjust the current (phase-shift type) or the timing are sometimes used to compensate for different work-metal thicknesses or number of pieces joined, changes in contour or condition of electrode tips, and changes in work, equipment or ambient conditions that affect welding results.

In the following example, in which double-electrode welding was used to make all but one of an uneven number of spot welds, a separate current-control setting, made by a manually actuated attachment, was used to make the single weld.

Example 371. Change From Single-Electrode to Single-Plus-Double-Electrode Spot Welding With Two Current-Control Settings, To Increase Production Rate and Reduce Costs (Fig. 4)

The low-carbon steel canister shown in Fig. 4 rotated as it was fired from a rifle. To control this rotation, three low-carbon steel flaps (ASTM A109, No. 4 temper) were spot welded to the canister along one edge only. These flaps opened up when the canister left the rifle, and acted as brakes. Initially, the 11 spot welds specified by the purchaser on each flap were welded one at a time, but a faster method for making the welds was needed to meet increased demand. In the improved method, which increased production rate by 66%, a single spot weld was made, followed by five sets of two spots each. To supply the proper current to the electrodes, two current-control settings were needed: one for making the single spot weld, and another for making the ten other spot welds two at a time. Equipment details and welding conditions for the improved method are given in the table with Fig. 4.



Equipment Details	
Power supply	440-v, single-phase, 60-cycle ac
Welding machine	Press type, air operated
Rating at 50% duty cycle	75 kva
Electrodes	Type B (dome), No. 4 taper, RWMA class 2
Fixturing	Indexing and manual(a)

Welding Conditions	Single electrode	Double electrode
Welding current, amp	8800	9000(b)
Electrode force, lb	650	550(b)
Squeeze time, cycles	10	10
Weld time, cycles	15	15
Hold time, cycles	8	8
Production per hour:		
Single-electrode method	3960 welds(c)	
Single-and-double electrode	6600 welds(d)	

(a) Indexing for radial, and manual for longitudinal, location of spot welds. (b) For each electrode. (c) Data are for 120 canisters. (d) Data are for 200 canisters.

In making 11 welds to attach each flap, a single weld was made first, followed by five pairs of welds at a different current-control setting. This method increased production by 66%, and reduced cost by 50%, over original method, in which all 11 welds were made one at a time using a single electrode.

Fig. 4. Canister on which three flaps were spot welded by use of single-and-double-electrode method, with two current-control settings, under conditions in table (Example 371)

In the first process modification, an upper electrode holder that contained two electrodes was used. This holder had a mechanical self-equalizing device designed to provide each electrode with the required working pressure. With this approach, production rate was increased, but it was difficult to maintain an even pressure on the two electrodes simultaneously. The mechanical equalizer was then replaced with two interconnecting hydraulic equalizing adapters. The hydraulic adapters provided the required equalized pressure on the two welding electrodes.

For the single spot weld, a manually operated attachment on the heat control shut off the current to one electrode and adjusted the current now supplied only to the other electrode. After the single spot weld was made, the current control was reset for making the welds two at a time, and welding was completed.

In producing two spot welds simultaneously, electrode maintenance was critical. Consistent production of acceptable weld nuggets of the dimensions shown in section A-A in Fig. 4 was achieved by dressing the electrodes after welding 100 to 200 canisters (3300 to 6600 spot welds), and replacing the electrodes after welding 500 to 600 canisters (16,500 to 19,800 spot welds).

With the original, single-electrode setup, scrap rate was 8% and production rate was 120 canisters per hour. The single-plus-double-electrode procedure decreased the scrap rate to less than 1%, increased production to 200 canisters per hour, and reduced the cost for welding each canister by approximately 50%.

Inspection consisted of a peel test on one flap welded to a scrap canister after completion of each production lot of 30 canisters. Minimum nugget diameter for acceptability of all welds on the test canister was ⅛ in. The location of the flaps on each canister was inspected visually.

Equipment for Direct-Energy Machines

The electrical system of a direct-energy resistance welding machine, shown schematically in Fig. 5, consists of a welding transformer, a tap switch, and the secondary circuit, which includes all the conductors from the transformer secondary terminals to the workpiece. The electrodes are considered here from their electrical standpoint; metallurgical and welding characteristics of electrodes are discussed in subsequent sections in this article.

Controls in the primary circuit are not part of the machine; these are discussed in the preceding section, "Controls for Direct-Energy Machines".

Welding Transformer. The transformer used in a direct-energy resistance welding machine changes the alternating current from high-voltage low-amperage current in the primary winding (or coil) to low-voltage high-amperage current in the secondary winding.

The primary winding is connected to the power supply and is made from edge-bent strip copper, insulated between turns, with the entire coil also thoroughly insulated.

There are three principal arrangements of transformer windings—multistep, series-parallel, and a combination consisting of multistep and series-parallel. The multistep winding consists of one primary coil with one or more intermediate taps to vary the effective number of turns, and thus to change the secondary voltage and current. The number of taps determines the number of different secondary-voltage steps or values that can be furnished by the transformer. The use of eight taps is common and is covered in RWMA standards.

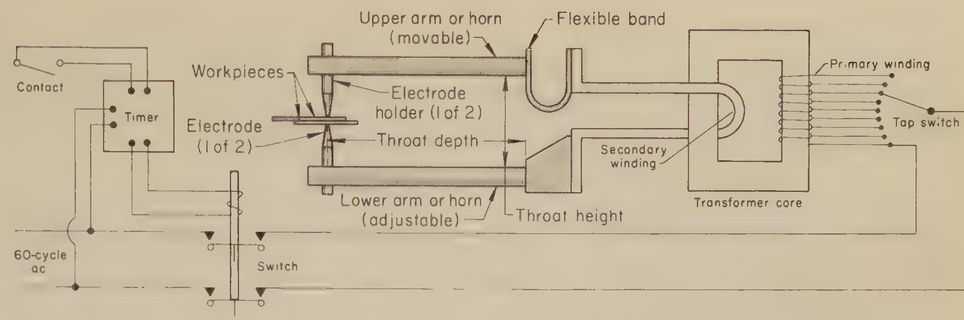


Fig. 5. Diagram of the electrical system of a direct-energy resistance welding machine

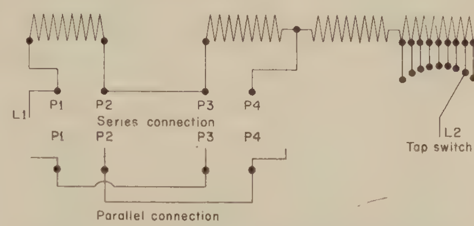

Fig. 6. Connection diagram for primary winding of a series-parallel transformer with an eight-step tap switch

Table 1. Rating Factors for Resistance Welding Machines (RWMA)

Duty cycle, %	Rating factor	Duty cycle, %	Rating factor
1	7.08	30	1.29
2	5.00	35	1.195
3	4.07	40	1.115
5	3.15	50	1.000
7.5	2.57	60	0.912
10	2.23	70	0.843
15	1.82	80	0.787
20	1.58	90	0.745
25	1.41	100	0.707

The series-parallel winding consists of two primary coils that can be connected in series or in parallel. There are no intermediate taps on the coils, and thus this winding provides only two values of secondary voltage. A multistep series-parallel winding results when taps are added to a series-parallel winding. This type of winding provides two different secondary voltages for each transformer tap. Thus, a transformer with a series-parallel winding with eight taps produces 16 secondary-voltage values.

The primary taps are numbered progressively, with the highest open-circuit secondary voltage associated with the highest-numbered tap. In a resistance welding transformer having a series-parallel primary winding, the terminal identification is P1, P2, P3 and P4, as shown schematically in Fig. 6. For series connection, P2 is connected to P3. For parallel connection, the terminals are connected in pairs: P1 is connected to P3, and P2 to P4.

The secondary winding must carry high currents, and therefore has a large cross section. Except in low-capacity equipment, the secondary winding is cooled by circulating water. The primary winding is cooled by conduction to the water-cooled secondary winding.

Transformer ratings for resistance welding machines are expressed in kva (kilovolt-amperes) for a specified duty cycle. Standard practice is to rate resistance welding transformers on a 50% duty cycle. This duty-cycle rating is a thermal rating, and states the amount of power the transformer can deliver for a stated percentage of a time period, usually one minute, without exceeding a specified temperature rise. Thus, a welding machine rated at 100 kva for a 50% duty cycle can deliver 100 kva for 30 seconds of each minute without the transformer components reaching a temperature greater than that for which they were designed. For a repetitive load, one "on" time and one "off" time are considered to be an integrating period, which must not be in excess of one minute.

The kva-demand rating of a welding transformer is the secondary open-circuit voltage multiplied by the secondary (or welding) current, divided by 1000.

The maximum permissible kva demand for a transformer used at a duty cycle other than the one for which the transformer is rated can be calculated from the factors listed in Table 1, in which a 50% duty cycle is assigned a rating factor of 1.000. The maximum kva demand is found by multiplying the rated kva by the factor for the required duty cycle. For example, a 100-kva transformer may be operated at a 25% duty cycle (15 seconds of each minute) at a maximum demand of 141 kva (100×1.41). For a 70% duty cycle (42 seconds of each minute), the maximum permissible demand is 84 kva (100×0.843). The rated kva needed to supply a maximum demand of 90 kva for a duty cycle of 15% (rating factor 1.82) is 90/1.82, or 50 kva.

Tap switches are switching devices for connecting the various taps on the primary winding of the transformer to the power-supply line. The tap setting determines the number of effective turns in the primary winding, and thus the secondary voltage and current. The switches are usually of the rotary dead-front type and are arranged for flush mounting in openings in the machine frame, or directly on the transformer. Most of the switch handles have locking buttons, so that the contacts are centered for each operating position. Some switches have an "off" position, which acts as a disconnect.

On very large transformers, spring contact switches are inadequate and bolted bar jumpers are used.

Tap switches should not be operated with the current flowing, because the resulting arc-over between contacts

will eventually cause damage to the contact surfaces.

The secondary voltage may also be controlled by electronic phase-shift devices. These are discussed in the preceding section, on Controls.

Characteristics of the Direct-Energy Secondary Circuit

The secondary circuit carries the welding current from the transformer to the electrodes, and thus to the workpiece, as shown in Fig. 5. The dimensions of the secondary circuit, or secondary loop, determine to a large extent the output performance of the welding machine. The secondary loop is roughly the area defined by the throat height times the throat depth (see Fig. 5).

Resistance and reactance in the secondary circuit at all points except at the weld should be kept as low as practical, to obtain sufficient welding current with minimum secondary voltage at the lowest possible kva demand on the alternating-current power line.

The materials used in the components of the secondary circuit are selected for low electrical resistivity, and conductors should be large in cross section, but no longer than is necessary. Throat depth and height should be no greater than those needed for the work to be handled.

The relation between throat depth and secondary current (welding current) for spot welding small assemblies of low-carbon steel sheet that do not extend into the throat has been studied for commercial spot welding machines. Some typical results are as follows. At 50 kva power input to the transformer, the welding current when the throat depth was 42 in. was about half that with a throat depth of 12 in. At 75 kva, the welding current with a throat depth of 42 in. was about 70% of that with a throat depth of 12 in.

Considering the results of the study from the viewpoint of the kva demand on the alternating-current power line for a given welding operation, one-third more power was needed to produce a given secondary (welding) current when the throat depth was 42 in. than when it was 18 in. Exact results would vary somewhat, depending on the machine, the work and the welding parameters.

Since magnetic material interposed between the arms or horns of the machine reduces the secondary current in relation to the size and thickness of the material, the extension of steel work metal or fixtures into the secondary loop should be kept to a minimum. An increase in the frequency of the alternating current also reduces the secondary current for a given kva demand.

Machine Construction

On the basis of mechanical construction, there are four basic types of resistance spot welding machines — rocker-arm, press, portable, and multiple-electrode machines.

Rocker-arm machines are the simplest stationary spot welding machines, and are made for use with foot-lever, air-cylinder, or motor operation. The machine, regardless of method of operation, consists of a frame that houses the transformer and tap switch, a vertically adjustable lower horizontal horn, and an upper horn mounted in a rocker arm that is pivoted at the front top edge of the frame.

Rocker-arm machines are available in throat depths of 12 to 48 in. and in transformer capacities of 10 to 300 kva.

Because the upper electrode of a rocker-arm machine moves in an arc, the electrodes should be set in the closed (or welding) position so that the upper electrode is perpendicular to the workpiece and the two horns are parallel. Settings with the horns out of parallel can result in electrode skidding and marking of workpieces.

A foot-operated rocker-arm machine consists of two simple levers connected by a rod and a compression spring. Force exerted on a foot lever is transmitted through the spring to the rocker-arm lever and then to the welding electrode. This machine is best suited for job-shop work with short production runs.

An air-operated machine has an air cylinder that replaces the foot lever, connecting rod, and spring of a foot-operated machine. The stroke of the air cylinder must be proportioned to the needed electrode opening, and the diameter of the cylinder must be proportioned to the needed electrode force and throat depth. For any given cylinder diameter, stroke and operating air pressure, welding force decreases and electrode opening increases as the throat depth of the machine increases, provided the distance between the rocker-arm pivot and cylinder connection is not changed. The welding force provided by any given cylinder is in direct proportion to the air pressure, and is controlled by a pressure regulator.

Air-operated spot welding machines are best suited for short or medium production runs where minimum setup time is needed.

Motor-operated machines are similar to foot-operated machines except that the rocker arm is operated by a power-driven cam instead of by a foot lever. The machine must not be started with the spring solidly compressed, because this can cause the motor to stall. The electrode opening is determined by the rise of the welding cam and by the throat depth. Welding force is dependent on the amount of spring compression and the ratios of leverage involved.

Motor-operated machines are usually more difficult to set up and adjust than foot-operated or air-operated machines, and are best suited for long production runs, or for use where compressed air is at a premium or not available.

Press-type machines have an upper electrode and welding head that move vertically in a straight line. The welding head is guided in bearings or ways of sufficient proportions to withstand the offset loads put on them. These machines have throat depths up to 48 in., and transformer capacities from 5 to 600 kva and greater. Some bench-type models used for radio, instrument, dental and jewelry work have throat depths of only a few inches, and may be rated at less than 5 kva.

Welding force is provided by air or hydraulic cylinders; manual operation is used on small bench-type machines.

Air cylinders are generally used in machines that have welding transformers with capacities up to 300 kva. Hydraulic operation is seldom used in machines with capacities of less than 200 kva, but is used in practically all machines with transformer capacities greater than 500 kva.

Press-type welding machines generally are designed for both spot and projection welding. Tables or platens are provided for mounting dies for projection welding, and fixtures and electrode holders for spot welding. The platens, ram and air or hydraulic cylinder have a common centerline. On standard machines, the spot welding electrodes are mounted six inches in front of this centerline. The knee supporting the lower platen can be vertically adjusted to compensate for reasonable variations in thickness of projection welding dies or in length of spot welding electrodes. For some spot welding applications, the knee can be replaced with an arm or horn to obtain clearance for the workpiece.

Portable machines, or guns, are used in spot welding when it is impractical or inconvenient to bring the work to the machine, and usually consist of four basic units:

1. Portable welding gun
2. Electrical controls such as a welding contactor and a sequence timer
3. Welding transformer
4. Secondary cables and hose needed to carry power between the transformer and the welding gun.

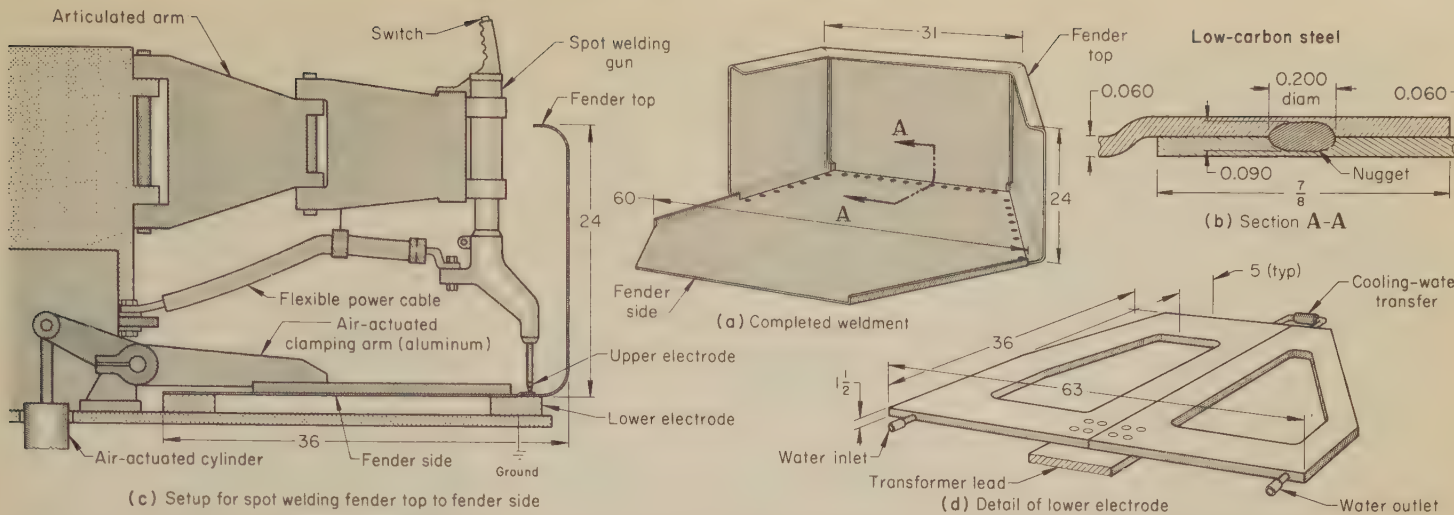
The portable welding gun consists of water-cooled electrode holders, an air or hydraulic actuating cylinder, hand grips, and an initiating switch. The gun usually is suspended from an adjustable balancing unit.

Welding force is supplied by the air or hydraulic cylinder. Hydraulic pressure usually is supplied by an air-hydraulic booster.

Because of the high secondary losses of portable machines, transformers used in these machines have secondary voltage two to four times as great as the voltage of transformers used in stationary machines of equal rating.

The transformer, tap switches, electrical controls, and air-line accessories are mounted on one end of a beam balancer above the work area. On the other end of the beam is a spring balancer that counterbalances the welding gun. The gun has a capacity for vertical movement equal to that of the balancer, and equal to or greater than the reach of the operator. The beam can be rotated 360°, and thus provides an operating area dependent only on the length of the secondary cables.

Welding current is transmitted between the transformer terminals and gun terminals through a secondary cable, usually of the low-impedance or kickless type. The reactance of this type of cable is near zero, which results in a high power factor and reduced kva demand. However, water cooling is necessary. Included with the secondary electric cables are air or hy-



Equipment Details	
Power supply	220-v, 3-phase frequency converter
Welding gun	Heavy-duty, portable, mounted on an articulated arm
Rating at 50% duty cycle	75 kva
Upper electrode	Adapter shank with No. 5 taper, type A (pointed) cap, RWMA class 2
Lower electrode	Casting, RWMA class 2
Welding controls	Synchronous electronic with phase-shift heat control

Welding Conditions	
Heat-control setting	70%
Electrode force	500 lb, max
Squeeze time	15 cycles
Weld time, approx	72 cycles (5 or 6 low-frequency 12-cycle pulses)
Hold time	15 cycles
Production rate(a):	
Fenders per hour	15(b)
Welds per hour	900(b)

(a) With one operator; two had been required for previous method. (b) Production rate in previous method had been 8 fenders (480 welds) per hour.

Fig. 7. Use of a special machine, employing a portable gun, for joining right or left tractor fenders by spot welding a lap joint between side panel and top, under conditions in table. Changing to this method from original method, in which parts were pinned together and welded in a standard press-type spot welding machine, reduced handling and improved weld quality. (Example 372)

draulic pressure hoses, cooling-water hoses, and cable to the initiating switch. This switch is usually operated at low voltage, for reasons of safety.

Current density in low-reactance water-cooled cables is as high as 50,000 amp per 1,000,000 circular mils. Cable sizes are in American Wire Gage (AWG) or thousand circular mils (MCM).

Some types of portable resistance spot welding machines combine the gun and transformer in one portable unit, but these have lower capacity than the separate units described in the preceding paragraphs.

Many large unassembled sheet-metal components without reinforcement are awkward to handle, position and clamp for welding because of their bulk and lack of rigidity, and may require more than one man to manipulate them. When production volume is high enough to justify the capital investment, it may be economical to adapt a portable gun to a special welding machine to allow efficient handling by one man, as in the following example.

Example 372. Use of a Portable Spot Welding Gun in a Special Machine To Improve Weld Quality and Reduce Labor Requirements (Fig. 7)

The tractor-fender assembly illustrated in Fig. 7(a) was made by spot welding a 2-by-5-ft fender top to a 3-by-5-ft side panel. Both components were made from commercial quality low-carbon steel sheet 0.060 in. thick. The lap joint was approximately 5 ft long and required about 60 spot welds spaced 1 in. apart. A section through the spot welded joint is shown in Fig. 7(b).

Originally, the two parts were pinned together through alignment holes in each part, and were welded in a standard press-type spot welding machine. Two men were needed to handle the pinned assembly, and production rate was eight fenders per hour. Weld quality was impaired by warping of the formed sheet-metal fender top during welding. The resulting mismatch and opening of the joint caused changes in the faying-surface contact area, and therefore in the electrical resistance of the workpieces. These changes affected the dimensions of the weld nugget and the strength of the welded joint, and could not be tolerated.

To avoid these difficulties and to allow the job to be performed by one man, a special welding machine was built that incorporated a portable spot welding gun (Fig. 7c). The essential elements of this machine were a clamping fixture that employed an air-actuated aluminum clamping arm, and an articulated arm that carried the portable spot welding gun. A flexible mounting allowed the gun to be moved to any position along the weld line, following a guide (not shown in Fig. 7) attached to the clamping arm.

In operation, insulated pins were passed through the lower electrode and into positioning holes in the side panel and fender top to align the lap joint. The clamping arm was then lowered and held down by an air cylinder, and the welding gun was moved by hand progressively into position for each spot weld along the joint. Once located into position, the welding gun was triggered and the spot weld was completed automatically.

To minimize changes in impedance due to variations in the length of the lower electrode as the welding gun was moved along the joint, the lower electrode was a casting (Fig. 7d) that provided support for the parts along the weld line and a path of fairly uniform resistance for the electrical return to the transformer. The electrode was cast from RWMA class 2 material.

The upper electrode was of RWMA standard cap-and-adapter construction with a No. 5 taper shank. Both cap and adapter were made of class 2 material. The cap was dressed after welding 30 fenders and was replaced about every three days.

Using this welding machine, one man placed the side panel and fender top on the clamping fixture, raised the locating pins, activated the clamping arm, and made the 60 spot welds along the joint. After being welded and unclamped, the fender assembly was removed by the same operator. With this revised production setup, the fender assemblies were completed by one operator at a rate of 15 per hour.

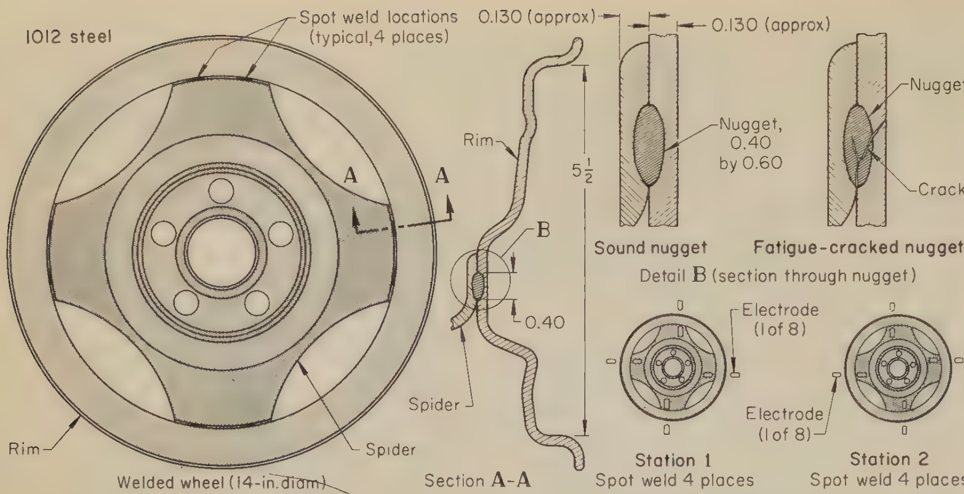
Nondestructive testing of the spot welds was done by attempting to pull the end welds apart manually, and the die side (outer side) of the welded assembly was inspected visually. In addition, test coupons were made and tested to destruction to ensure that the welding-machine settings had not changed. The test coupons used for destructive testing were random samples obtained during production.

The aluminum clamping arms had little effect on the reactance of the machine. Also, the amount of steel in the throat of the machine did not vary enough to affect the resistance or the power factor. These conditions helped in maintaining consistent weld quality.

Power was supplied to the electrodes from a 220-volt three-phase frequency-converter machine with a 50%-duty-cycle rating of 75 kva. Additional equipment details and welding conditions are given in the table that accompanies Fig. 7.

Multiple-electrode machines are considered special-purpose machines, usually designed and built for a specific job. These machines are used when there are so many assemblies to be welded or so many welds per assembly that, even though the machines have a high initial cost, it is more economical to use them than to make the spot welds one at a time. Most of these machines are of the multiple-transformer type, in which each welding gun or pair of guns is connected to an individual transformer and all welds can be made simultaneously, as well as sequentially. Transformers built for such service are provided with two secondaries, enabling each transformer to supply two guns. Often two welds can be made in series, allowing four welds for each transformer.

Guns with 2-in.-diam tandem air cylinders are used for spot welding 0.025-in.-thick cold rolled steel. Tandem cylinders 4 in. in diameter can weld



Equipment Details	
Power supply	440 v, 3-phase
Welding guns	Four at each of two stations
Rating at 50% duty cycle	125 kva per gun
Electrodes	Elliptical, 0.375 by 0.60 in., RWMA class 2
Welding controls	Electronic contactors; phase-shift heat control

Welding Conditions	
Welding current, per spot	19,000 amp, approx
Heating-control setting	30%
Electrode pressure	5000 psi
Weld time	Approx 91 cycles(a)
Production per hour	714 wheels (5712 welds)
Shear strength of welds	Approx 40,000 psi
Fatigue test on welds	1 million cycles(b)

(a) Four heating and three cooling pulses; 12 to 14 cycles each. (b) Minimum, at 150% overload.

Fig. 8. Automotive wheel of which spider and rim were joined with eight spot welds in two four-gun stations of a production line. Service failures by fatigue cracking, as shown at upper right, were rare. (Example 373)

steel up to 0.125 in. thick. Spacing of spot welds is governed by the cylinder diameter. Guns with small-diameter, high-pressure hydraulic cylinders can be used for thicker metal.

The major use of multiple-electrode spot welding machines is in the automobile industry. Multiple spot welding of automotive wheels in a high-volume production line is described in the following example.

Example 373. Use of Two Multiple-Gun Spot Welding Stations in a Production Line, for Making Eight Spot Welds in Wheels (Fig. 8)

In the manufacture of automobile wheels from 1012 steel, the spider was joined to the rim of the wheel with eight spot welds as shown in Fig. 8. The rim, flash welded and contour roll formed as described in Example 445 in the article on Flash Welding, was degreased and dried in an automatic system and conveyed to the assembly end of a production line, where the spider was press fitted into the rim in an assembling press. The outside diameter of the spider was about 0.30 in. greater than the inside diameter of the rim. The spider was flanged, to provide a surface for welding.

The assembly was joined with eight oval-shape spot welds approximately 0.40 by 0.60 in., having a shear strength of about 40,000 psi. The nugget shape and dimensions were selected on the basis of extensive testing, for maximum fatigue life. The 0.60-in. length of each nugget was parallel to the circumference of the wheel, and penetration was typically about 50%. Subsequently, a hole was pierced in the rim for a valve stem and, when specified, the welds were coined on both sides in a ring die to increase their fatigue life.

The production line consisted of a pressing station for assembly, two four-gun spot welding stations capable of applying electrode pressure of approximately 5000 psi during welding, a valve-hole punching station, and a weld-coining station. As shown at lower right in Fig. 8, at the first welding station one spot weld was made in each of the four tabs on the spider, and another spot weld was made in each tab at the second station, for the total of eight welds per wheel. Equipment details and welding conditions are given in the table with Fig. 8.

The completed wheel was visually and mechanically inspected for weld integrity and dimensional accuracy. Wheels were periodically and randomly selected for destructive testing, which was done by placing the wheel in a press and forcing the spider through the rim. This caused the metal to tear out around the eight spot welds, and the size and quality of the welds were easily determined.

The spot welds were fatigue tested to a minimum of one million cycles at 150% overload. Weld failures in service were rare. In a typical failure, as shown at upper right in Fig. 8, fatigue cracks that originated in the weld penetrated to the surface of the rim, causing the wheel to leak air.

Roll spot welding machines are essentially the same as resistance seam welding machines, which are described in the article on Resistance Seam Welding, page 425 in this volume.

The use of a circular seam welding machine for roll spot welding is described in Example 379 in this article.

Function of Electrodes

Electrodes in resistance spot welding perform three major functions:

1 Conducting the welding current to the workpieces
2 Transmitting to the workpieces in the weld area the amount of force needed to produce a satisfactory weld
3 Rapidly dissipating the heat from the weld zone.

During the welding operation the electrodes are subject to great compressive stresses at elevated temperature, and must be frequently dressed and periodically replaced. Because the current conducted to the workpieces must remain localized within a fixed area, the electrodes must resist these stresses without excessive deformation. The electrode force, in addition to forging the heated workpieces together, influences the passage of current to the localized area (see the section on Effect of Welding Force on Heating, page 413).

Maintenance of Electrodes. The shape, dimensions and surface condition of the electrode tips or contact surfaces are important for consistent weld quality in resistance spot welding. Shape and dimensions of electrode tips are affected by mechanical wear and deformation or "mushrooming", at a rate depending on tip material and design, operating temperatures, rates of heating and cooling (thermal shock), and welding force.

Alloying between the electrode tip and the work metal can greatly increase the rate of deterioration of the electrode tip. Deterioration is especially rapid when copper alloy electrodes are used in welding work metal coated with tin, zinc or aluminum, which alloy readily with the electrode metal.

Careful attention to electrode-tip condition is needed in order to avoid such defects as weak or missed welds, irregularly shaped welds, erratic indentation, burning or discoloration of the work surface, surface melting, and electrode deposits on the work surface. Electrode tips should be dressed and replaced at scheduled intervals.

Programs of preventive electrode maintenance are described in Examples 371 and 377; the program should be developed to meet the specific needs of the individual welding facility or plant. Preventive maintenance is particularly important when multiple-electrode holders are used, to ensure uniformity of resistance at each spot.

Electrode Materials

Materials for spot welding electrodes should have sufficiently high thermal and electrical conductivities, and sufficiently low contact resistance, to prevent burning of the workpiece surface or alloying of the electrode face with it, and should have adequate strength to resist deformation at operating pressures and temperatures. Because that part of the electrode that contacts the workpiece becomes heated to high temperatures during welding, hardness and annealing temperature must also be considered.

Electrode materials have been classified by RWMA into two composition groups — copper-base alloys and refractory-metal compositions. These classifications cover a wide range of resistance welding electrode materials to meet most applications.

Copper-Base Alloys (RWMA Group A). Table 2 gives the minimum properties for copper-base alloys (RWMA group A) used as electrode materials for resistance spot welding of steel. This group includes classes 1, 2 and 3.

Class 1 material is a copper-base alloy having a nominal composition of 1% cadmium and 99% copper. It has high strength and hardness coupled with high electrical and thermal conductivities. Class 1 material is non-heat-treatable, and is strengthened and hardened by cold working, which does not affect the high electrical and thermal conductivity. Class 1 material is recommended for spot welding of low-carbon steel coated with tin, terne metal, chromium or zinc; scaly hot rolled

(a) Nominal compositions: class 1, 1% cadmium, rem copper; class 2, 0.8% chromium, rem copper; and class 3, 0.5% beryllium, 1.0% nickel and/or 1.0% cobalt, rem copper. (b) International Annealed Copper Standard. (c) Or in a length equal to four times the diameter of the test specimen. (d) For hot worked and heat treated (but not cold worked) electrode material.

low-carbon steel; and some nonferrous metals, such as aluminum and magnesium alloys. It is available as drawn rod and bar, forgings, strip and plate.

Class 2 material is a copper-base alloy having a nominal composition of 0.8% chromium, remainder copper, and has higher mechanical properties but lower electrical and thermal conductivities than those of class 1 material. Optimum mechanical and physical properties are developed by heat treatment or by a combination of heat treatment and cold working. Class 2 material is the best general-purpose electrode material and can be used with a wide range of metals and conditions.

Class 2 material is used in electrodes for spot welding of cold rolled low-carbon steel, hot rolled pickled low-carbon steel, nickel-plated steel, stainless steel, nickel alloys, and copper-base alloys such as silicon bronze and nickel silver. It is also suitable for shafts, arms, dies, fixtures, platens, gun jaws and other current-carrying structural members of resistance welding equipment. It is available as drawn rod and bar, strip stock, plate, castings and forgings. Class 2 electrodes were used in all examples in this article for which the electrode material was identified.

Class 3 material is a copper-base alloy having a nominal composition of 0.5% beryllium, 1.0% nickel (sometimes omitted), 1.0% cobalt, remainder copper. It is a hardenable alloy with higher mechanical properties but lower electrical and thermal conductivities than those of either class 1 or class 2 materials.

The high hardness, good wear resistance and high annealing temperature of class 3 material, coupled with medium electrical conductivity (45 to 50% IACS), make it a good material for electrodes used in spot welding applications where pressures and workpiece resistance are high. It is used on thick sections of low-carbon steel, and on such materials as stainless steel, Monel and Inconel.

Class 3 material is available as drawn bar and rod, strip, castings and forgings.

Refractory-Metal Compositions (RWMA Group B). Table 3 gives minimum properties for refractory-metal compositions (RWMA group B) used as electrode materials for resistance spot welding of steel. This group includes classes 10 through 14.

These electrode materials are used where high heat, long weld time, inadequate cooling or high pressure would cause rapid deterioration of the copper-base alloys. In choosing among them, each application must be considered separately on the basis of design of electrode and workpieces, type of opposing electrode and type of spot

Table 3. Minimum Properties for RWMA Group B Electrode Materials (Refractory-Metal Compositions) (a)

Class	Rockwell hardness	Electrical conductivity, % IACS(c)	Compressive strength, psi
10	B 72	35	135,000
11	B 94	28	160,000
12	B 98	27	170,000
13	A 69	30	200,000
14	B 85	30	...

(a) Properties are for rods, bars and inserts. Classes 10, 11 and 12 are copper-tungsten mixtures; class 13 is unalloyed tungsten; and class 14 is unalloyed molybdenum. (c) International Annealed Copper Standard. [Source of table: Same as that for Table 2]

welding equipment. When a copper alloy is being welded to steel, a group B electrode is used to contact the copper alloy, and a group A electrode of class 1 or 2 is used to contact the steel.

Class 10 material is a high-melting-point copper-tungsten refractory metal recommended for use in facings on spot welding electrodes for applications requiring a compromise between the high electrical and thermal conductivities of the copper-base alloys and the high hardness and strength provided by the other refractory-metal compositions.

Class 11 material is a 42% copper, 58% tungsten (by volume) refractory metal with a higher hardness but lower electrical conductivity than those of class 10 material. It is specially recommended for spot welding of ferrous metals having high electrical resistance, such as stainless steel. (Class 11 insert buttons were selected in Example 374.)

Class 12 material is a copper-tungsten refractory metal that has higher hardness and lower electrical conductivity than those of class 11 material.

Classes 13 and 14 materials consist of unalloyed tungsten and unalloyed molybdenum, respectively. Their properties are not usually needed in resistance spot welding of low-carbon steel, except for joining it to such metals as copper alloys. (Class 13 was an optional material in Example 374.)

Special alloys, such as copper-zirconium and copper-cadmium-zirconium, have properties similar to class 1 and class 2 materials and have been used as resistance welding electrodes. They are suitable for spot welding of steel coated or plated with metals such as zinc, aluminum, tin, terne metal and cadmium, and for spot welding of aluminum and magnesium alloys.

In any application where a class 1 material can be used, a copper-zirconium alloy can be used if increased resistance to annealing (or softening) of the electrode face is needed.

Electrode Design

Electrode design involves four structural features of the electrode: face; shank or body; means of attachment to the electrode holder; and provision for cooling (see Fig. 9).

The face of a spot welding electrode contacts the workpiece directly above or below the point of fusion, and this small area is subject to repeated application of high temperature and pres-

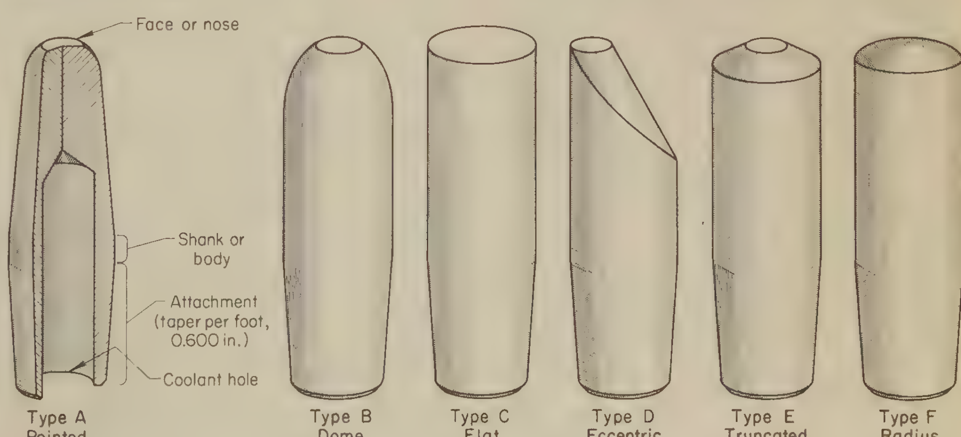

Fig. 9. Standard types of electrode face or nose shapes. (Type D was formerly called offset.)

sure in production welding; therefore, the probability of pickup, alloying and deformation is a major consideration in electrode design. In minimizing pickup or alloying of the work metal and electrode material, the affinity of one for the other is important. Resistance to deformation depends on the hardness and strength of the electrode material. In choosing the electrode material that will produce the best results, a compromise between properties is frequently necessary. The size and shape of the electrode tip sometimes can be modified to compensate for compromises in electrode material.

Dimensions of the electrode face are governed by thickness of the work metal, desired size of the weld nugget, and shape and size of the assembly.

Electrode face shapes have been standardized by RWMA; Fig. 9 shows the six standard face or nose shapes, identified by letters A through F. Electrodes with type A (pointed) tips are used in applications for which full-diameter tips are too wide. Type D (eccentric; formerly called offset) faces are used in corners or close to upturned flanges. Special tools are available for dressing electrode faces, either in or out of the welding machine.

Shank ends or attachments of standard RWMA electrodes are made with Jarno tapers 3, 4, 5, 6 and 7. Body diameters are equal to the Jarno taper number divided by eight (3/8, 1/2, 5/8, 3/4 and 7/8 in.). Some manufacturers continue to follow an earlier standard, and use the Morse taper numbers 1, 2 and 3, which are essentially the same as RWMA (Jarno) tapers 4, 5 and 7.

Coolant holes in electrodes are either round or fluted. Fluted holes offer more cooling surface than do round holes. Coolant holes should extent as close to the face of the electrode as possible, without endangering electrode strength.

The electrode designs shown in Fig. 9 cannot be used for all applications. Also available are electrodes having the shape of buttons about 3/16 in. high, and electrodes with single-bend and double-bend offsets, irregular offsets, square or rectangular faces, and caps with male or female tapers or threads.

Buttons and caps of various nose designs, which are used with special adapter shanks that are placed in standard holders, are interchangeable in their respective adapters.

The diameter of the tip or contact face of the electrode controls the size of the weld nugget. If the diameter of the tip is too small, the resulting spot weld may be weak, even though it is sound. Small-diameter tips also may cause severe heat concentration and surface marking or indentation.

Electrodes with large-diameter faces may overheat because of insufficient electrode pressure, especially at high welding current, and cause voids, blowholes, or a poor surface appearance.

The minimum face diameter for type A, B, D and E electrodes can be determined by using the following formula:

$$\text{Face diameter, in.} = 0.10 + 2t$$

where t is the thickness, in inches, of the base metal contacting the electrode.

RWMA Designation Code. For identification of straight group A (copper-base alloy) electrodes, RWMA has established four-part code numbers:

1. A letter, A through F, that indicates the type of face (see Fig. 9)
2. A number from 1 through 5 that indicates the RWMA class of electrode material
3. A number from 3 through 7 that designates the RWMA (Jarno) taper of the shank end and, when divided by 8, indicates nominal body diameter
4. A two-digit number that indicates the length of the electrode in increments of 1/4 in.

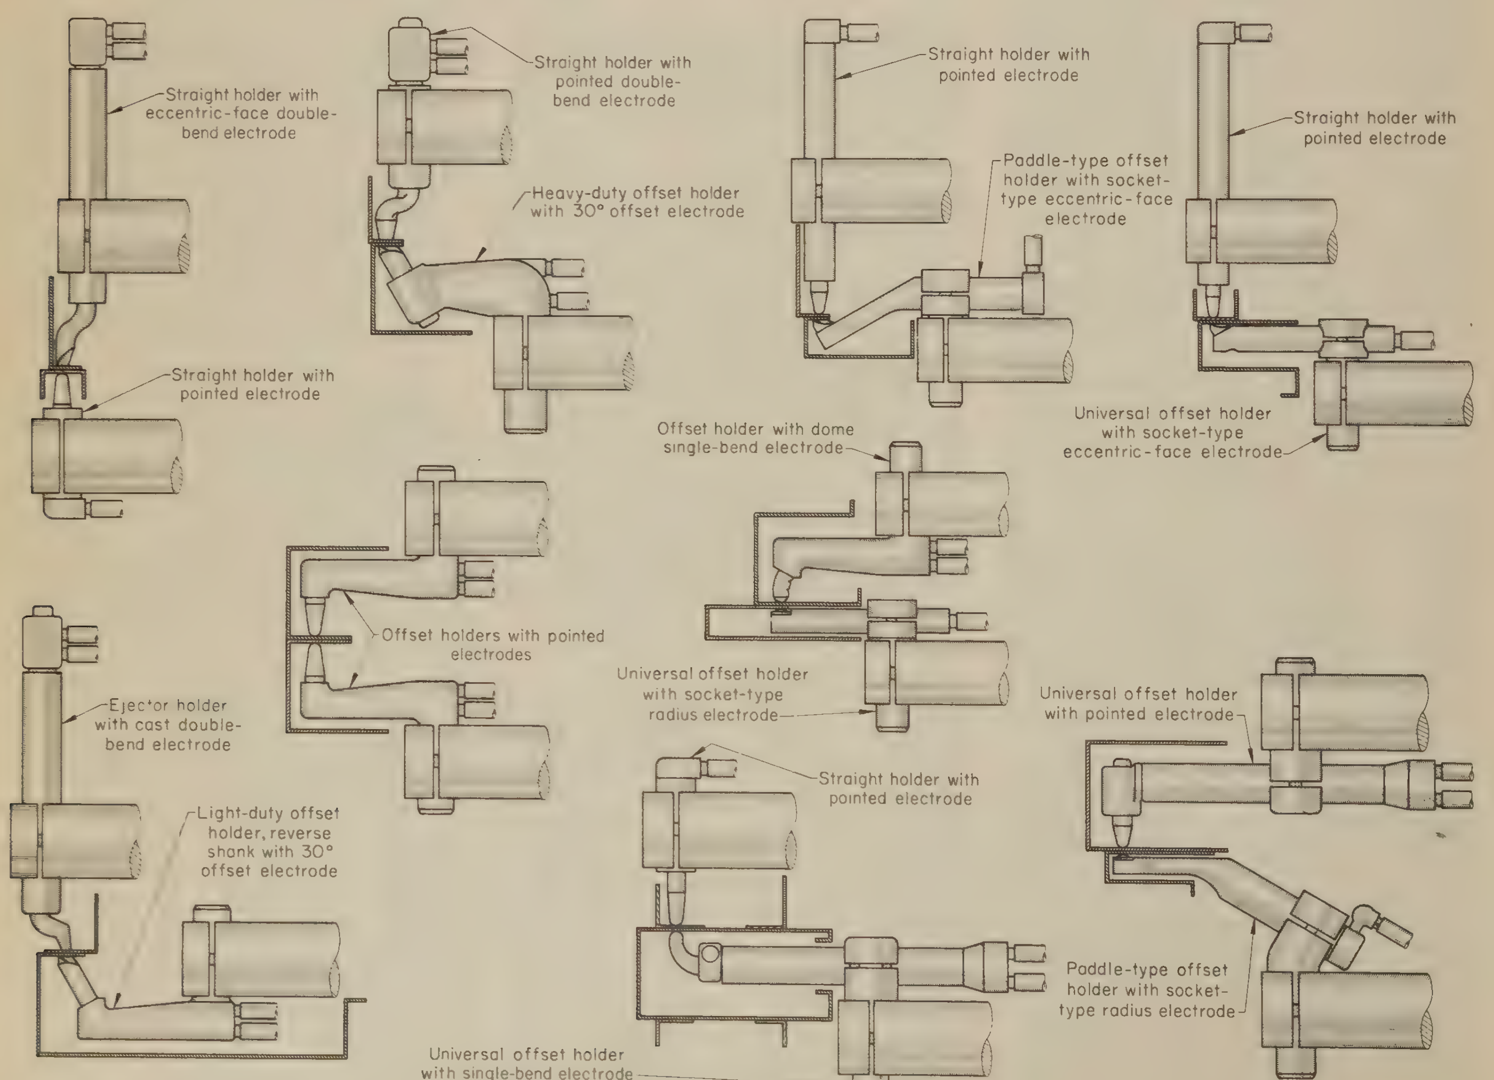

Fig. 10. Combinations of standard holders, adapters and electrodes for resistance spot welding with various workpiece configurations

Thus, an electrode having an RWMA code number A-2516 has a type A (pointed) face, is made of class 2 material, has a No. 5 RWMA taper on the shank end and a ⅝-in.-diam body, and is 4 in. long.

No designation code of this type has been established for group B (refractory-metal) electrodes, since these electrodes are used as facings, inserts, buttons or other nonstandard forms.

Electrode Holders

In resistance spot welding, electrodes are placed in holders that are mounted in the machine so that the position of the electrode can be adjusted to suit the workpieces. Most holders have an ejector mechanism for removing the electrodes and have hose connections to provide water cooling. Holders are made in straight and offset designs for taper-shank and threaded-shank electrodes or adapters, and for button-type and cap-type electrodes.

Holders for taper-shank electrodes may either be straight or have 90° or 30° offsets. Most holders for threaded-shank electrodes are straight but have 90° and 30° adapters. Universal and paddle-type holders have a relatively long, thin extension into which button-type electrodes are inserted.

Some combinations of standard holders, adapters and electrodes that permit the handling of various workpiece configurations and joint arrangements are shown in Fig. 10.

Multiple-electrode holders are used for simultaneously making two or more spot welds in an assembly, using conventional spot welding machines. These holders, which are generally used for the upper electrodes, have springs, mechanical devices, or hydraulic equalizers so that the same force is applied to the workpiece by each electrode. Equal electrode force for each spot weld helps to maintain uniform weld quality. The electrodes can be connected to the transformer in different arrangements for direct or series spot welding (see Fig. 13 for typical arrangements of transformer secondary circuits).

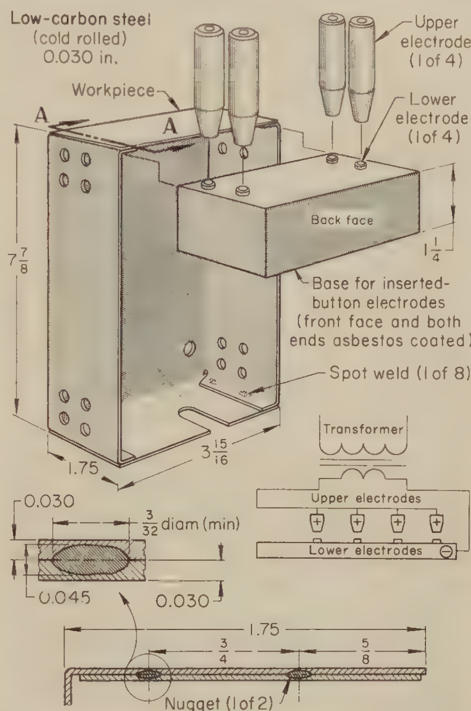
The lower electrode may be a solid piece of metal large enough to oppose all the upper electrodes, or a solid piece of metal with inserts positioned opposite to the upper electrodes, or it may consist of individual tips mounted in a fixed holder. Provision must be made for the necessary electrical connection of the electrodes to the machine, and for adequate water cooling.

In the next example, electrodes and electrode holders were designed to enable four parallel spot welds to be made simultaneously in the end of a low-carbon steel box by direct welding. Similar setups were used to make three to six welds at a spacing of 4 in. (max) on copper alloys and stainless steels.

Example 374. Use of Multiple-Electrode Holders To Make Four Spot Welds Simultaneously (Fig. 11)

Folded boxes (open-top containers) like the one shown in Fig. 11 were made of 0.030-in.-thick cold rolled low-carbon steel by forming the sides and ends in a press or a press brake, and then spot welding the corners. On each end of the box four spot welds (two parallel pairs) were made simultaneously, using specially designed electrodes and electrode holders.

The upper electrode holder was mounted in a spring-counterbalanced head that provided a low-inertia reaction as the work metal was heated and the spot weld was formed. The upper electrodes were mounted in a spring-loaded equalizer, so that each electrode exerted a force of about 180 lb on the workpiece. The base, or holder, for the four inserted-button lower electrodes was offset ahead of the horn so that the box would not touch the horn in the welding position. Also, the front face and both ends of the lower-electrode base were covered with a thin coating of asbestos cement to insulate them from the box during welding, and to prevent shunting.



Equipment Details

Welding machine	Bench mounted, press type, single-phase
Rating at 50% duty cycle	30 kva
Current, max	14,000 amp
Transformer taps	Eight
Upper electrodes (4)	Type A (pointed), ¼-in. diam, RWMA class 2
Lower electrodes (4)	Button type, ¼-in. diam with $\frac{1}{32}$ by 45° chamfer, RWMA class 11 or 13, mounted in a class 2 base
Heat control	8 taps and phase shift

Welding Conditions

Welding current (total for 4 spots)	6000 amp
Transformer tap setting	No. 6
Heat-control setting	60%
Electrode force	180 lb per electrode
Squeeze time	2 cycles
Weld time	4 to 5 cycles
Hold time	2 cycles
Production per hour	640 welds (80 boxes)

Fig. 11. Folded box in which four spot welds were made simultaneously in each end, by direct welding with a multiple-electrode holder (Example 374)

The upper electrodes were made of RWMA class 2 material. The lower electrodes were insert buttons made of either class 11 (copper-tungsten) or class 13 (tungsten) material, and were mounted in a class 2 base. The selection of copper-tungsten electrode buttons permitted the use of lower welding current and electrode force than are normally recommended for welding low-carbon steel, and reduced wear on the buttons.

The electrode design was developed experimentally, and the electrodes were carefully machined to close dimensional tolerances. The electrode force was carefully balanced to give equal loading to all spots, and the electrodes were dressed frequently to give uniform contact at all spots.

The welds had a minimum diameter of $\frac{3}{32}$ in. and had adequate strength for the low stress to which they were subjected in use. Equipment details and welding conditions are given in the table with Fig. 11.

Direct and Series (Indirect) Welding

The arrangement of the electrodes and workpieces in the secondary circuit in resistance spot welding determines whether welding is direct or series (indirect). Welding is direct if all of the secondary current passes through the weld nugget (or nuggets) being formed, so that no effective shunt path bypasses the nugget. Welding is series (also called indirect) if there is a shunt path that allows a portion of the secondary current to bypass the weld nugget. Some arrangements of secondary circuits for direct and series welding of two thicknesses of metal are described below; in general, these arrangements also apply for welding of three or more thicknesses.

Direct Single-Spot Welding. Single spot welds are usually made by direct welding. Figure 12 shows schematically three arrangements used for making this type of weld; these arrangements may be modified to meet special requirements. In all of the arrangements shown, one transformer secondary circuit makes one spot weld.

The simplest and most common arrangement, in which two workpieces are sandwiched between opposing upper and lower electrodes, is shown in Fig. 12(a). In the arrangement shown in Fig. 12(b), a conductive plate or mandrel having a large contacting surface is used as the lower electrode; this reduces marking on the lower workpiece and conducts heat away from the weld more rapidly, and may be necessary because of the shape of the workpiece. In the arrangement in Fig. 12(c), a conductive plate or mandrel beneath the lower workpiece is

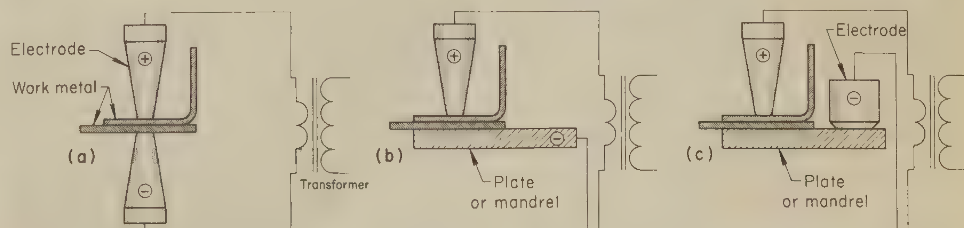


Fig. 12. Three arrangements of work metal and electrodes used for making single spot welds by direct welding

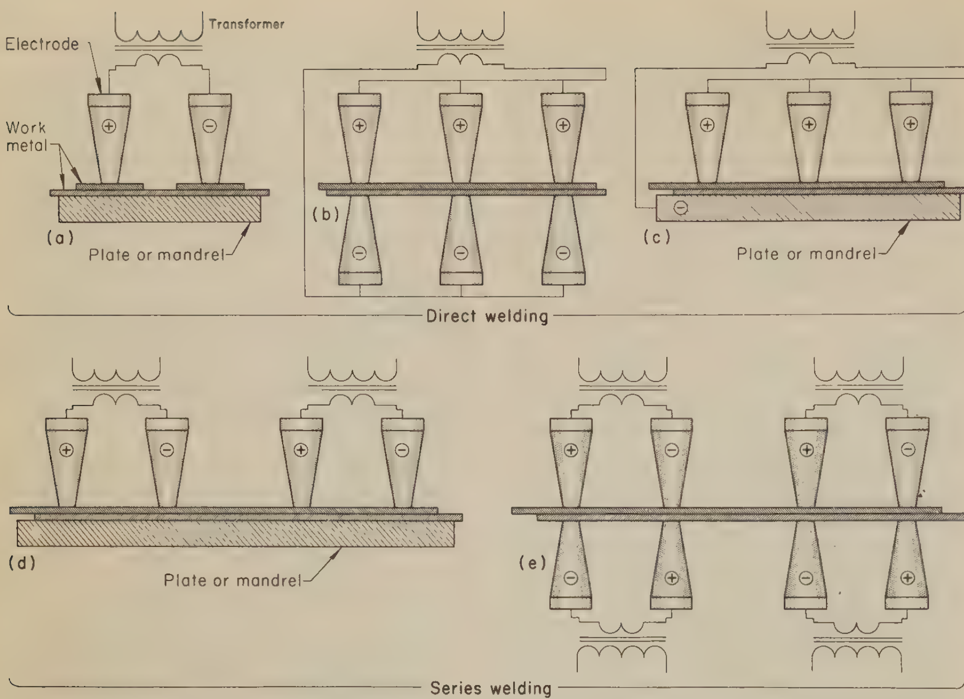

Fig. 13. Five arrangements of work metal and electrodes used for making multiple spot welds simultaneously by direct and series welding, using one or more secondary circuits

used for the same purposes, but in conjunction with a second upper electrode. Because this second upper electrode is intended to serve as a contact only and not to make a weld, it may be larger (as shown in Fig. 12c) to avoid overheating.

Direct Multiple-Spot Welding. Three arrangements of the secondary circuit for making two or more spot welds simultaneously by direct welding are shown schematically in Fig. 13(a), (b) and (c). One transformer secondary circuit can be arranged as shown in Fig. 13(a) to make two spot welds, joining two upper workpieces to one lower workpiece. In this application, the plate or mandrel need not be an electrical conductor.

A single transformer secondary circuit can also be arranged as shown in Fig. 13(b) and (c) to make two, three or more spot welds simultaneously by direct welding, joining two workpieces. Special care must be taken in this method (sometimes called parallel spot welding) to ensure that resistance (impedance) in the circuit for each spot weld is the same as for all the others; otherwise, current will not be uniform for each weld. Tip contour and surface condition must be the same for each electrode. Also, the force exerted by all the electrodes on the workpieces must be equal, regardless of inequalities in work-metal thickness. The force can be equalized by using a spring-loaded electrode holder or a hydraulic equalizing system.

The use of a conductive plate or mandrel, as in Fig. 13(c), minimizes weld marks on the lower workpiece.

Series Multiple-Spot Welding. Two arrangements for making a number of spot welds simultaneously by series welding are shown schematically in Fig. 13(d) and (e). In Fig. 13(d), each of the two transformer secondary circuits makes two spot welds. A portion of the current bypasses the weld nuggets through the upper workpiece. Four spot welds are conveniently made simultaneously in this way, using the two separate secondary circuits of a standard "package" type of resistance welding transformer. Several transformers of this type can be combined to make a larger number of spot welds simultaneously, or one of the two secondary circuits can be used alone to make just two welds at a time.

Figure 13(e) shows the arrangement for push-pull, or over-and-under, series multiple-spot welding. In this arrangement, each weld is made between a pair of opposing electrodes of opposite polarity, with each electrode being connected to a separate transformer secondary winding, and only one weld is produced for each secondary circuit. This arrangement provides a relatively high voltage at the welds, because the voltages of the two secondary windings for each pair of spot welds reinforce each other. This arrangement also permits the use of transformers having lower kva ratings than can be used with the arrangement shown in Fig. 13(d), but care is needed to limit shunting to an acceptable amount.

Heat for Resistance Welding

The secondary circuit of a resistance spot welding machine, including the work being welded, is a series of resistances, the total of which affects the flow of current. The current flow (in amperes) must be the same in all parts of the circuit, regardless of the resistance at any point; however, the heat generated at any point is directly proportional to the resistance at that point. Electrical systems in the secondary circuit are designed to produce heat where it is wanted, leaving the other components of the circuit relatively cool.

The composite effects of heat generation and dissipation in the workpieces and electrodes are shown in Fig. 14. There are seven resistances connected in series for a two-thickness joint: (*a*) the upper electrode, (*b*) the contact surface between the upper electrode and upper workpiece, (*c*) the upper workpiece, (*d*) the contact surface between the upper and lower workpieces, (*e*) the lower workpiece, (*f*) the contact surface between the lower workpiece and lower electrode, and (*g*) the lower electrode.

Heat is generated at each of these points in proportion to the resistance at that point. The greatest amount of heat is desired at the weld point or interface between the workpieces (point *d* in Fig. 14), and steps must be taken to reduce the heat as much as possible at the other points.

The temperature of all parts at the start of the weld is represented by the line marked "Starting temperature" in Fig. 14. Temperature is rapidly increased at point *d*, the interface between the workpieces, where the resistance is greatest. Points of next greatest resistance are *b* and *f*, where the temperature rises rapidly, but not as fast as at *d*. The heat generated at points *b* and *f* is rapidly dissipated into the water-cooled electrodes at points *a* and *g*, whereas the heat generated at point *d* is dissipated much more slowly.

After about 20% of the weld time has elapsed, the heat gradient corresponds to the inner curve in Fig. 14. The outer curve represents the heat gradient at the end of the weld time (100% of weld time). When welding conditions are properly controlled, the welding temperature is first reached at sites near *d*, the interface between workpieces. During the heating period, these tiny regions of molten metal enlarge and become continuous, to form the weld nugget.

The temperature gradients shown in Fig. 14 are also affected by the relative thermal conductivities of work metal and electrodes, and by the size, shape and cooling rate of the electrodes (explained in the next sections).

Effect of Welding Current on Heating

Welding current flows through a secondary circuit that consists of the transformer secondary coil, the flexible bands connecting the coil to the horns, the horns, the electrodes, and the workpiece. Heat is generated in all portions of the circuit according to the following formula:

$$H = I^2Rt$$

where H is the heat in watt-seconds or joules; I is the current in amperes; R is the resistance in ohms; and t is the duration of current flow in seconds. Some heat is lost through conduction, convection and radiation from the electrodes and the workpieces. Generally, the magnitudes of these losses are unknown.

The thermal conductivity of steel is about 12% that of copper; therefore, if sufficient welding current is used in

welding steel with copper-base electrodes, the heat generated along the interface of the workpieces (point *d* in Fig. 14) is conducted away from the weld zone more slowly than the heat generated at the electrode faces (points *b* and *f* in Fig. 14) is conducted into the water-cooled electrodes (points *a* and *g* in Fig. 14). Thus, the interface of the workpieces reaches the fusion temperature first, and a weld is produced at this interface.

There is a lower limit for current density below which fusion cannot be obtained. Enough heat must be generated to offset the heat that is lost through conduction into the electrodes, surrounding air, and that part of the work metal not between the electrodes.

As the current density is increased, the weld time can be decreased sufficiently to produce a weld without heating the electrode contact surfaces to more than a few hundred degrees.

There is also an upper limit for the welding current. If the welding current is too high, the entire thickness of the work metal between the electrodes is heated to the plastic range by the time the weld zone reaches the fusion temperature, and the electrodes embed themselves deeply into the metal. The outer surfaces of the electrodes may also be overheated and burned.

For a given electrode force, there is an upper limit of current density above which pitting and expulsion of hot metal occur at one or more workpiece surfaces, causing low-quality welds. Maximum spot strength is obtained by welding at a current density slightly below the value at which expulsion takes place (setting of the current for production runs is commonly based on this relation).

The effects of welding current on nugget diameter, joint tensile-shear strength, and electrode indentation are shown in Fig. 15. The welds were made in annealed low-carbon steel, 0.029 in. thick, using a type A (pointed) electrode with a ¼-in.-diam tip, an electrode pressure of 15,000 psi (a force of about 735 lb), and a weld time of 6 cycles. At the optimum current value (13,500 amp), the diameter of the nugget was nearly the same as the diameter of the electrode tip (¼ in.). Increasing the current above 13,500 amp did not significantly increase the nugget diameter, but caused a marked increase in electrode indentation. Tensile-shear strength increased rapidly until the optimum current was reached, but decreased slightly when the current was increased to slightly above 14,000 amp. Indentation increased from about 2% of the sheet thickness at a welding current of 13,500 amp to about 10% at a welding current slightly above 14,000 amp.

Effect of Electrode Composition and Design on Heating

Electrodes should have high electrical conductivity and low contact resistance to minimize electrode heating, and high thermal conductivity to dissipate the heat from the contact area between the electrode tip and the workpiece (zones *b* and *f* in Fig. 14).

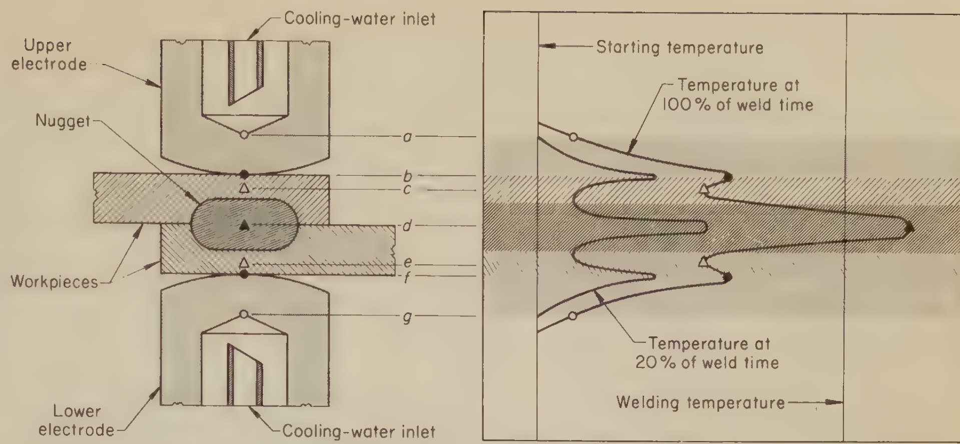

Fig. 14. Major points of heat generation, and temperature gradients after 20% and 100% of weld time, in electrodes, workpieces, and nugget during formation of a resistance spot weld

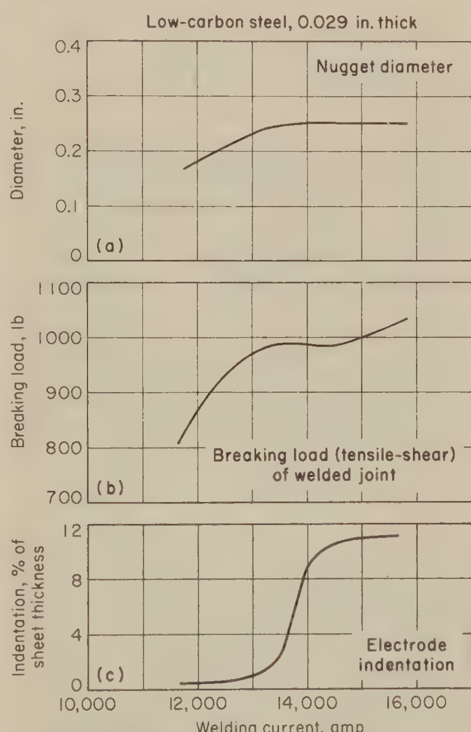


Electrode had a type A (pointed) face, ¼-in.-diam tip; electrode pressure was 15,000 psi; weld time was 6 cycles. (SOURCE: RWMA Resistance Welding Manual, 3rd Ed., Vol 1, p 122)

Fig. 15. Effects of welding current on nugget diameter, joint tensile-shear strength, and electrode indentation, in spot welding of annealed low-carbon steel 0.029 in. thick

Electrodes should also be strong enough to resist deformation caused by repeated applications of high welding force.

Effect of Electrode Composition. Generally, the harder an alloy is, the greater is its thermal and electrical resistance, and in choosing the best alloy for electrodes, a suitable compromise among electrical, thermal and mechanical properties must be found.

Commercially pure copper has excellent electrical conductivity, but because of its low resistance to compressive forces and low annealing temperature, it has been replaced by other copper-base alloys as an electrode material. The copper-base alloys that have been adopted as standard materials for resistance spot welding electrodes (RWMA group A, classes 1, 2 and 3) are described on page 408, and minimum properties for these standard electrode materials appear in Table 2.

Standard refractory-metal compositions for resistance spot welding electrodes (RWMA group B, classes 10 to 14) are described on page 409, and minimum properties for these materials are given in Table 3.

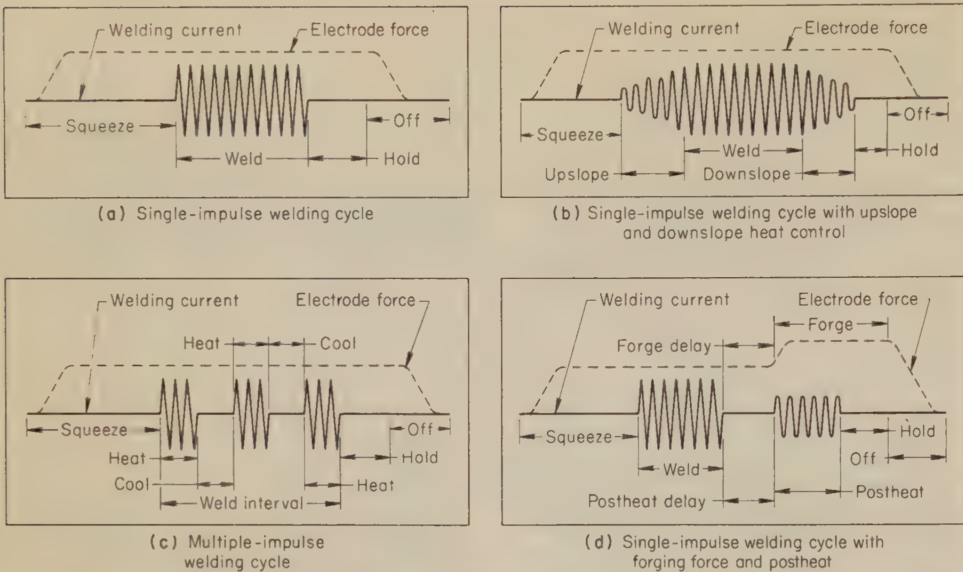
Class 2 (chromium-copper) electrodes were used in all examples in this article for which the electrode material was identified. Class 11 (copper-tungsten refractory-metal composition) insert buttons were used in Example 374 to reduce electrode wear and to permit the use of lower welding current and electrode force than are usually recommended for welding low-carbon steel.

Effect of Electrode Design. When two workpieces of similar composition and equal thickness are being welded, the tip diameters of the electrodes should be the same. However, if the workpieces are of unequal thickness, the tip diameter of the electrode contacting the thicker piece may need to be larger to maintain proper heat balance. In welding dissimilar metals, the same considerations hold true if one piece has higher electrical resistivity than the other. The dissimilarity can be compensated for by increasing the diameter of the electrode tip contacting the higher-resistance workpiece, or by using a material of higher resistance for the electrode contacting the lower-resistance workpiece.

The diameter of the weld nugget is slightly less than the diameter of the electrode-contact area. As the electrode tips are worn or increase in diameter because of "mushrooming", the diameter of the weld nugget increases. An increase in tip diameter of more than 5% can affect the weld quality, because the current density is decreased and the heat generated may be insufficient to produce a good weld.

Effect of Welding Force on Heating

Welding force, or electrode force, is the force applied to the workpieces by the electrodes during the welding cycle.



(a) Single-impulse welding cycle

(b) Single-impulse welding cycle with upslope and downslope heat control

(c) Multiple-impulse welding cycle

(d) Single-impulse welding cycle with forging force and postheat

Fig. 16. Types of resistance spot welding cycles, showing relative time for each segment, and relative values of welding current and electrode force for each segment

Electrode force, usually measured and expressed as a static value, is, in operation, a dynamic force, and is affected by the friction and inertia of the moving parts of the welding machine.

The workpieces to be spot welded must be held tightly together at the intended location of the weld to allow passage of current. However, because increasing the electrode force decreases the contact resistance of the work metal, and therefore decreases the total heat generated between the faying surfaces of the workpieces by the welding current, electrode force should not be excessive. (See the section on Effect of Surface Condition on Heating, page 415 in this article.)

The electrode force must be compatible with a welding current that is within the capacity of the equipment, and must permit the use of a welding time long enough to be reproducible. Also, the workpieces must be in reasonably intimate contact at the weld area without excessive electrode force. If the workpieces are deformed so that contact is not intimate in the weld zone, an excessively high force may be needed to overcome the deformation. Variations in weld strength and quality often result from the variations in electrode force required to bring the workpieces into proper contact, especially in the spot welding of stampings, formed workpieces, or thick sections of work metal.

Sometimes, a squeeze time longer than that normally used is needed to force the workpieces together. Also, because of the possibility of springback, hold time must be sufficiently long to permit solidification of the weld metal.

Effect of Time on Heating

The effect of time on the temperature distribution in workpieces and electrodes during spot welding is shown by the two curves in Fig. 14. The inner curve represents the temperature in each zone after 20% of the weld time has elapsed, and shows that the temperature rise at the faying workpiece surfaces (point *d*) during this period is proportionately lower than in the other zones in relation to temperature rise during the remainder of weld time.

The heat formula $H = I^2Rt$ shows that, with the total resistance held constant, the amount of heat generated in any part of the circuit is proportional to both the weld time (the time the welding current is on) and the square of the welding current. Since heat transfer is a function of time, the time required for development of the proper nugget size can be shortened only to a limited extent, regardless of how much the current is increased. Pitting and spitting (expulsion of metal), especially at the electrode contacting surfaces, results when the heat is generated too rapidly at the three contacting surfaces (zones *b*, *d* and *f* in Fig. 14).

Some reduction in weld time can be accomplished if the welding current, initial pressure and follow-up pressure are increased. Higher initial pressure is needed to prevent spitting, because of the increase in current. Higher follow-up pressure and fast follow-up are needed to maintain firm contact and adequate pressure of electrode on the workpiece until the metal of the weld has solidified.

The welding cycle is divided into four major time segments: squeeze, weld, hold and off. These are shown in Fig. 16 (see also "Time and Sequence Controls", page 403).

Squeeze time is an interval of delay between closing of the initiating switch and application of the welding current. It provides time for the solenoid-actuated head cylinder valve to operate and for the welding head to bring the upper electrode in contact with the workpiece and develop full electrode force.

Weld time is the interval during which the welding current flows through the circuit.

Hold time is the interval during which, after the welding current is off, the electrode force is held on the workpiece until the metal of the spot weld has solidified.

Off time is the interval from the end of the hold time until the beginning of the squeeze time for the next cycle. In an automatic cycle, off time is the time needed to retract the electrodes and to index, remove or reposition the work. In manual operation, it is not fixed as a maximum period by the control equipment, but depends on time taken by the operator to start a new cycle. Figure 16(a) shows the relative durations of these four basic segments for a single-impulse resistance spot welding cycle.

All of the segments are usually expressed in cycles, meaning the number of cycles in a 60-cycle system, where one cycle is $\frac{1}{60}$ sec.

The simplest welding cycle supplies uniform welding current and electrode force throughout the weld interval, but the addition of slope control enables the welding current to be varied. As shown in Fig. 16(b), a welding cycle that incorporates slope control has an increase in current before the weld and a decrease after the weld.

Upslope permits the welding current to be increased over several cycles from a low value to that needed for welding, instead of having the full welding current applied instantly. A

(a) Steel to be welded should be pickled, or otherwise cleaned, to obtain a surface contact resistance not exceeding 200 microhms. (b) HR = hot rolled; N&T = normalized and tempered. (c) Welding conditions are for joining two pieces of equal thickness, each of thickness t. (d) Minimum spacing for which no special precautions are needed to compensate for shunted-current effect of adjacent welds. [SOURCE OF TABLE: Same as Table 4]

low initial welding current reduces or prevents expulsion of metal (spitting) when the current is first applied. Upslope control is used for welding at high current values, and for welding scaly stock as well as most kinds of plated metals.

Downslope permits the welding current to decay gradually to a low value instead of ending suddenly, and it helps to produce good welds in some types of heat treatable metals by lengthening the cooling-time gradient. It is rarely needed in welding low-carbon steel, particularly if the carbon content does not exceed 0.15%, but is used when cooling rate must be limited, as in welding hardenable steels.

The high welding currents and long weld times needed for welding sheets greater than ⅛ in. in thickness may cause overheating of the electrodes. This can be minimized by applying the current in pulses during the weld interval, as shown in Fig. 16(c). Heat is dissipated more rapidly from the electrodes than from the workpieces. Therefore, during the cool time, when the welding current is off, the electrodes dissipate most of their heat while the workpieces lose very little. With a series of impulses each followed by a cooling period, the workpieces are brought to welding temperature while the electrode temperature remains at a safe level. A multiple-impulse weld interval was used in Example 373 (see page 408) in spot welding of an automotive-wheel assembly.

Two other elements that can be added to a welding cycle are forge and postheat, both shown in Fig. 16(d). They are both used chiefly for grain refinement on hardenable carbon and alloy steels, and are not used on low-carbon steel. After welding there is a short delay, or current-off period, to allow the weld to cool before the application of a tempering current. Postheat, during which the current is on at a low value, is followed by a hold time. During postheating, the electrode force may be increased, as shown in Fig. 16(d). This increased force is called a forging force and is applied during the postheat and hold times. The welding force usually is maintained until the postheat current is applied, after which it is increased to the forging force.

Effect of Workpiece Surface Condition on Heating

For consistent production of spot welds of the highest quality, the resistance at the workpiece surfaces that contact the electrodes (zones b and f in Fig. 14) must be kept to a minimum. This can be done by having smooth, clean work-metal surfaces and by controlling the electrode force. If the workpiece surfaces that contact the electrodes have too high a contact resistance, the temperature rise at these surfaces is almost as fast as at the faying surfaces (zone d in Fig. 14). Also, inconsistent results can be obtained because of variations in the contact resistance and corresponding variations in the time it takes for current flow to be established.

The surfaces of metal sheets are not smooth on a micro scale, and the actual metal-to-metal contact area may be only a small prcentage of the entire contact surface when light electrode pressures are used. As the electrode force is increased, the high spots are depressed, increasing the actual metal-to-metal contact area and thus decreasing the electrical resistance. Increased electrode force also decreases the resistance at the interface of the workpieces. When the electrode material is softer than the work metal, the application of a given electrode force will result in better contact at the contacting surfaces between electrodes and workpieces than at the interface of the two workpieces.

Although electrode force does not enter directly into the heat formula $H = I^2Rt$, its effect on electrical resistance has a direct effect on the flow of the welding current. Surface resistance is inversely proportional to electrode force.

Surface Preparation. Recommended practices for spot welding steel, as given in Tables 4, 5 and 6, call for the work metal to be free from scale, oxides, paint, grease and oil.

The work to be welded, or, as a minimum, the faying surfaces, should be cleaned to ensure that the welds will be free of inclusions. Dirt, scale, rust and oxide film that may come in contact with the electrodes should be removed or reduced to ensure good surface appearance of the welds. Also, removal of foreign substances from workpiece surfaces reduces electrode pickup and consequently increases electrode life.

A film of dirt or oil can be removed from the surfaces of the workpieces by vapor degreasers and chemical baths; however, careful hand wiping of the surfaces to be spot welded may be sufficient. Oxide films can be removed by mechanical methods; the action must be severe enough to cut through the film, but must not be so severe as to cause the formation of a rough or scratched surface.

Where it is impractical to use pickled or cold rolled steel, the surfaces to be welded can be machined, ground or wire brushed far enough back from the edge of the workpiece to clear the electrodes, or for a distance equal to the overlap. Annealing in a reducing at-

(a) Steel should be free from scale, oxides, paint, grease and oil. (b) For type A, D and E faces. Body diameters apply also to type F electrodes with 3-in. spherical-radius face. (c) Each impulse consists of 20 cycles on (heating) and 5 cycles off (cooling), at 60 cycles per second. (d) For steel with a tensile strength of less than 70,000 psi. [SOURCE OF TABLE: Same as Table 4]

mosphere is also an acceptable cleaning method for some metals.

Abrasive blast cleaning methods using sand, coarse grit or shot usually are not satisfactory because particles of sand or scale are left embedded in the surface. Fine, sharp steel grit is satisfactory in some applications.

For information on metal cleaning, see Volume 2 of this Handbook.

Effect of Oil Coatings. Thin coatings of oil on cold rolled or hot rolled pickled and oiled steel have little effect on the quality of spot welds. Tests have shown that the strength of spot welds made on steel having a thin coating of oil is ordinarily about 2 to 3% less than that of spot welds made on the same metal after removing the oil by degreasing.

Excessive amounts of oil should be wiped off or removed in a degreasing operation. The oil itself may not be detrimental to the weld, but the dirt and other contaminants adhering to the oil may cause poor welds.

Effect of Rust, Scale or Oxide. Steel coated with rust, scale or thermally produced black or blue oxide finishes can be resistance spot welded in production, but quality and consistency of welds are lower than on steel from which these coatings have been removed. Thin films that have low and uniform electrical resistance have the smallest effect on welding. Steel that is coated with extremely thick and nonuniform mill scale may not be weldable on a practical production basis without first removing the scale.

Steel on which uniform but heavy mill scale or oxide coatings are present can be welded in production by applying low-to-medium current in a series of pulsations at fairly high electrode pressure. The electrical conductivity of mill scale or oxide increases with temperature, and these coatings become fairly good conductors when red hot. Because of the variable time needed to break through the coating and establish current flow, manual timing gives more satisfactory results than automatic timing.

When metal having heavy scale or oxide coatings is welded, much or all of the scale or coating on the faying surfaces remains in the welds, regardless of current, surface resistance, or electrode pressure. These inclusions in the weld metal can cause voids, blowholes and other internal defects that may sometimes be difficult to detect.

Effect of Weld Spacing on Heating

Shunting occurs when a second spot weld is made so close to the first one that the welding current can flow either through the metal at the first weld or through the metal between the electrodes at the point of the second weld. The welding current will flow in inverse proportion to the resistance of the two paths. Division of current will depend chiefly on the ratio of resistance of the base metal to interface resistance at the point of the second weld.

When making a second and following spot welds, the metal between the electrodes becomes a divided circuit; part of the current travels through the metal to the previously made spot weld, while the remainder travels through the metal between the electrode faces at the point of the second weld. If the distance to the first spot weld is great enough, the resistance of the path through the first spot weld, compared to that directly through the metal, will be high, and the shunting effect can be neglected. If the distance to the first spot weld is short, a significant fraction of the current will be shunted through the first spot weld.

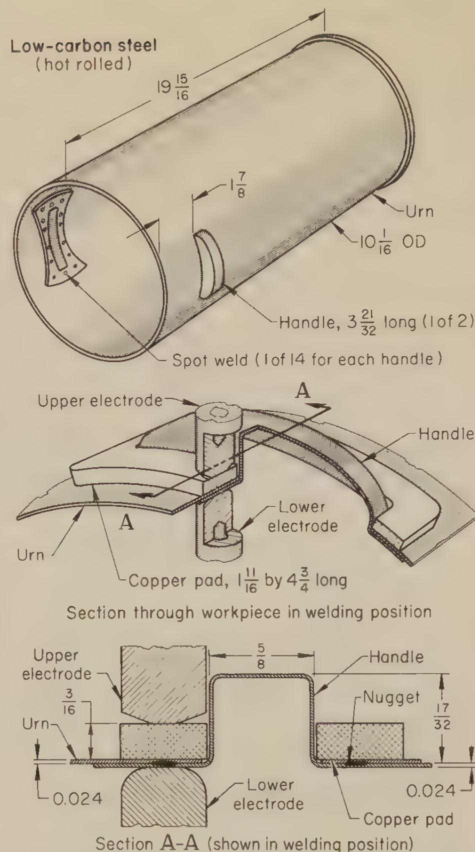

Fig. 17. Sand urn on which electrode indentations on exterior surface were avoided by using a copper pad to diffuse force of upper electrode in spot welding of handles **(Example 375)**

As the temperature of the metal between the electrode tips rises, the resistance at that point increases, thus adding to the shunting effect. Metals having high electrical resistivity are less influenced by the shunting effect than are low-resistivity metals.

The minimum spacing of spot welds in low-carbon steel workpieces depends on stock thickness, diameter of the fused zone, and cleanness of the faying surfaces. The minimum recommended weld spacing for low-carbon, medium-carbon and low-alloy steels is given in Tables 4, 5 and 6. Welds can be made at less than recommended minimum spacing without significant shunting by using higher current and electrode force, shorter weld time and fast follow-up.

If spot welds are made too close to the edge of a sheet or flange, there is an insufficient volume of base metal to withstand electrode pressure and heating. This results in a reduction in the effective force along the edge and uneven heating, causing the hot metal to be expelled from the weld. When spot welds are made too close to an upright flange or sidewall, arcing may occur between the electrode and workpiece, or there may be a poor fit at the faying surface because of the bend radius. If large-diameter electrodes are needed because of the metal thickness, eccentric (offset) faces may be used.

The minimum contacting overlap between two pieces of metal depends somewhat on the metal thickness, which in turn governs the electrode diameter and diameter of the fused zone. The minimum overlaps for low-carbon, medium-carbon and low-alloy steels are given in Tables 4, 5 and 6.

Effect of Surface-Finish Requirements on Heating

In spot welding of assemblies that are to be porcelain enameled or painted, or are to receive other decorative surface finishes, the surface condition and close fit of parts after welding are as important as weld strength. Excessive indentation, overheating of the outside surfaces, spatter and crevices interfere with the finishing operations, and must be avoided.

Welding schedules and conditions must be selected that will produce a weld of adequate strength with a minimum of indentation and minimum evidence of heating. This requires a uniform welding procedure that is best obtained with automatic control of current, time and force. Electrode faces should be dressed at regular intervals, before they have worn so much that unsatisfactory spot welds are produced. The workpieces should be cleaned thoroughly before welding.

In the following example, electrode indentations that were noticeable after spray painting were avoided by using a pressure pad between the electrode and the outer surface of the work.

Example 375. Use of a Conductive Pressure Pad Between an Electrode and the Work To Avoid Electrode Indentation (Fig. 17)

When flanged press-drawn handles were inserted through slots in a sand urn and joined to the inside wall of the urn with 14 spot welds along the flange of each handle (Fig. 17, top view), small dents were present on the outside of the urn, at locations of contact by the face of the upper electrode. These dents were noticeable after spray painting and caused a rejection rate of 5 to 6%, which was considered to be unacceptable.

The dents were avoided by placing a conforming copper plate, or pressure pad, between the upper (outside) electrode and the urn wall, as shown in the middle and bottom views in Fig. 17. This pressure pad fit over the handle and made general contact with the steel urn wall to provide an electrical circuit. The force of the upper electrode, although not reduced, was spread out by the pad so that, after the urn was painted, no dents were visible at the weld spots.

The stress field from the lower (inside) electrode, which was critical for satisfactory spot welding, was not greatly modified by this change, nor was the flow of current through the joint changed substantially.

The welding machine was a foot-operated rocker-arm type, supplied with single-phase alternating current; rating at 50% duty cycle was 20 kva. The upper elec-

trode had a type A (pointed) face, and the lower electrode a type B (dome) face; both were of class 2 material. The No. 2 transformer tap setting was used for welding.

Welding Schedules

Low-carbon steel can be satisfactorily resistance spot welded using wide ranges of time, current and electrode force. Limitations in machine capabilities in any of these variables can be partly compensated for by making suitable adjustments of the others. Practices recommended by the American Welding Society for resistance spot welding of low-carbon, medium-carbon and low-alloy steels are listed in Tables 4, 5 and 6.

The data in these tables can serve as starting points for the establishment of optimum settings for welding of workpieces on which previous experience is lacking, and as an approximate guide to the results that may be expected when good shop practice is followed in resistance spot welding. They are subject to adjustment as necessary to meet the requirements of individual applications.

In addition to giving recommended welding schedules and expected weld properties, these tables also provide guidance on the permissible ratios of thickness for the workpieces, limits on total thickness of pile-up, and recommendations on minimum contacting overlap and minimum weld spacing.

Setting-up Welding Schedules. A typical sequence of steps for determining the most satisfactory conditions for resistance spot welding work for which previous experience is lacking is given in the following list. The usual criteria for satisfactory welds in steps 1 to 4 are penetration, nugget diameter and indentation suitable for the application, and the absence of porosity and gross defects.

1. **Make a preliminary selection of electrode force** for the work to be welded and the electrodes to be used. Tables of recommended practices such as Tables 4 to 7 may provide starting points for this selection, as well as guidance in choosing preliminary values of current, weld time and hold time for making trial welds to verify or correct this preliminary selection of electrode force.
2. **Establish the weld time and hold time.** This is done by evaluating trial welds made at several levels of current for each of a number of combinations of weld time and hold time. Squeeze time is not critical in welding trials and is usually set at a convenient value that is long enough to allow for a wide range of test conditions.
3. **Select electrode force.** Using the established combination of weld time and hold time, make welds at several different current levels, using a number of values of electrode force to cover a wide range of force.
4. **Select the welding current.** Using the established weld time, hold time and electrode force, make test welds at current levels that cover a wide range of amperage.
5. **Verify selection of conditions.** Make trial runs under the welding conditions established by steps 1 to 4, to verify these selections as well as to establish reference data on weld quality and reliability for use in process control. A more complete evaluation than for steps 1 to 4 is performed at this stage (see the discussion in the section on Quality Control, which follows in the next column).

If the results of trial runs in step 5 are not satisfactory, the five-step procedure may be repeated, with changes in the welding variables being made as indicated by the test results. Changes in equipment, electrode material and electrode design may also be made at this time, and the five-step procedure (or a shortened version) repeated until acceptable results are obtained.

The five steps described above not only determine optimum values for each of the welding variables, but also establish ranges of satisfactory values for them and the criticality or noncriticality of each.

The sequence of steps followed in setting up a resistance spot welding schedule may vary, depending on special aspects of the equipment or the work, the extent of experience with similar types of work, and requirements imposed by the purchaser or applicable specifications.

When adjustment of welding conditions is needed at the start of or during production runs, the adjustment is usually made on weld time, hold time or current, whichever is most convenient and effective. Work-metal variables that necessitate adjustments in welding conditions, and a system used by one manufacturer to control these variables and provide for the continuing setting of schedules on the basis of pre-acceptance evaluation of raw material, are described in Example 377.

Quality Control

General practice in resistance spot welding is to base quality control on weld properties and also on the uniformity and consistency of results. For any given requirement, a minimum value may be set that must be equaled or exceeded by all test results; it is often also required that all tests in a given sample should fall within ±10% of the mean for that sample.

The quality of spot welds generally is checked by visual inspection and by destructive testing. Nondestructive testing methods are not ordinarily used in inspection of resistance spot welds.

For a detailed discussion of standard test methods and quality-control procedures for resistance welding, see AWS C1.1, "Recommended Practices for Resistance Welding", Section V.

Quality standards must be related to the requirements of the specific application. It is seldom possible, for instance, to obtain maximum joint strength and minimum indentation using the same machine settings, as shown in Fig. 15.

Visual Inspection. On the surface of a resistance spot welded assembly, the weld spot should be uniform in shape and relatively smooth, and it should be free of surface fusion, deep electrode indentations, electrode deposits, pits, cracks, sheet separation, abnormal discoloration around the weld, or other conditions indicating improper maintenance of electrodes or functioning of equipment. However, surface appearance is not always a good indicator of spot weld quality, because shunting and other causes of insufficient heating or inadequate penetration usually leave no visible effects on the workpiece.

Destructive testing can be performed on the actual workpiece or on test specimens. For small, inexpensive parts, actual production samples from each machine are taken on a random-selection basis or at prescribed regular intervals for destructive testing. Test coupons are not entirely satisfactory, because of the effect of a different amount of magnetic material in the throat of the welding machine on welding current. They are used, however, where production parts are large or costly, and with experience in interpretation of results can give valuable information on the quality of production welds.

Destructive tests made on spot welds include tension-shear, tension, peel, impact, twist, hardness and macro-etch tests. Fatigue tests and radiography have also been used.

Strength of the weld is usually determined by the tension-shear and tension tests. Separation of the joint as observed in one of the first five tests can be used to approximate the diameter of the weld nugget. Examination of macro-etch specimens can reveal the nugget diameter and penetration, and the structure of the weld.

Quality standards on nugget diameter and penetration vary with the requirements of the specific application. For maximum weld strength, a rule of thumb that can be applied as a starting point in welding most metals, in the absence of more specific requirements, is that the minimum nugget diameter should be 0.06 in. plus three times the thickness of the thinnest workpiece. Tables 4, 5 and 6, as developed by the American Welding Society, give recommended nugget diameters for spot welding low-carbon, medium-carbon and low-alloy steels, in relation to shear strength of the welds. These nugget diameters are for welds of the highest average shear strength that can ordinarily be obtained in production with high reliability.

Penetration, or the depth that fusion extends into the outer workpieces, should be 20 to 80% of the workpiece thickness, with welds of maximum strength usually being obtained when penetration is about 70% of stock thickness. When workpieces of unequal thickness are welded, penetration into the thicker piece ordinarily need not exceed the penetration into the thinner piece.

Where surface finish is critical, extent of indentation, discoloration, spatter and sheet separation may be as important as weld strength.

The structure of a spot weld in low-carbon steel ordinarily has the following features:

1. A columnar dendritic structure in the fusion zone
2. A heat-affected outer zone showing gradual transition from a coarse overheated structure through a normalized region, to the original structure of the unaffected base metal
3. A narrow ferritic zone in the interface of the overheated and unaffected zones. This zone is not always well defined, particularly at the interface of the two workpieces.

Process Variables That Affect Weld Quality. In addition to current, electrode force, and timing, the process

variables that affect weld quality in resistance spot welding include:

1 Ability of the welding equipment to operate consistently at the specified current in continuous production
2 Closeness of fit of the components to be welded
3 Strength and rigidity of fixtures
4 Adequacy of clamping.

When only one or a few spot welds are used to join workpieces, the probability of exceeding the duty-cycle rating of the machine is much less than when many spots are made in rapid succession. Exceeding the duty-cycle rating causes the transformer to overheat, resulting in underheating of the workpieces and production of poor-quality welds (or, if extreme or of sufficiently long duration, in shutting down the equipment).

Poorly fitting workpieces may not permit proper contact. Poor contact can cause insufficient flow of current, small-diameter welds, or welds that have inadequate fusion and pull apart because of springback.

Magnetic materials in or near the throat of the machine affect kva demand and power factor, and should not be used in fixtures that are to be placed in the throat of the machine. The fixtures should have sufficient strength and rigidity to prevent warping of workpieces.

In spot welding long sections of thick material, the four process variables listed above have a critical effect on weld quality. In the example that follows, many welding trials and substantial changes in equipment and procedures were needed to solve problems of weld quality related to these variables.

Example 376. Changes in Major Process Variables To Avoid Warping of Workpieces and Overheating of Equipment in Making 73 Spot Welds in a Long Assembly of Thick Steel (Fig. 18)

A total of 73 spot welds were made in joining two steel workpieces, each 75 in. long and 0.089 in. thick (0.178-in. total thickness), as shown in Fig. 18. Fit-up in the overlapping portions of the workpieces, where the welds were to be made, was very poor in spots. In the first welding trials, a heavy-duty portable welding gun was used with a fixture equipped with hand-operated clamps.

Two major problems were encountered: (*a*) as the welds were made, the clamps loosened so that the assembly was twisted and bent when removed from the fixture; and (*b*) weld strength and nugget diameter deteriorated progressively after 38 or 39 welds, and the last few welds failed even to hold the workpieces together.

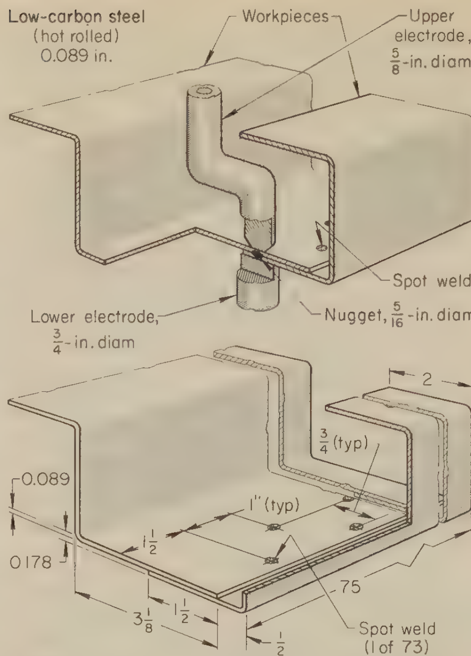
In an attempt to eliminate the warping of the assembly and loosening of the clamps during welding, several welding trials were conducted in which the welds were made in various staggered sequences. None of these efforts substantially reduced the amount of warping or the loosening of the clamps.

Further experimentation led to the adoption of the following three changes to improve fit-up and eliminate warping of the workpieces and loosening of the clamps during welding: (*a*) the forming dies were reworked to improve fit-up; (*b*) the welding fixture was rebuilt to make it more rigid; and (*c*) the hand clamps were replaced by stronger air-operated clamps, and more clamps were used.

The addition of a second welding gun and control of cooling-water flow rates in the equipment were used to eliminate the progressive deterioration of weld characteristics in making the 73 spot welds.

It appeared that the inability to produce 73 sound welds in succession was the result of cumulative temperature rise in the welding equipment. When two welding guns, each connected to a separate transformer, were used alternately and with adequate cooling-water flow, acceptable weld quality was obtained in continuous production. Apparently, the "off" time for each welding unit allowed sufficient cooling of the welding guns and power-supply components. To maintain adequate cooling of the welding components, the flow of cooling water in the system was controlled with the aid of flowmeters at the rates shown in the table that accompanies Fig. 18.

Additional equipment details and welding conditions are also given in the table that accompanies Fig. 18.



Equipment Details

Welding guns (2)	Portable, heavy-duty, air operated
Transformers (2)	Series-parallel with 5-step tap switch(a)
Rating at 50% duty cycle	200 kva (each transformer)
Upper electrode	Offset body, ⅝-in. diam, with ⅜-in.-diam type E (truncated) face(b)
Lower electrode	Type C (flat), ¾-in. diam
Cables (2)	450 MCM (450,000 circular mils), kickless, water cooled, 6 ft long
Disconnect switches	800 amp

Welding Conditions

Transformer tap setting	Series and No. 3 tap
Electrode force	1400 lb
Squeeze time	40 cycles
Hold time	25 cycles
Weld time	2 pulses of 12 cycles weld, 6 cycles cool
Cooling-water flow rate:	
In cables and electrodes	1½ gal per min
In transformers	1¾ gal per min

(a) Phase-shift heat control was not used. (b) Space was not sufficient for a ¾-in.-diam electrode.

Two water-cooled transformer-and-gun units were used alternately to avoid overheating; and rigid fixturing, air-operated clamps, and crowned workpieces were used to avoid warping.

Fig. 18. Long, poorly fitting assembly of thick steel for which overheating and warping were avoided in spot welding (Example 376)

Workpiece variables that affect weld quality include work-metal composition, heat treatment, and degree of cold work before welding. Consistency of hardness, strength, stock thickness, phase distribution and alloy content is needed to ensure consistency of results in resistance welding of any material. Variations in work-metal properties that have the greatest effects on weld quality usually can be detected by relatively simple tests such as measurement of tensile strength or hardness tests on the raw material.

In the example that follows, variations in hardness and tensile strength of greater than ±10% from an established mean value, or in stock thickness, were found to have adverse effects on quality of spot welds, and methods were developed to control these variables. (Related programs, which made use of the same control of raw material and the same system for evaluating welding machines and welds, were applied to gas tungsten-arc and gas metal-arc spot welding.)

Example 377. Procedure for Control of Work-Metal and Processing Variables To Ensure Quality of Spot Welds (Fig. 19)

In one plant, failures of spot welds in sheet-metal assemblies were threatening to halt production. The exact contribution of each factor involved could not be assessed accurately, but excessive variation in quality of raw material was suspected as one of the chief contributors. Most of the assemblies welded were made of commercial quality, cold rolled low-carbon (0.13 max C) steel sheets 0.060 or 0.048 in. thick. Class 2 electrodes were used for all spot welding of low-carbon steel.

A five-part program instituted to bring the quality of the spot welds under control included:

1 Establishment of standards for incoming raw material
2 Initiation of a quality-control program for incoming stock, based on the standards established in step 1
3 Determination and systematic recording of machine capabilities for making the spot welds
4 Initiation of a program of electrode maintenance
5 Establishment of standards for in-process inspection and control.

The entire program was put into effect after completion of a three-year study and development period.

Standards for Incoming Material. A three-year study was made of all incoming steel sheet from all sources to determine which characteristics of the material most affected weld quality. At the end of this study, the findings were incorporated into a plant purchasing specification for sheet steel.

Variations in thickness, tensile strength and hardness were found to have the largest effects on weld quality, and plant standards were set up for these and other characteristics. Sheet thickness was required to conform to AISI standards as described in the Steel Products Manual for Carbon Steel Sheets. Tensile strength had to be within 10% of an established mean, and hardness had to be less than Rockwell B 60.

Sheet steel had to be free from laminations and to be capable of being bent flat on itself in any direction at room temperature without cracking along the bend. It also had to pass weldability tests for resistance spot welding, as outlined below under "Quality Control of Incoming Stock", for acceptance under the plant purchasing specification for sheet steel.

Quality Control of Incoming Stock. All incoming stock was subjected to routine identification and visual examination, and to inspection procedures established by the special purchasing specifications written under the first step of this quality-control program.

Two sheets of steel were selected at random from each incoming shipment and from them were sheared a number of 1-by-6-in. coupons for testing. (Coupons were cut from more than two sheets if quality of heat was in doubt.) Ten of these coupons were tested for tensile strength (breaking load), others were tested for hardness, and the thickness of the steel was measured.

Finally, ten coupons were spot welded to make five samples. Of these samples, four were broken in tensile-shear tests, and one was sectioned and examined for penetration and diameter of weld nugget. Penetration of the nugget was to be a minimum of 50% of sheet thickness into each member of any joint, and variation of tensile-shear strength from standard was to be no more than ±10%.

Material that passed these tests was accepted and released for production. Figure 19 shows the amount of variation in tensile strength (breaking load), hardness and thickness of incoming stock, and in tensile-shear strength of spot welded joints between samples, over a ten-year period, for the two thicknesses (0.048 and 0.060 in.) that comprised most of the steel sheet that was resistance spot welded.

Machine Capability. Sample coupons from shipments of steel sheet that had been tested and found to conform to the plant purchasing specification were used in evaluating the capability of each production resistance spot welding machine.

In the initial qualification of a machine, the settings on the machine were varied systematically and welds were made and checked to establish control settings for the machine on the thicknesses of stock to be run on that machine. Records of these control settings were kept for use in setting up for production runs.

Before making a production run in any machine, the control settings on that machine were tested by welding four pairs of specimens for inspection. Three of these samples were pulled apart in tensile-shear tests, and the fourth was sectioned for metallographic examination. The production welding machine was adjusted until the welds met the quality-control standards.

Then 25 test welds were made to determine the uniformity of operation of the machine. Of these 25, five were sectioned and 20 were tested to destruction in tensile-shear tests.

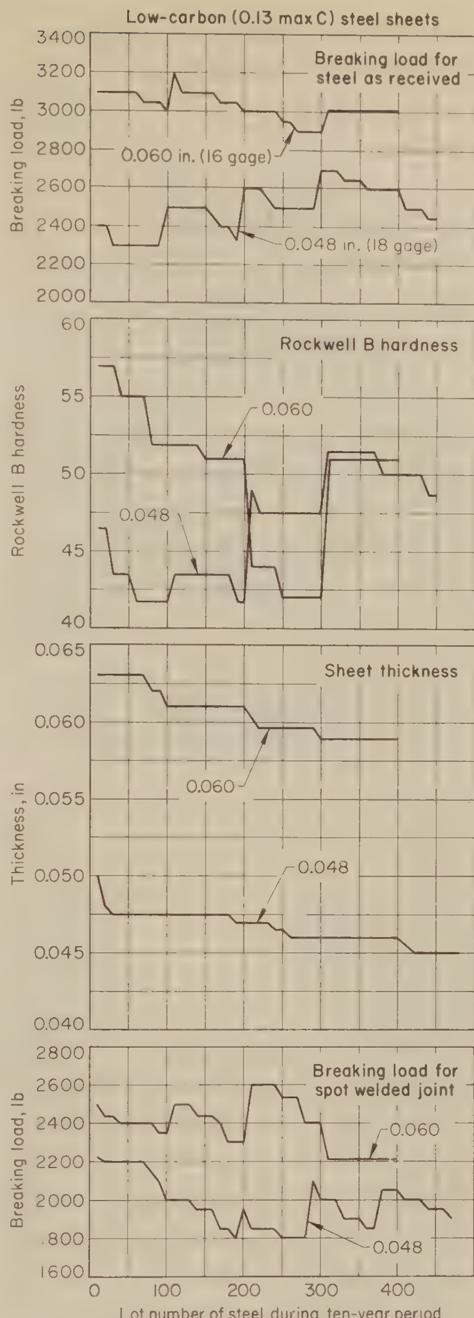
If the test samples were acceptable, the machine settings were approved for production. Before each start-up, four samples were made and tested to ensure that meanwhile none of the settings had changed.

Electrode Maintenance. Shape of the electrode face was found to have an important influence on weld quality. Usually, the best spot welds were made by electrodes with radius faces (type F, Fig. 9). The spherical radii of the electrode faces ranged from 2 to 6 in. For even penetration of stock with equal thickness in both members, a 2-in. radius was normally used on both electrode faces.

Sometimes, an electrode with a flat face (type C, Fig. 9) was used with an opposing electrode having a radius face. When sheets of different thicknesses were joined, electrode faces with differing radii were used; this ensured heat balance and resulted in equal penetration of both members of the joint.

The face contour of radius-face electrodes was maintained by dressing with a specially shaped paddle, faced with 240-mesh aluminum oxide cloth. The faces of the paddle had a concave surface that fit the spherical end of the electrode to be dressed. After eight hours of use, the electrodes were replaced, and the worn ends were remachined to the original spherical shape, regardless of their condition, as a preventive-maintenance practice.

In-Process Inspection. For in-process inspection, random spot welded assemblies were taken from the production line and sectioned for metallographic examination,



Equipment Details(a)

Welding machine ......220-v, 60-cycle, 3-phase press type; throat, 10 by 36 in.
Rating at 50% duty cycle ....100 kva
Secondary voltage, max ....4.9 v
Secondary current, max ....70,000 amp
Electrode force ....3000 lb max(b)
Electrode ....Type F, 2-in. radius; class 2

Typical Welding Conditions(a)	0.048-in. sheet	0.060-in. sheet
Heat-control setting, %	36	36
Electrode force, lb	750	750
Squeeze time, cycles	40	40
Weld time, cycles	10	12
Hold time, cycles	40	40
Heat time, cycles(c)	6	9
Cool time, cycles(c)	4	4

(a) Over the ten years, various welding machines were used; details here illustrate general machine capability. Operating conditions varied among machines. (b) At 80-psi air pressure. (c) Not available on all machines.

Data plotted represent mean values as determined for each ten lots of steel received.

Fig. 19. Ten-year record of characteristics of sheet and spot welded joints, used to establish process controls (Example 377)

or tested to destruction in a tensile-shear test. As in the weldability tests done for quality control of incoming stock, nugget penetration had to be a minimum of 50% of sheet thickness into each member of the joint, and tensile-shear strength could not vary more than ±10% from the established standard. The frequency of testing depended on the cost of the assembly, and on the need for control as indicated by previous history of variation. These in-process inspection tests were in addition to the routine tests done just before each production run, as described above under "Machine Capability".

Results of Program. Since several phases of this program were developed simultaneously, and since their development was interdependent, several minor adjustments had to be made in the level of the standards in the first year or two of operation. A record of the first 17 years under this program showed that the problem of failure of spot welds in finished assemblies was completely eliminated, and that there were no reports of failure of weldments in the field.

Overlapping Spot Welds

Spot welds that overlap instead of being spaced apart frequently are used to produce leakproof seams. Normally, these seams are made by resistance seam welding; however, when the seam or the workpieces are too small for conventional electrode wheels to track, or when a workpiece interferes with the operation of a cup-type seam welding electrode, individual spots must be made with modified resistance spot welding methods.

In the following example, when overlapping spot welds were used instead of spot welding plus silver brazing to make an airtight seam, production rate was increased and cost was reduced.

Example 378. Use of Overlapping Spot Welds To Increase Production Rate and Reduce Unit Cost in Making an Airtight Seam (Fig. 20)

The type 430 stainless steel outer wrap of a gasoline-burning car heater was joined to the nickel-plated low-carbon steel exhaust tube of the heater as shown in Fig. 20. The joint had to be strong and, for safety, airtight when tested at a pressure of 5 psi. Originally, the assembly was joined by separate spot welds, for strength, and then the joint was silver brazed, to make it airtight. Acceptable parts with strong, airtight joints were made by this method, but a faster and less costly method for joining was needed to meet increased demand.

Seam welding was considered, but the 1¾-in.-diam circular seam was too small to track with wheel electrodes. Therefore, a method of making overlapping spots in a press-type resistance spot welding machine was adopted.

The head of the welding machine was equipped with an automatic rotary-indexing mechanism to which was mounted a holder for two upper electrodes 180° apart, which were operated against a one-piece lower electrode that conformed with the internal contour of the components at the joint (see Fig. 20). Clamps held the components on the lower electrode holder during welding. The upper electrodes were ⅝ in. in diameter, with tips machined to 5/32 in. in diameter, and had a 45° offset. All electrodes were made of RWMA class 2 material. The upper electrodes were connected to the welding transformer so that both were of the same polarity (see Fig. 13c, page 412).

Although the type 430 stainless steel had an electrical conductivity of 3% IACS, as compared to 14.5% for the low-carbon steel, and was somewhat thinner, no problems were encountered in obtaining satisfactory

heat balance, using the electrodes shown in Fig. 20.

The total cycle time for making a pair of spot welds, including indexing time, was 39 cycles. Thus a 5½-in.-long circular seam of 80 individual spot welds about 3/32 in. in diameter, each with about 35% overlap of the preceding spot, was completed in 26 sec.

With the improved joining method, production rate was almost eight times that of the original method, and cost for direct labor and material was only one-tenth as much. The assemblies joined by overlapping spot welds were leak tested at a pressure of 5 psi, and rejection rate was 0.5%. Additional equipment details and welding conditions are given in the table that accompanies Fig. 20.

Roll Spot Welding

Resistance roll spot welding consists of making a series of separate, spaced spot welds in a row by means of resistance seam welding machines and electrode wheels. The roll spot welds are made without retracting the electrode wheels or removing the electrode force between spots.

Current, welding time and electrode force are essentially the same as for resistance spot welding of similar workpieces. An individual roll spot weld has the same appearance as a spot weld made in the usual manner, except that the weld nugget is usually slightly elongated in the direction of electrode travel.

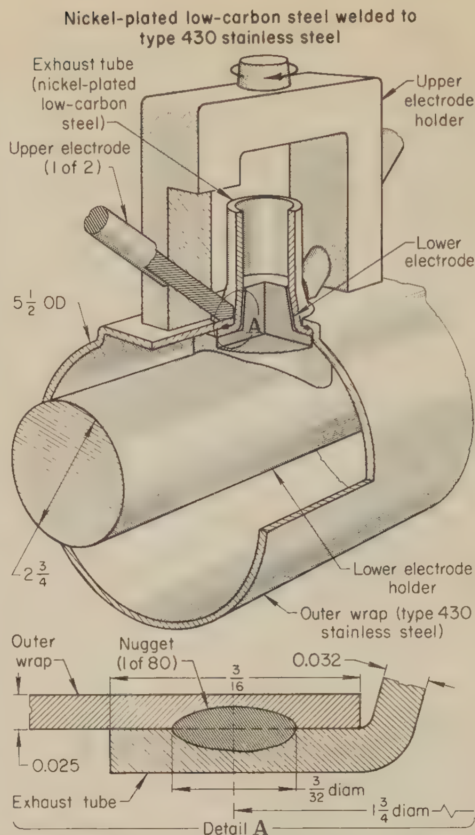
Roll spot welds are made using either continuous or interrupted motion of the electrode wheel, depending on the weld time needed to develop the necessary heat, and the hold time needed to solidify the weld metal (with continuous motion of the electrode wheel, hold time is zero). The desired weld spacing is obtained by adjustment of the electrode-wheel speed and of the current on and off times.

Nugget width (transverse to direction of travel) is determined primarily by the contacting width of the periphery of the electrode wheel. When electrode motion is continuous during welding, nugget length is a function of electrode diameter, rotation speed and heating time; when interrupted electrode motion is used, nugget length depends mainly on wheel diameter and heating time. For some roll spot welded assemblies (for example, the one shown in Fig. 21), nugget width may be governed chiefly by the shape and dimensions of one of the components.

Design and arrangement of fixtures and electrodes must be coordinated to ensure accurate match-up and intimate contact of the workpieces at all weld spots for roll spot welding. Fixturing was of special importance in roll spot welding a circular seam in the example that follows, in which a steel ring was joined to the bottom of a sheet steel can.

Example 379. Roll Spot Welding for Which Change in Fixturing and Method Reduced Rejection Rate and Increased Production (Fig. 21)

Roll spot welding was used for attaching a 15 21/32-in.-OD skid ring of ½-in.-diam low-carbon steel rod to the 0.048-in.-thick low-carbon steel bottom of a general-purpose can (see view at upper right in Fig. 21). The ring reinforced the sheet-metal bottom and provided a solid surface on which to move and store the can.



Equipment Details

Welding machine	Press type, semiautomatic, air-operated
Rating at 50% duty cycle	50 kva
Rating of secondary circuit	32,500 amp
Transformer taps	Six
Electrode material	RWMA class 2
Electrode force, max	1000 lb
Heat control	Phase shift
Timing control	Synchronous

Welding Conditions

Transformer tap setting	3
Heat-control setting	87%
Electrode force	312 lb, each electrode
Squeeze time	11 cycles
Weld time	8 cycles
Hold time	12 cycles
Off (indexing) time	8 cycles
Load time	8 sec
Unload time	10 sec
Production per hour	88 assemblies(a)
Direct labor, hr per 1000 assemblies:	
Original method	55
Improved method	7

(a) The machine operator also ran another resistance welding machine on which other types of assemblies were welded.

Use of overlapping spot welds increased production and reduced cost, compared with original method (spot welding plus silver brazing).

Fig. 20. Setup for joining a car-heater subassembly with 80 overlapping spot welds, to make an airtight joint (Example 378)

In the method originally used, the assembly was tack spot welded before being roll spot welded. For tack welding, the ring was held in position on the bottom surface of the can by a locating fixture (see upper left view in Fig. 21) and then was tack spot welded to the bottom in four places. After removal of the fixture, the assembly was placed in a circular seam welding machine that had one electrode wheel contoured to hold the ring and a flat-face electrode wheel that contacted the can bottom, and 65 roll spot welds were made around the ring.

Rejection rate was unacceptably high because a number of the welds on a significant percentage of assemblies were weak. It appeared that the fixture used for tack welding did not provide sufficiently accurate alignment between the can bottom and the skid ring. Under these conditions, the electrode force was not sufficient to bring the components into intimate contact for all welds during roll spot welding.

The tack and roll spot welded assembly was dropped from a height of 3 ft onto a concrete platform to test the soundness of the welds, which was determined by the ringing sound made when the assembly struck the platform. An assembly with some loose spot welds sounded noticeably different from one with all sound welds. After testing, the assemblies were hot dipped in a galvanizing bath at 860 F. Some of the spot welds that had previously been passed came apart in this operation, during which the more rapid heating and cooling of the sheet-metal bottom than of the thicker ring produced high local stresses at the welds and caused weaker welds to fail. Over-all rejection rate was 4½% — more than twice the plant standard maximum acceptable rejection rate of 2%.

A new roll spot welding fixture was designed that would eliminate the need for preliminary tack spot welding. The new fixture, shown at lower right in Fig. 21, was equipped with two sets of guide rolls. One set guided the can bottom at its periphery; the other set, which engaged the skid ring, supported the assembly at the proper level for the spot welding electrode rolls. Thus, the assembly was not removed from the fixture until all 65 spot welds were made.

The rigid new fixture held the components in accurate alignment and permitted intimate contact for all 65 spot welds. Use of the new fixture and technique, plus tightening of control over all operating variables, eliminated the preliminary tack welding operation and at the same time improved weld quality and reliability substantially. Over-all rejection rate was reduced from 4½% to between 0.1 and 0.4%.

Elimination of the extra handling operation increased production from 70 to 88 assemblies per hour, and the over-all improvement allowed a reduction of more than 20% in the price of the finished cans.

Tack welding, in the original method, was done with a single-phase alternating-current foot-operated spot welding machine rated at 50 kva (at 50% duty cycle). Roll spot welding, in both the original method and the improved method, was done with a single-phase alternating-current circular seam welding machine with 150-kva rating (at 50% duty cycle) and electronic controls. Heat-control setting in the improved method was 79%.

Spot Welding of Coated Steel

Low-carbon steel sheet that has been coated, by hot dipping, electroplating or other processes, with corrosion-resistant metals or alloys (such as zinc, aluminum, tin, and tin-zinc) is spot welded in large-scale production, as described in the next three sections of this article. Terne-coated steel (steel coated with a lead-tin alloy) is spot welded in large volume in making automobile mufflers, but otherwise not many individual plants use spot welding on this material.

Steel sheet with metallic coatings (such as nickel and chromium plating) that are intended to serve primarily as decorative coatings can be spot welded, sometimes (depending on plating thickness and properties) under the same welding conditions as those used in welding uncoated steel. However, because of the need to avoid marking of decorative surfaces, spot welding of steel that has been plated for this purpose is relatively infrequent.

Steel that has been electroplated with a functional (not decorative only) coating of another metal is spot welded in some high-production applications. For instance, nickel-plated steel is spot welded for use in electrical equipment, principally for terminals or contacts.

Steel sheet with phosphate or other conversion coatings is not ordinarily spot welded without removing the coating first. The high electrical resistance of these nonmetallic coatings (which varies with type and thickness of coating) makes it necessary to use high electrode forces and also may cause excessive sparking from between the workpieces when the flow of welding current is initiated. Variation in the thickness of a coating affects its electrical resistance and may interfere with welding. Also, the electrode tips may become badly pitted, requiring frequent cleaning and reconditioning, and particles of coating material may be intermixed with the weld metal.

Steel sheet is not ordinarily resistance spot welded through paint or plastic coatings on a production basis. However, techniques that use specially designed and operated electrodes to heat and penetrate organic coatings have been used with success in volume production (see Example 421, in the article on Resistance Welding of Copper Alloys, and Example 399, in the article on Projection Welding). The coating is softened at the weld site, and is displaced into the immediately adjacent areas of the work.

Spot Welding of Zinc-Coated Steel

Direct spot welding (see circuits in Fig. 13) is recommended for zinc-coated steel (which may be either hot dip galvanized or electroplated), because the shunting current associated with series welding, when added to the higher-than-normal current needed to weld zinc-coated steel, results in excessive electrode heating and short electrode life. When large panels are welded, the welding machine can be set up as shown schematically in Fig. 13(e) to reduce the throat depth.

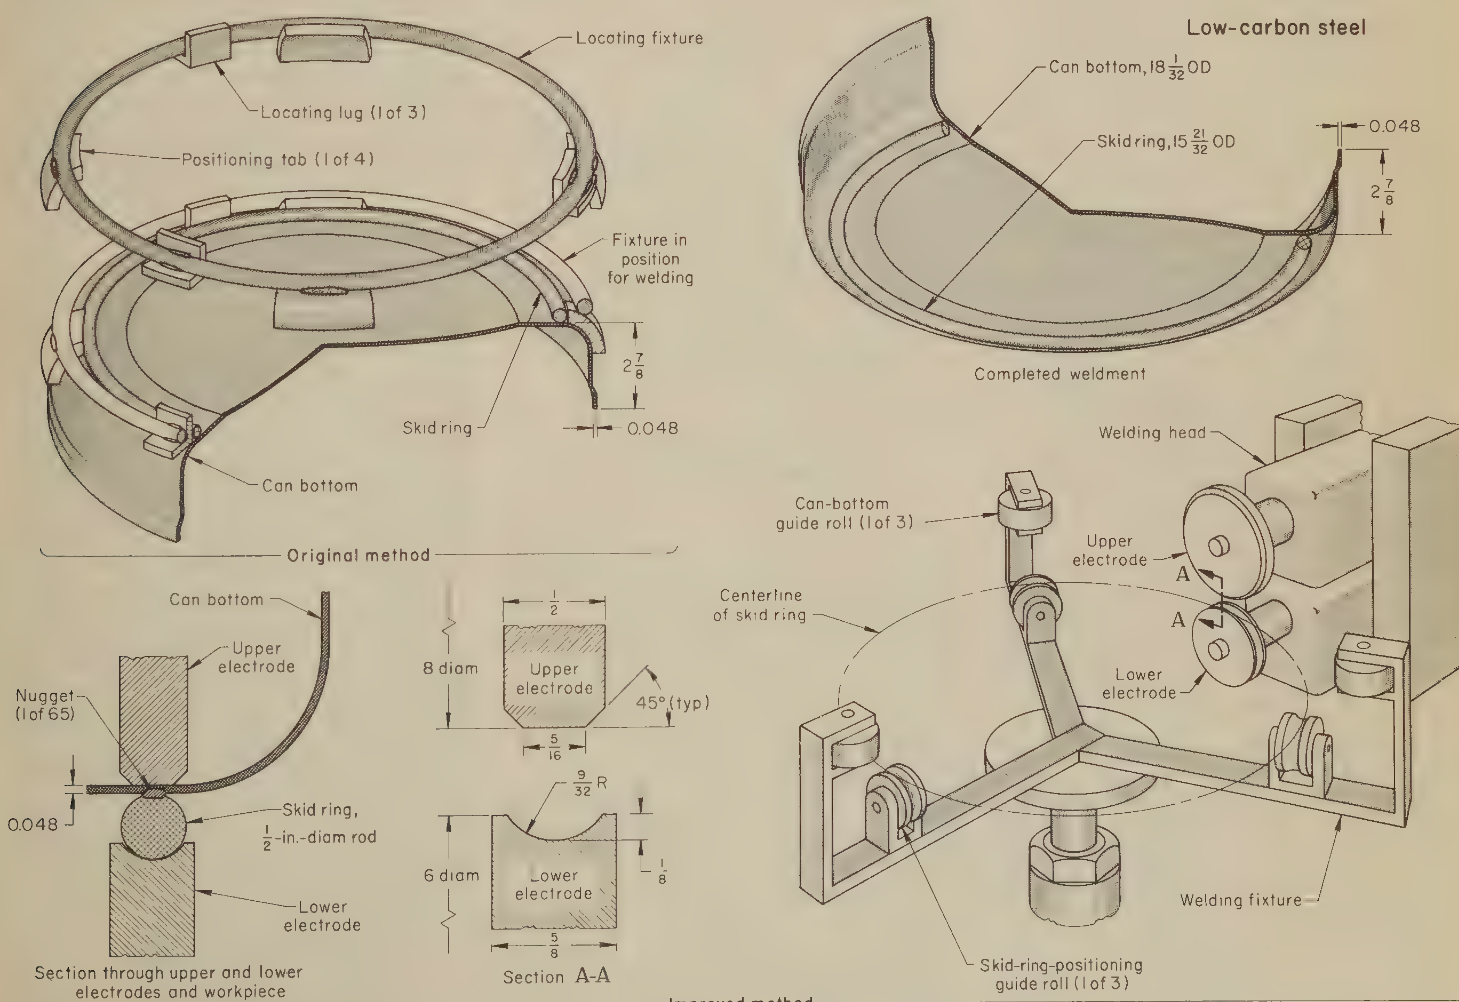
Weldability of thin sheets electroplated with zinc decreases as the coating thickness increases, in the range of 0.0002 to 0.001 in. However, as thickness of sheets increases above 0.060 in., weldability increases regardless of coating thickness. The welding behavior of hot dip galvanized steel is affected by the thickness and uniformity of the zinc-iron alloy layer, as well as the thickness of unalloyed zinc.

Electrode Design. Truncated-cone (type E) electrodes (see Fig. 9) are recommended for spot welding zinc-coated steel. The included angle of the cone should be from 120° to 140°, with the smaller angle being used where fit-up problems exist. The face diameter of the electrode should be four to five times the thickness of the thinner sheet for two-thickness welds. A larger face diameter requires greater current and results in shorter electrode life.

Flat-face (type C) electrodes are not recommended, because the melted zinc forced from the weld area forms an annular deposit on the electrode body surrounding the face. As the thickness of this deposit increases, the weld quality decreases.

When portable welding guns are used, a type F electrode having a radius of 1 to 2 in. is recommended. A smaller radius can result in increased indentation, and a larger radius in reduced electrode life.

Electrode Composition. RWMA class 2 (copper-chromium) electrode material generally provides the best electrode life. A copper-zirconium alloy also produces good electrode life, provided it has been sufficiently cold worked to



Fixture used in original method held components only while four tack spot welds were made; tack welded assembly was then transferred to a circular seam welding machine for application of roll spot welds. Improved fixture positioned and held assembly for application of roll spot welds in circular seam welding machine, thus eliminating tack spot welding.

Fig. 21. Change in fixturing that reduced rejections and raised production in roll spot welding a skid ring to a can bottom (Example 379)

Table 7. Conditions for Resistance Spot Welding of 1010 Steel 0.040 and 0.125 In. Thick, With and Without Zinc Coating (a)

Welding condition(b)	Steel 0.040 in. thick: Zinc coated(c)	Steel 0.040 in. thick: Uncoated	Steel 0.125 in. thick: Zinc coated(c)	Steel 0.125 in. thick: Uncoated
Weld time, cycles (60 cps)	13	10	42	26
Welding current, amp	14,000	9500	20,000	19,000
Electrode force, lb	650	500	2000	1800
Minimum weld spacing, in.	0.75	0.75	2	1.75
Nugget diameter, in.	0.21	0.19	0.48	0.33
Minimum contacting overlap, in.	⅝	½	1⅛	⅞

(a) Data for zinc-coated steel are from AWS C1.3, "Recommended Practices for Resistance Welding Coated Low Carbon Steels". Data for uncoated steel are from Table 4 in the present article. All data are for welding with class 2 electrodes. (b) For joining two sheets of steel in each of the two thicknesses. (c) Coated with 1.25 oz of zinc per square foot of sheet size.

achieve the hardness needed to resist plastic deformation of the electrode face. The buildup of zinc on and around the electrode face is a problem with both copper-chromium and copper-zirconium alloys, and the electrodes must be cleaned or replaced at regular intervals.

Where weld appearance is important and electrode sticking must be avoided, class 1 material can be used. The high conductivity of this alloy reduces heating at the interface of the electrode and the work. Resistance to deformation is not as great as that of class 2 material.

Cooling of electrodes is ordinarily done with a minimum water-flow rate of 2 gal per minute; cooling requirements vary with electrode material and dimensions, work metal and zinc thickness, and the welding conditions. If the water temperature exceeds 85 F, the rate of flow to the electrode should be increased. Overheating of an electrode softens it, and deformation of the electrode face occurs. Also, the higher temperature of the electrode results in an accelerated alloying of the copper electrode material with the zinc coating on the work metal.

Welding Conditions. To produce nuggets of adequate size in zinc-coated steel, longer weld times (25 to 50% longer) and higher currents are required than for uncoated low-carbon steel. Also, the range of welding times is narrower for zinc-coated steel.

The welding current can be as much as 50% greater than that required for uncoated steel, depending on work-metal thickness. Thinner work metals require proportionately higher currents than do thick metals.

The electrode forces used for welding zinc-coated steel are 10 to 25% greater than those used for welding uncoated steel. The increase in electrode force is necessary because the coating reduces the faying surface contact resistance to almost zero; also, the softened zinc must be extruded from between the sheets as quickly as possible, lest the base metal be softened.

To produce true welds of steel to steel, which must be done for strength greater than that of a soldered-type joint, the welding conditions must be such as to melt the zinc completely between the faying surfaces of the workpieces, over an area approximately the size of the electrode face, and to squeeze out this molten zinc in this weld-nugget area. Melting of the zinc on the surfaces of work in contact with the electrodes should be avoided if possible, to minimize electrode alloying and sticking, and to retain a uniform layer of zinc on the exposed work surfaces for corrosion resistance. The hold time should be of sufficient duration so that cooling by the electrodes continues long enough to avoid melting of the zinc on the work surfaces in contact with the electrodes, from the residual heat in the nugget and adjacent portions of the steel, and to allow any molten zinc in the vicinity of the weld to resolidify before the clamping force is released. The use of upslope and downslope of the welding current is sometimes helpful in producing the desired weld characteristics.

Table 7 compares welding conditions for 0.040 and 0.125-in.-thick 1010 steel coated with 1.25 oz of zinc per square foot of sheet size, with conditions for uncoated 1010 steel of the same two thicknesses.

For welding heavy-coated steel (1.50 oz of zinc per square foot), weld time must be increased by up to 45% over that used for welding commercial-coated steel (1.25 oz per square foot), or welding current increased by up to 10%. For welding light-coated steel (0.9 oz per square foot), weld time is decreased by 5 to 10% from that used for welding commercial-coated steel, or welding current decreased by up to 5%. (The nominal coating weights given here are based on sheet size, not on total surface of two sides; for coating weight per unit of surface area, multiply by two.)

Spot Welding of Aluminum-Coated Steel

Steel coated on both sides with aluminum in a hot dip process is available in two types. One type is coated with an aluminum-silicon alloy approximately 0.001 in. thick, and is used in high-temperature applications (up to 1250 F). The second type is coated with pure aluminum approximately 0.002 in. thick. Spot welds having good strength can be made on both types of aluminum-coated steel.

These coatings require high welding current, because they have high electrical and thermal conductivities. No special cleaning of the coating surface is needed. Grease and other foreign material should be removed by solvent cleaning or by a light pass with a power-driven wire brush.

The high welding current results in considerable heating at the contact surface between the electrode and the coated workpiece. The aluminum coating that forms on the electrode face can alter welding conditions, and therefore the machine settings may need adjustment after a few workpieces have been welded.

Electrodes with a type F (radius) face (see Fig. 9) and made of RWMA class 2 material are recommended. The radius of the electrode face should be 1 in. for sheet up to 0.025 in. thick, and 2 in. for sheet thicker than 0.025 in. The electrodes should be dressed with 160-mesh or 240-mesh aluminum oxide cloth after a predetermined number of welds have been made.

Welding Conditions. The weld time, welding current and electrode force are about the same as, or slightly greater than, those recommended for uncoated low-carbon steel. For work metal up to 0.030 in. thick, the welding current may be increased 15 to 25% over that used for uncoated low-carbon steel.

Spot Welding of Tin-Coated and Tin-Zinc-Coated Steel

Spot welding of steel with a tin or tin-zinc coating (hot dipped or electroplated) is done commercially. However, the machine settings are more critical than for welding uncoated low-carbon steel, and machines with low-inertia welding heads are recommended. Steel with a 0.0003-in.-thick coating of 80% tin and 20% zinc is easier to weld than a steel sheet coated with pure tin 0.0001 in. thick.

Electrodes with a truncated-cone (type E) face (see Fig. 9) and made of RWMA class 2 material are recommended. Class 1 electrode material gives good results in welding steel with tin or tin-zinc coating, but with shorter electrode life. Included angle of the cone should be 120°, and face diameter should be four to five times the thickness of the thinnest sheet.

Where marking of one sheet is undesirable, a large flat-face (type C; see Fig. 9) electrode can be used in contact with that sheet, and a radius-face (type F) electrode used with the second sheet, if the sheet thicknesses permit. Additional current is needed, because the current density is low. Greater indentation occurs on the second sheet, and electrode life is reduced. Initially, the electrodes may adhere to the surface of the sheet, but sticking decreases after a number of welds have been made.

Welding Conditions. Relatively short weld times are used, and the welding current should be adjusted so that there is no expulsion of steel from between the sheets. However, none of the tin or tin-zinc coating should be entrapped at the faying surfaces, and to prevent formation of solder-type joints, electrode force must be sufficient to extrude the melted coating before the base metal begins to soften. Optimum electrode pressure is about 10,000 psi; greater pressures cause indentation.

Spot Welding of Dissimilar Metals

Low-carbon steel can be resistance spot welded to most other ferrous metals and to many nonferrous metals, producing a weld nugget that is an alloy of the two metals.

In making a spot weld between dissimilar metals, a heat balance must be achieved that compensates for the differing properties of the two metals and results in the production of a weld nugget having approximately the same thickness on each side of the interface. More heat must be provided to the more thermally and electrically conductive metal, which generates less resistive heat and has greater loss of heat by conduction. The higher-melting of two dissimilar metals of approximately equal conductivity also needs more heat.

If two metals being welded do not differ greatly in conductivity, a satisfactory heat balance can be obtained by using an electrode of smaller face diameter, or an electrode fitted with a facing of higher resistivity (such as an RWMA group B electrode material), on the more conductive member of the joint. To compensate for a greater difference in conductivity between the two work metals, both techniques can be used simultaneously.

In a variation of the second technique described above (facing an electrode with a higher-resistivity material) the more conductive workpiece can be provided with a thin layer of a less conductive metal on its surface, either by a coating method such as electroplating, or by inserting a layer of poorly conducting foil between the workpiece and the electrode.

Another technique, which can be used alone or in combination with one or more of the methods just described, is to increase the thickness of the more conductive member of the joint.

Spot Welding vs Alternative Processes

For some applications, resistance spot welding is the only economical method for joining given workpieces. This was true for attaching brake flaps to a canister in Example 371, and for welding a large tractor fender in Example 372.

Under certain conditions, spot welding can replace riveting or bolting, or other welding methods. Because spot welding is a fast, efficient, low-cost joining method, it is sometimes used in the manufacture of highly competitive products such as disposable containers.

In the following example, to minimize cost, spot welding was used instead of gas metal-arc welding for joining attachments to a mass-produced disposable refrigerant container.

Example 380. Use of Spot Welding Instead of Gas Metal-Arc Welding To Minimize Cost (Fig. 22)

The two 0.045-in.-thick low-carbon steel shells shown in Fig. 22 were joined by means of an arc girth weld to form a disposable spherical refrigerant container with a capacity of 0.4 cu ft. This mass-produced container had to be both inexpensive and easy to handle, and because of the spherical shape, which was necessary for strength and structural stability, needed both a collar (to serve as a handle) and a stand.

On containers produced by other manufacturers, the stands either were three or four small bulges drawn into the bottom of the lower tank half or were foot rings attached by gas metal-arc welding; the collar was attached to the upper tank half by gas metal-arc welding or mechanically.

In considering spot welding as an alternative process for attaching the foot ring and collar, it was concluded that spot welding would provide savings in labor and supplies, and would result in a product equivalent to that joined by arc welding.

The 0.060-in.-thick collar and the 0.048-in.-thick foot ring were spot welded to the two tank halves, each of which had an inside spherical radius of 5³⁵⁄₆₄ in., before the tank halves were joined by girth welding. The electrodes were contoured so as not to damage the surface of the work. The upper (outer) electrode had an RWMA type E (truncated) face with a ¼-in.-diam flat; the lower (inner) electrode had a type F (radius) face with a 4-in. spherical radius. Both electrodes were of RWMA class 2 material, had RWMA No. 5 taper shanks and ⅝-in. body diameters, and were 3 in. long.

With these electrode contours, and the welding conditions shown in the table with Fig. 22, there was no expulsion of metal from the weld nugget, only slight denting of the outer tank-half surfaces, and no denting of the inner surfaces. Typical weld nuggets for the collar and the foot ring are shown in Fig. 22.

Two fixtures (not shown in Fig. 22) were used to position the collar and foot ring. The first of these was a ring to locate the collar with reference to a threaded spud (not shown in Fig. 22) that allowed access to the inside of the container. The second was a basket fixture that positioned the foot ring with reference to the equator of the container.

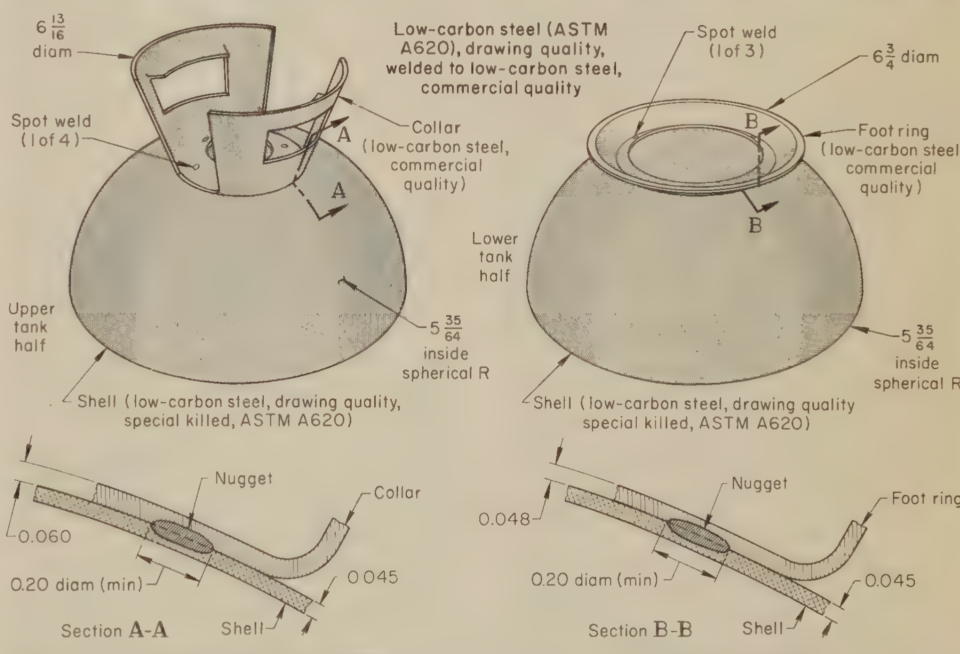
Production of the container was completed in the following steps:

1. The collar, foot ring, and tank halves were formed and vapor degreased.
2. The threaded spud was gas metal-arc welded to the upper tank half.
3. With the ring fixture located by the spud, the collar was positioned on the upper tank half and attached with four spot welds made one at a time, with the work manually located on the lower electrode.
4. The foot ring and lower tank half were placed in the basket fixture and were joined by three spot welds made one at a time, with the work manually located on the lower electrode.
5. The tank halves were then joined by girth welding by the gas metal-arc process. (See Example 81 in the article on Gas Metal-Arc Welding.)

All spot welds were visually inspected for weld soundness, and during each shift one production sample was destructively tested by twisting the collar from the upper tank half. These tests were made either by the operator or by quality-control personnel. The requirement for a satisfactory test was that the nuggets of all four spot welds be pulled away with the handle. The foot ring served only as a support and was not subject to large tensile loads, and the three welds attaching it to the lower tank half were evaluated by visual inspection only.

When spot welding was used to attach the collar and the foot ring, one operator could prepare enough completed upper and lower tank halves to supply a second operator running two girth-welding lathes. Containers produced in this way were neater in appearance than those for which the attachments were joined to the tank halves by arc welding.

Because the arc welded joints and spot welded joints were made by different manufacturers, no direct cost comparisons could be made. However, it was estimated that

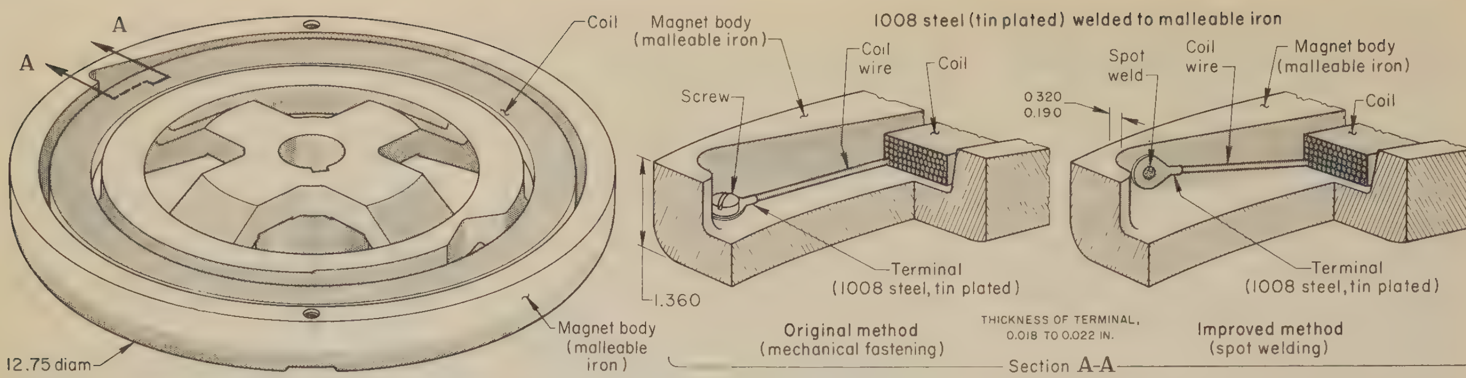


Equipment Details	
Welding machine	Rocker arm, air operated(a)
Rating at 50% duty cycle	50 kva
Rating of secondary circuit	14,200 amp
Transformer taps	Eight
Upper electrode(b)	Type E (truncated), ¼-in.-diam flat
Lower electrode(b)	Type F, 4-in. spherical radius
Electrode force, max	740 lb(c)
Controls	Nonsynchronous (NEMA N2H)

Welding Conditions	
Welding current	10,000 amp
Transformer tap setting	No. 4
Electrode force	500 lb
Squeeze time	10 cycles
Weld time	11 to 14 cycles, single impulse
Hold time	10 cycles
Off time	To suit operator
Production rate:	
Containers per hour	125 to 175
Welds per hour	875 to 1225

(a) Throat, 8 by 30 in. (b) Electrodes were removed from machine for dressing as needed. Both had RWMA No. 5 taper shanks and ⅝-in. body diameters, were made of RWMA class 2 material, and were 3 in. long. (c) Maximum electrode force at an air pressure of 80 psi.

Fig. 22. Components of a mass-produced disposable pressurized refrigerant container for which, to minimize cost, spot welding was used in preference to gas metal-arc welding for attaching a formed collar (handle) and a formed foot ring to the two tank halves, before joining halves by gas metal-arc welding as described in Example 81 on page 92 (Example 380)



Details of Equipment for Improved Method

Power supply	230-v, single-phase, 60-cycle ac
Welding machine	Portable push-type gun, mechanically operated
Rating at 50% duty cycle	15 kva
Rating of secondary circuit	8200 amp, 2 v
Electrodes	Type A (pointed), ⅛-in.-diam flat, No. 4 taper, RWMA class 2
Electrode force, max	1000 lb
Controls	Solid-state synchronous with voltage regulator

Operation	Original method	Improved method
Processing Times, Hours per 100 Magnets		
Drill and tap	3.320	0
Assemble and screw	2.050	0
Position terminal to side of housing	0	0.084
Position gun and weld	0	0.419
Release and return gun	0	0.032
Total standard hours	5.370	0.535
Time per magnet	3.22 min	19.26 sec(a)

(a) Includes 0.75 sec squeeze time, 0.50 sec weld time, and 0.50 sec hold time.

Fig. 23. Electromagnet for which tin-plated steel ground terminal of coil was spot welded to malleable iron magnet body, or housing, in 10% of the time needed for original method, mechanical fastening with a screw (Example 381)

labor expenditure was much lower for the spot welds than for the arc welds used to attach the handle and foot ring, and that the cost of supplies for arc welding (electrode wire and protective gases) was much greater than the cost of electrodes and electrode dressing for spot welding. Since the disposable containers were made in large quantities, amortization charges on the welding equipment were only a small fraction of the unit welding cost, and thus had little effect on process selection.

Spot Welding vs Bolting. Resistance spot welding frequently can be used for attaching items that need not be replaceable. It is the welding process most frequently used in place of mechanical fastening with screws or bolts for attaching electrical connectors when a permanent connection is desired. Bolting requires drilling, and sometimes tapping, of a hole, but a spot weld usually is completed in a fraction of a second.

In the following example, assembly time was greatly reduced when mechanical fastening with a screw was replaced by spot welding to make a permanent electrical connection.

Example 381. Change From Mechanical Fastening to Spot Welding To Reduce Time (Fig. 23)

Originally, the tin-plated 1008 steel ground terminal of an electromagnet coil was joined to the malleable iron body, or housing, of the magnet by mechanical fastening with a screw (see "Original method" view in section A-A in Fig. 23). This required drilling and tapping a hole, assembling the terminal to a screw, and turning the screw into the tapped hole.

The location of the ground terminal in the magnet body was not critical, and the terminal was repositioned for attachment by spot welding, as shown in the "Improved method" view in section A-A in Fig. 23. The only preparation needed for the new method was setting up the spot welding machine — a push-type portable gun, which was hung vertically above the magnet so that it could be pulled down quickly to complete the weld.

Equipment details and welding conditions are given in the table that accompanies Fig. 23, along with a comparison of the time needed for attaching the terminal to the housing by screwing and by spot welding. As shown in the table, the change to spot welding reduced the assembly time per magnet by 90%. Cost of the new equipment needed for spot welding was $550.

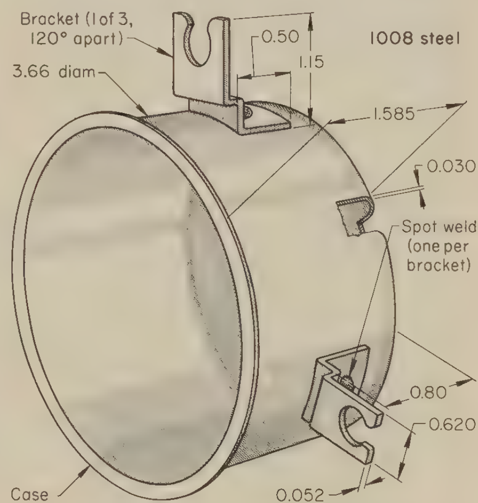


Fig. 24. Clock case for which method of attaching three brackets was changed from riveting to spot welding (Example 382)

Spot Welding vs Riveting. Spot welding can be done rapidly and is competitive with, and sometimes superior to, bolting or riveting as a method of attaching fittings to small housings such as those used in household and automotive electrical equipment.

In the following example, spot welding was found to cost less, and to provide stronger and more accurate fastening, than was possible with the former riveting method for joining brackets to a clock case.

Example 382. Change From Riveting to Spot Welding for Attaching Mounting Brackets (Fig. 24)

Figure 24 shows a clock case with three brackets that were used for mounting the clock to an external panel or a decorative housing. Originally, the brackets had been joined to the case by riveting, but spot welding provided stronger and more accurate fastening, at less cost.

The clock case was made of 0.030-in.-thick drawing quality 1008 steel; the brackets, of 0.052-in.-thick 1008 steel.

After the case was drawn and the brackets were formed, the components were degreased in solvent. Then the brackets, one at a time, were manually positioned on the clock case and were spot welded. The resistance spot welding machine had a 20-kva rating at 50% duty cycle. The maximum rating of the secondary circuit of the machine was 21,000 amp at 3.2 volts.

The welded assemblies were inspected visually, and sample assemblies were tested to destruction in pull tests. A test was considered satisfactory if a slug of metal was pulled from one of the two components when they were separated.

Table 8. Examples of Resistance Spot Welding That Are Presented Elsewhere in This Volume

Example	Description
388	Spot vs projection welding for joining low-carbon steel brackets to panels
400	Spot vs projection welding of type 430 stainless to galvanized steel
401	Spot vs projection welding a galvanized steel handle to a can cover
405	Spot vs projection welding for joining galvanized or low-carbon steel plate to a doorjamb made of the same metal
409	PH 15-7 Mo stainless steel upper and lower face sheets welded to a corrugated core
419	Aluminum alloy 6061-T4 sheet welded to 6061-T6 extrusions, in press-type and portable machines
...	Aluminum alloy 3003 flange 0.102 in. thick welded to a 0.125-in.-thick pan by multiple-impulse welding
...	Aluminum alloy 2024-T3 sheet and rolled sections roll spot welded using dual electrode force
420	Copper alloy 110 (braided wire) spot welded to alloy 184 vs induction brazing for clean, distortion-free parts
421	Copper alloy 110 plastic-coated wire joined to pins using an auxiliary ac heating circuit to melt the plastic
422	Copper alloy 110 stranded wire spot welded to a coin silver (90 Ag – 10 Cu) ring instead of being soldered
423	Effect of composition of gold plating on nickel strip on weldability to copper terminal clad with BCuP-5
424	Copper alloy 172 to alloy 260; size and location of spot weld were critical for performance and life of switch.

Resistance Seam Welding

*By the ASM Committee on Resistance Welding of Steel**

RESISTANCE SEAM WELDING is a process in which heat caused by resistance to the flow of electric current in the work metal is combined with pressure to produce a welded seam (which normally is gastight or liquid-tight) consisting of a series of overlapping spot welds. Two rotating, circular electrodes (electrode wheels), or one circular and one bar-type electrode, are used for transmitting the current to the work metal. When two electrode wheels are used, one or both wheels are driven, to move the workpiece, by means of a gear-driven shaft or by a knurl or friction drive that contacts the periphery of the electrode wheel.

The series of spot welds is made without retracting the electrode wheels or releasing the electrode force between spots, although the electrode wheels may advance either continuously or intermittently. The magnitude of the current, the duration of current flow, the electrode force, and the speed of workpiece or electrode travel are all related, and must be properly chosen and controlled to produce a satisfactory resistance seam welded joint. The principles described on page 401 for resistance spot welding are applicable also to resistance seam welding.

Applications. Resistance seam welding can be applied to a variety of workpiece shapes. Girth welds can be made in round, square or rectangular parts by using two electrode wheels of suitable diameter.

Longitudinal welds can be made by using two electrode wheels, or by using one wheel and a mandrel (stationary bar) over which the wheel travels. When two electrode wheels are used, they can be mounted either on parallel shafts or, if necessary for workpiece clearance, on shafts at an angle to each other.

Most resistance seam welds are lap seam welds. However, by special techniques (discussed in the sections on butt seam welds and foil butt seam welds, on page 433), butt seam welds can be made by resistance heating the two abutting edges and lightly forging them together, or by placing foil strip on one or both surfaces adjacent to the joint before applying heat and force with the electrodes.

Advantages of resistance seam welding, as compared with resistance spot and projection welding, are:

1 Gastight or liquid-tight joints can be produced.
2 Overlap can be less than for resistance spot welds or projection welds, and seam width can be less than the diameter of spot or projection welds.

Limitations of resistance seam welding, apart from those it shares with spot and projection welding (see the articles on pages 401 and 434), are:

1 The weld ordinarily must proceed in a straight or uniformly curved line.
2 Obstructions along the path of the electrode wheel must be avoided or be compensated for in the design of the wheel.
3 Sharp corner radii or abrupt changes in contour along the path of the electrode wheel must be avoided.
4 Length of joints made in a longitudinal seam welding machine is limited by the throat depth of the machine.
5 Fatigue life of resistance seam welds is usually less than that for welds made by other seam welding methods.
6 Stock thicknesses greater than ⅛ in. are more difficult to weld than by spot or projection welding.

Metals Welded. Low-carbon, high-carbon, low-alloy, stainless, and many coated steels can be resistance seam welded satisfactorily. Aluminum, aluminum alloys, nickel, nickel alloys and magnesium alloys can be seam welded, but seam welding is not recommended for copper and high-copper alloys. Compatible combinations of dissimilar metals and alloys also can be seam welded.

For information on the seam welding of stainless steel, aluminum alloys, and copper alloys, see the articles that begin on pages 456, 466 and 475.

Preweld Cleaning. Resistance seam welding of surfaces contaminated with grease, paint, scale or rust results in nonuniform welds, porosity in the weld nugget, and excessive burning and marking of workpiece surfaces in the region of contact with the electrodes. It can also cause rapid deterioration of the electrode-wheel contact surfaces. Methods suitable for cleaning the surfaces of ferrous and nonferrous metals prior to welding are described in Volume 2 of this Handbook. See also the section on Effect of Workpiece Surface Condition on Heating, page 415 in the article on Resistance Spot Welding in the present volume.

Seam Welding Machines

A seam welding machine is similar in construction to a spot welding machine, except that one or two electrode wheels are substituted for the spot welding electrodes. Generally, seam welding is done in a press-type resistance welding machine with a means of driving the electrode wheels, or of moving the workpiece between the electrodes, and with a direct-acting air or hydraulic cylinder for supplying the required electrode force.

Most seam welding machines are powered by alternating current; some are designed for use with three-phase supplies, but a majority operate on single-phase alternating current. Stored-energy seam welding machines have been built, but this type finds little use.

Equipment needed for seam welding consists essentially of: (*a*) a power supply capable of delivering low-voltage, high-amperage current; (*b*) a means of supporting the electrodes and the workpiece, and of applying the electrode force; (*c*) a means of moving the workpiece or of driving the electrodes; and (*d*) controls for regulating, timing and sequencing the application of the welding current and force and the rate of movement of the work between the electrodes.

Power supplies used for resistance seam welding are similar to those used for resistance spot welding, and consist of a welding transformer (usually with a tap switch in the primary circuit) and a secondary circuit with electrodes for transferring the welding current to the work metal.

Electrode Force and Support. The upper electrode wheel is mounted to, and insulated from, the operating head. The head, which is actuated by a direct-acting air or hydraulic cylinder, applies the electrode force.

The lower electrode is either a wheel, a platen or a mandrel, and is mounted on a supporting arm, table or knee. The supporting element can be adjustable for applications in which the work metal must be maintained at a constant level above the floor.

Electrode or Workpiece Drives. Workpieces can be moved by rotating the electrodes with knurl or friction drive, with gear drive, or by clamping the workpieces to a bar electrode and moving the bar electrode.

In knurl or friction drive, one or both of the electrodes are rotated by a knurl or friction wheel on the periphery of the electrode wheel. With this type of drive, a constant linear speed is maintained, regardless of the diameter of the electrode wheel, and the electrode wheel is continuously trimmed by the drive wheel, and thus is prevented from mushrooming. Knurl drive, in which ridges or beads on the circumference of the roll-shape steel drive wheel aid in gripping the electrode, minimizes slippage and is more positive than friction drive, in which the gripping edge of the drive wheel is smooth. Knurl drive is used for welding scaly stock and coated metals such as galvanized steel and terneplate, or in any application where the electrodes are likely to pick up material from the work metal; the knurled wheel removes much of the pickup from the electrode wheels. Knurl or friction drive can be used only with electrode wheels that have a diameter large enough to allow clearance between the drive wheel and the workpiece. Knurl drive usually is not employed where the highest weld quality and appearance are required.

*For committee list, see page 401. Some of the examples presented in this article were contributed by members of other Metals Handbook welding committees. Eight examples of resistance seam welding appear in other articles in this volume (see Table 4, page 434).

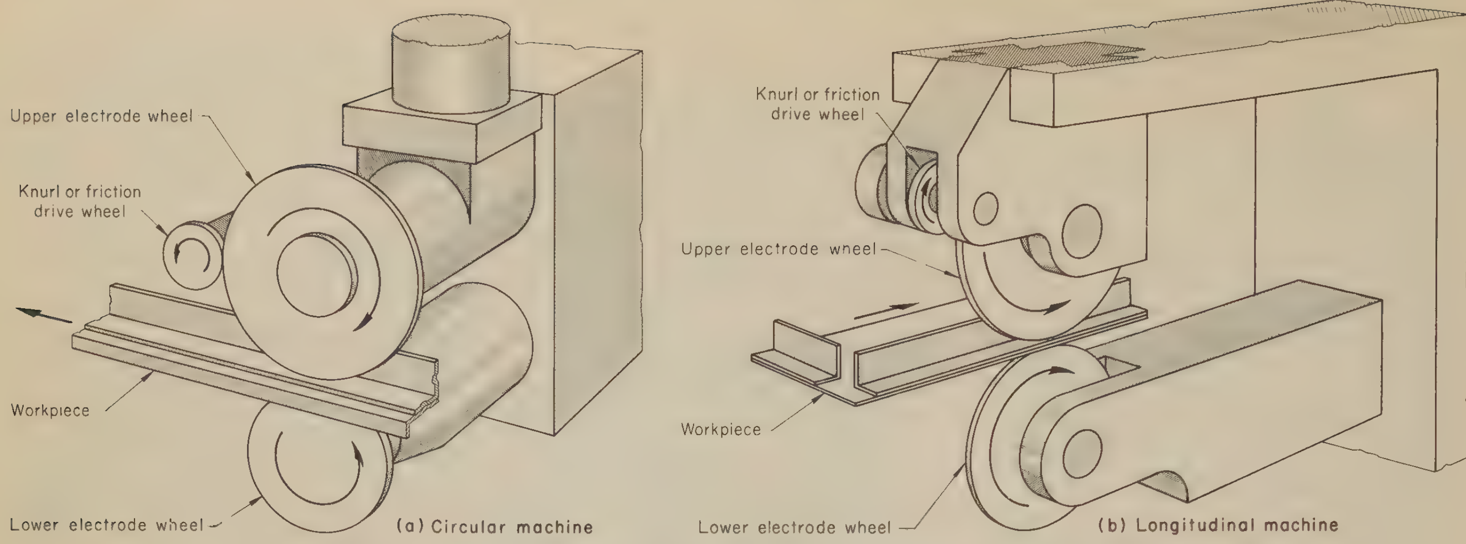

Fig. 1. Position of electrode wheels on circular and longitudinal resistance seam welding machines

Gear drive is used with small-diameter electrode wheels that cannot be driven by the use of knurled or friction wheels because of interference with workpiece clearance, or where the application cannot tolerate an electrode wheel that has been roughened by a knurled drive roll. With gear drive, in which the mounting shaft of the electrode wheel is rotated, there is no minimum limitation on electrode-wheel diameter. Normally, because of problems in synchronizing the speed of the two electrode wheels, only the lower wheel is driven. In a standard seam welding machine, there is a minimum distance between electrode-wheel centers, and if one wheel must be small to clear the workpiece, the other must be correspondingly large. If the ratio of the electrode-wheel diameters is greater than 2 to 1, the smaller wheel should be driven, to minimize slippage. As the diameter of the driven electrode wheel is gradually reduced by wear and by re-dressing, welding speed is decreased, reducing output and sometimes making it necessary to change the heat-control setting. Welding speed can be kept constant in spite of wheel wear by a variable-speed gear-drive mechanism.

When a mandrel or a platen is used as the lower electrode, the operating head carrying the upper electrode may be mounted in a carriage. The carriage is moved by an air or hydraulic cylinder, or by a motor-driven screw, and thus the upper electrode is passed over both the workpiece and the lower electrode. The upper electrode is free-wheeling, but it may be equipped with an idling knurl for dressing. In some machines, the workpiece is clamped to a bar-type lower electrode and moved under an idling fixed-position upper electrode wheel.

Controls for resistance seam welding are generally similar to those for resistance spot welding, except for those differences related to the relative motion of the work and the electrodes.

Because of the brevity of the heating and cooling (current on and off) cycles, a synchronous timing control connected to the primary circuit of the transformer is necessary for consistently accurate timing, unless the welding speed is such that the frequency of the welding current acts itself as an interrupter. A phase-shift heat control is also used, as well as tap switches for changing the transformer output.

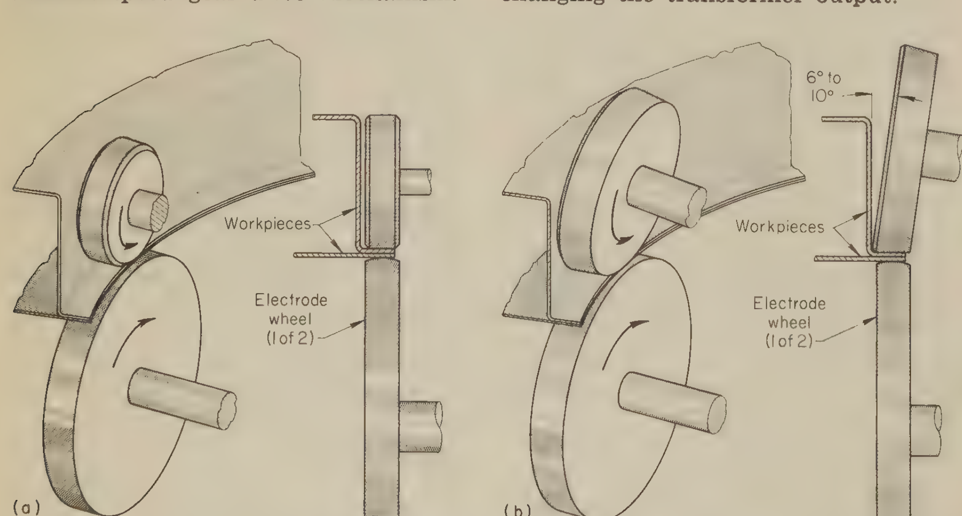

Fig. 2. Use of a small-diameter upper electrode wheel (a) *or of a canted larger-diameter upper electrode wheel* (b) *to avoid interference with a sidewall in welding a narrow flange along an inside radius*

Types of Machines. There are four basic types of resistance seam welding machines:

1. **Circular,** in which the faces of the electrode wheels are at right angles to the throat of the machine (see Fig. 1a). This type is used for circular work, such as welding the heads on containers, and for flat work requiring long seams.
2. **Longitudinal,** in which the faces of the electrode wheels are parallel to the throat of the machine (see Fig. 1b), and throat depth is typically 12 to 36 in. This type is used for welding short longitudinal seams in containers, for attaching pieces to containers, and for similar work. Machines with traveling heads or traveling electrodes, in which a mandrel or a platen is used for the lower electrode, are normally of the longitudinal type.
3. **Universal,** in which a swivel-type head and interchangeable lower arms allow the faces of the electrode wheels to be set either parallel or perpendicular to the throat of the machine.
4. **Portable,** in which the work is clamped in a fixture and a portable welding head is moved over the seam. This type of machine is used for workpieces that are too bulky to be handled by regular machines, and for applications where it is more efficient to move a portable welding head to the work than to move the work to the welding head on a regular machine. The portable welding head is moved by motor-driven wheels, and an air-cylinder mechanism provides the electrode force.

Because the arms of circular, longitudinal and universal seam welding machines are part of the secondary electrical circuit, the reactance of the secondary circuit and the welding current both are affected by the amount of magnetic material that passes between the arms, or through the throat, of the welding machine, unless automatic current regulators are included in the control circuit. The usable throat depth governs the size of workpiece that can be welded in a particular machine.

Electrodes

Electrode wheels made of RWMA class 1 material have been used for seam welding aluminum and magnesium alloys, galvanized steel, and tin-

plated steel. With adequate cooling, the high electrical and thermal conductivities of this material keep the electrode temperature below the point at which work metals such as aluminum readily alloy with copper from the electrode and cause electrode sticking or pickup.

High-production seam welding of low-carbon and low-alloy steels is usually done with electrodes made of class 2 or class 3 material. Class 3 materials have higher mechanical properties and lower electrical conductivity than do class 2 materials, and are used in applications where electrode pressure and workpiece resistance are high. In such applications, the resistance of the electrode wheel to deformation is more important than its electrical conductivity. (See Table 2 and page 409 in the article on Resistance Spot Welding for a description of the properties and use of RWMA electrode materials.)

Size of Electrodes. Electrode wheels range in diameter from 2 to 24 in. Table 1 shows the diameters and body widths of electrodes most often used, in relation to the size of the welding machine. Narrower wheels are used in machines with knurl or friction drive; wider wheels, in gear-drive and idler machines.

A small-diameter electrode wheel (Fig. 2a), or a large-diameter wheel mounted on a canted axis (Fig. 2b), can be used to avoid interference with a sidewall when a narrow flange is being welded on an inside radius or on a re-entrant curve. In both applications, the diameter of the opposing wheel must be adjusted in accordance with the spacing of the mounting shafts. Canting of electrode wheels usually is limited to 6° to 10°, to minimize the effect of this type of loading on the machine components. Larger angles can be used if the machine is suitably designed.

When the sides and ends of square or rectangular containers are being joined, welding of corners requires electrode wheels of different diameters. An electrode wheel with a radius smaller than the corner radius of the workpiece is used to contact the inside of the flange joint at the corners. Length of periphery in contact with the work metal at any instant is shorter for the outer wheel than for the inner wheel. The inner wheel is the driving wheel, and for this reason, as well as because of its shorter circumference, it has a shorter life than the outer wheel.

Beads, ribs and other extensions on the surfaces to be seam welded can be passed over by cutting notches in the electrode wheels, as shown in Fig. 3.

When thick work metal is being welded, the higher current and force requirements necessitate increasing the electrode face width (as shown in Table 3), to avoid excessive pressure and current density. Typical electrode face widths range from 3/16 to 1/2 in. for the wheel body widths listed in Tables 1 and 3. The width of a resistance seam weld is usually about 80% of the width of the electrode face.

Basic Face Contours. The four basic electrode-face contours in common use — straight flat, single-bevel flat, double-bevel flat, and radius — are shown in Fig. 4. Flat-face electrodes, although more difficult to set up, control and maintain than radius-face electrodes, may be necessary for welding certain workpieces. Electrode wheels must be of sufficient width (*W* in Fig. 4) to provide stability, but can be single or double beveled to provide a narrower contact surface (*w* in Fig. 4), and to minimize mushrooming of the wheel face. Radius-face electrodes, or one radius-face electrode used with one flat-face electrode, give good weld appearance, and aid in guiding the travel of the workpiece.

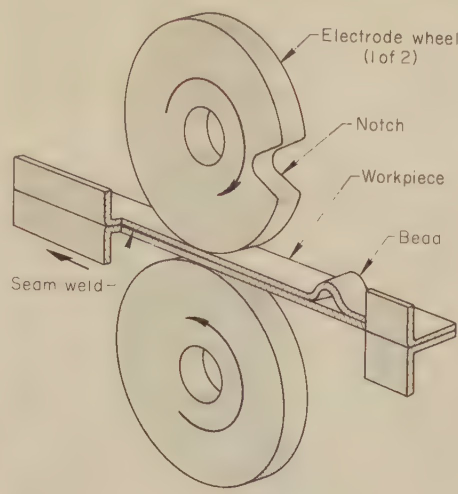

Fig. 3. Use of a notched electrode wheel for seam welding of a workpiece having beads (or other obstructions) in the path of the wheel (see also Fig. 11)

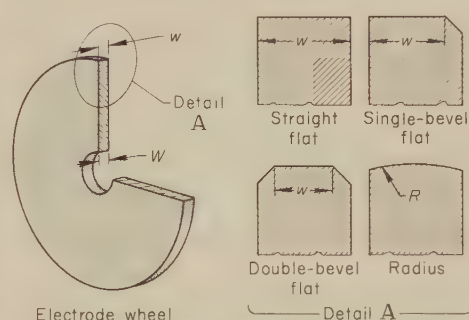

Fig. 4. Four basic types of faces on electrode wheels used for seam welding. (W is wheel width and w is the width of contact surface on flat or beveled wheels.)

Table 1. Common Sizes of Electrode Wheels Used for Resistance Seam Welding

Machine size	Wheel diameter, in.	Wheel width, in.(a)
Small	7	3/8
Medium	8	3/8 to 1/2
Large	10 to 12	3/8 to 3/4

(a) Data are for body width; see Fig. 4 and footnote (c) in Table 3.

Cup-shape electrodes, mounted on a canted axis (see Fig. 5), are used for upper electrodes in applications requiring small-diameter ring-type seam welds. The axis gyrates in a cone-shape path, bringing succeeding areas of the face of the moving electrode into contact with the work. The angle at which the axis is canted and the diameter of the cup-shape electrode determine the diameter of the seam weld that can be obtained. With this arrangement, the work is engaged by the axial face, and not by the periphery, of the electrode. The design of the lower electrode depends on the workpiece; Fig. 5 shows an annular lower electrode used, with a cup-shape upper electrode, for welding a flanged workpiece.

A disadvantage of a gyrating cup-shape electrode is that it may skid and cause distortion of the work metal, especially when welding thin material.

Bar electrodes, which are made of the same materials as electrode wheels, are used as lower electrodes in conjunction with upper electrode wheels.

The size and shape of a bar electrode depend on the size, shape and arrange-

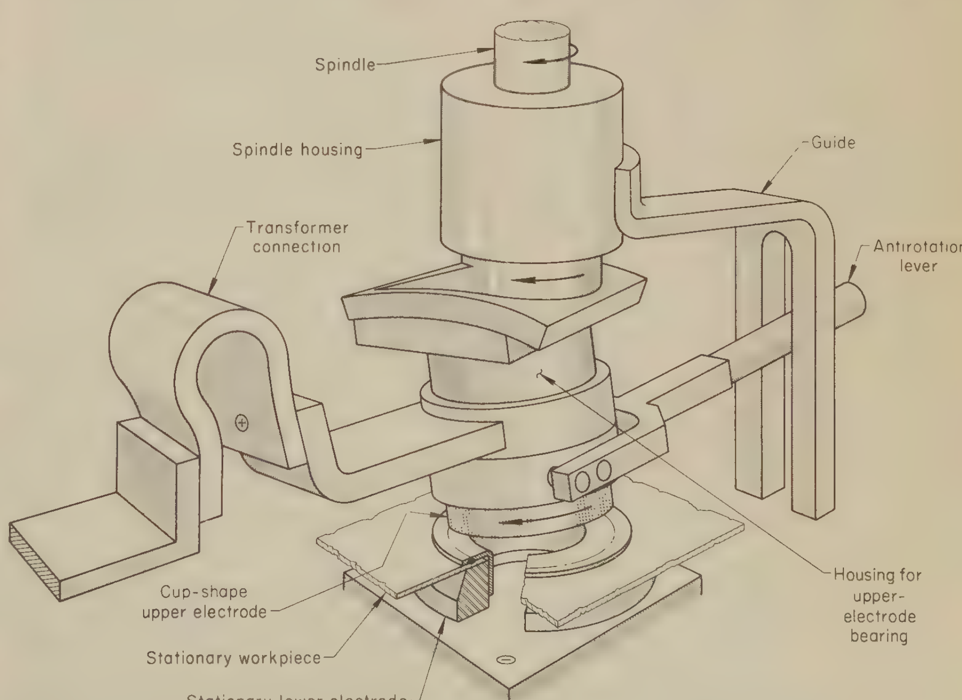

Fig. 5. Use of a free-rotating cup-shape upper electrode mounted on a canted axis for making a flat circular seam weld

ment of the work. In Example 387, the lower electrode was a conforming bar mounted in a mandrel that provided internal support for a hollow workpiece.

Cooling of electrodes and work during welding is mandatory. It is usually done by flooding or by directing jets of water on the electrodes and the work. (In welding low-carbon steel, a 5% borax solution is sometimes used to minimize rusting.) In applications where such cooling techniques have adverse effects on workpieces, mounting shafts can be cooled, and internally cooled electrodes can be designed. Inadequate cooling results in overheating of the work metal and shortening of the life of the electrodes.

Maintenance of wheel contour within established limits is essential to the control of current density, electrode pressure, and consistency of weld quality. Only light cleaning of the electrode face should be done while the electrode is in the machine. Dressing the electrode wheel in a lathe after a predetermined number of welds or feet of weld seam have been made maintains a uniform contour, saves electrode material and reduces the number of rejected workpieces.

Knurl drive provided continuous electrode-wheel dressing in Example 385, which describes the semiautomatic resistance seam welding of a sump to a washer tub. Automatic wheel dressers have been used in large high-production machines, such as those used in seam welding of roof decking. The use of knurl or friction drive or of automatic wheel dressers does not necessarily ensure removal of pickup; the electrode wheels should be periodically inspected to determine the need for supplementary, off-machine dressing.

Methods of Welding

In resistance seam welding, a series of overlapping spot welds is made by either continuous or intermittent motion of the electrode wheel or wheels and the work, and by suitable application of welding current. The type of motion used depends on work-metal thickness, welding speed and weld spacing.

Continuous motion is used for joining workpieces less than about 3/16 in. thick. Optimum electrode-wheel speed depends on wheel diameter, cooling methods that are available or permissible, and the thickness and surface condition of the work metal. For a given cycle of heat and cool time, the peripheral speed of the electrode wheel determines the number of welds per inch, and therefore the tightness of the joint. Table 2 lists the number of spot welds per inch needed to produce a gastight seam in various thicknesses of low-carbon steel. The application of the welding current can be either continuous or interrupted (see the section on Effect of Welding Current).

Table 2. Approximate Number of Spot Welds per Inch Needed To Produce a Gastight Seam in Low-Carbon Steel

Thickness of one sheet, in.	Number of spot welds per inch	Thickness of one sheet, in.	Number of spot welds per inch
0.010	18 to 24	0.051	12 to 14
0.016	16 to 20	0.064	11 to 13
0.020	15 to 18	0.081	10 to 12
0.025	14 to 16	0.102	9 to 11
0.032	12 to 14	0.125	8 to 10

Intermittent motion is used for joining metals more than 3/16 in. thick, or where postheating or forging cycles are used. The electrode wheels are stopped as each spot weld is made, and then are automatically rotated to move the work the proper distance for the next weld. A synchronous precision electronic timer or a solid-state nonsynchronous timer is recommended for controlling the electrode motion and the application of current. Mechanical timers are slow, nonsynchronous, and otherwise inaccurate, and are not recommended.

Control of Welding Conditions

Welding current, electrode force, heat time, cool time and welding speed all directly affect weld quality, and must be carefully controlled. A compromise among variables is often necessary in defining welding schedules. The amount of heat generated can be controlled either directly by increasing or decreasing the welding current, or indirectly by increasing or decreasing the electrode force, which affects the contact resistance.

As in resistance spot welding, the main factors that influence the selection of welding current and electrode force are: (*a*) the required nugget size, which is related to weld strength; (*b*) the probability of porosity; and (*c*) the desired surface condition of the finished weld. The factors that influence the selection of heat time, cool time and welding speed are: (*a*) the ability of the operator, or of the material-handling equipment, to handle the workpiece during welding; (*b*) the nugget size; (*c*) the extent to which weld nuggets must overlap to ensure pressure-tight joints; and (*d*) the probability of electrode pickup.

Recommended practices for resistance seam welding of low-carbon steel are given in Table 3. The values listed are starting conditions and should be adjusted to suit the application.

Table 3. Recommended Practices for Seam Welding of Low-Carbon Steel(a)

Thickness (t) of thinnest outside piece, in.(b)	Electrode dimensions, in.(c): Wheel width, W	Electrode dimensions, in.(c): Face width, w	Net electrode force, lb	Heat time, cycles (60 Hz)	Cool time (pressure tight), cycles (60 Hz)	Welding speed, in. per min	Welds per in. SOURCE: "Recommended Practices for Resistance Welding", AWS C1.1; also "Welding Handbook", 6th Ed., Section 2, American Welding Society, 1969. Published here by permission.

(a) Data are for 1010 steel; material should be free of scale, oxides, paint, grease and oil. Welding conditions are determined by thickness of thinnest outside piece. (b) Data for total thickness of pile-up not exceeding 4t. Maximum ratio between thicknesses, 3 to 1. (c) For RWMA class 2 electrode material (minimum conductivity, 75% IACS; maximum hardness, Rockwell B 75). Wheel width is over-all width of a flat-face wheel or of a wheel with a 3-in.-radius face; face width is that of the contacting surface of flat-face wheels (see Fig. 4). (d) For large assemblies, minimum contacting overlap indicated should be increased 30%.

Setting up Welding Schedules. The sequence of steps followed in setting up a resistance seam welding schedule may vary, depending on special aspects of the equipment or the work, the extent of experience with similar types of work, and requirements imposed by the purchaser or applicable specifications. A typical sequence of steps for determining the most satisfactory conditions for resistance seam welding for which previous experience is lacking is as follows:

1. **Make a preliminary selection of welding speed and electrode force** that represent practical working values and are not near the upper or lower limits of the welding-machine capability. The recommended practices that are shown in Table 3 may provide starting points for this selection, as well as guidance in choosing preliminary values of heat and cool times and welding current for making trial welds.
2. **Establish criteria for satisfactory welds,** based on the requirements of the specific application. Generally, the weld nugget should have no porosity, nugget overlap should be about 15 to 20% of nugget length to yield leaktight seams, and nugget penetration should average 45 to 50% of the thickness of the thinnest sheet but be within the limits of 30 to 70%.
3. **Select Heat and Cool Time.** This is done by evaluating test welds made at several welding currents for each of a number of combinations of heat and cool times. Welding speed and electrode force are those provisionally chosen in step 1.
4. **Select Electrode Force.** Using the provisionally chosen welding speed and heat and cool times, make welds at several different currents, using a number of values of electrode force to cover a range of force.
5. **Select Welding Current.** Using the provisionally chosen welding speed, heat and cool times and electrode force, make test welds at various welding currents that cover a wide range of current.
6. **Select Welding Speed.** Using the provisionally chosen other welding conditions, make test welds with welding speeds that cover a wide range. The welding speed selected should yield suitable nugget overlap, penetration with negligible indentation or surface pitting, and no porosity. Also, the speed should be such that the operator can control the travel of the workpieces between the electrodes.
7. **Verify Selection of Conditions.** Make test welds under the provisional welding conditions to verify these selections and to establish reference data on weld quality and reliability for process control. A more complete evaluation than for steps 1 to 6 is done at this stage, and ordinarily involves detailed metallographic examination, as well as the usual measurements on macrosec-

tions of welds. Depending on the application, nondestructive examination may also be done, using radiography and ultrasonic, sonic and eddy-current techniques.

The seven steps described above not only determine optimum values for each of the welding variables, but also establish ranges of satisfactory values for them and the criticality or noncriticality of each.

If the results of the test welds in step 7 are not satisfactory, the seven-step procedure may be repeated, making changes in the welding conditions as indicated by the test results. Changes in welding equipment, electrode material and electrode design may also be made at this time, although these are ordinarily well-determined in advance. If a change in machines or electrodes is necessary, the seven-step procedure (or parts of the procedure) should be repeated until acceptable results are obtained.

When adjustment of welding conditions is needed at the start of or during production runs, the adjustment is usually made on heat time, cool time or welding current, whichever is most convenient and effective. No adjustments outside the acceptable ranges determined in the development of the welding schedule should be made without special qualification by the evaluation of a suitable number of trial welds.

Sufficient cooling water should be used to cool the electrodes and the workpiece; nonuniform cooling results in the production of asymmetrical weld nuggets. The effects of varying amounts of magnetic material (either in the welding fixture or the workpiece) in the throat of the welding machine also must be considered in establishing welding conditions.

Welding of a corner arc is more difficult than welding of straight sections, especially when the corner radius is small; different and more closely controlled operating conditions generally are needed for optimum weld quality, and usually involve decreased welding speed. When the corner radius is large and quality requirements are not unduly critical, machine settings based on welding of the corners may also be satisfactory for the straight sections.

Where the same machine settings will not produce an acceptable seam weld on corners and straight sections, a two-speed control or automatic changing of heat settings can be used. The two-speed system permits taking advantage of the higher welding speed possible on straight sections.

Quality Control. General practice in quality control in resistance seam welding is similar to that described for resistance spot welding, beginning on page 417.

One test method that is not applicable to spot and projection welding but is especially useful in evaluating seam welds is pressure testing to determine if seams are liquid-tight or gastight. A standard method for pressure testing of resistance seam welds is the pillow test. (This test was used in obtaining the data on joint strength plotted in Fig. 10.) For a comprehensive discussion of the pillow test and other standard methods for testing resistance welds, the reader is referred to Section V in AWS C1.1-66, "Recommended Practices for Resistance Welding".

Fig. 7. Effects of welding current and electrode force on nugget penetration in seam welding 0.078-in.-thick 1010 steel

Effect of Welding Current

In resistance seam welding, much as in resistance spot welding, heat is generated by resistance to the flow of electric current (*a*) at the contact interfaces between the electrode wheels and the surfaces of the workpieces; (*b*) in the work metal itself; (*c*) at the interface of the workpieces; and (*d*) in the electrodes.

The points of heat generation and temperature gradients after 20% and 100% of weld time in electrodes, workpieces and nugget during the formation of a spot weld are shown in Fig. 14 on page 413 in the article on Resistance Spot Welding. For a more complete discussion, see the section on Effect of Welding Current on Heating, page 412.

For a given heating-and-cooling cycle and a given welding speed, the magnitude of the current determines the depth to which the weld metal penetrates the base metal and the amount that the individual nuggets overlap. The effects of welding current on nugget penetration and nugget overlap in welding 0.078-in.-thick 1010 steel are shown in Fig. 6. (See also Fig. 7 and 8, which show, respectively, nugget penetration and nugget width obtained at three levels of current.)

In welding low-carbon steel, the average nugget penetration should be within 30 to 70% of the sheet thickness, with 45 to 50% as optimum. For leaktight seams, nugget overlap should be 15 to 20% of nugget length.

Welding-current values in excess of those giving full joint strength increase nugget penetration and nugget overlap, but do not add to joint strength, and are uneconomical. Also, they can cause excessive indentation and, if extreme, burning of the weld. Generally, resistance seam welded joints are sufficiently strong that test samples fail in the heat-affected base metal adjacent to the weld.

Continuous alternating current with partial wave form and interrupted current are both used for resistance seam welding. Continuous current can be used for high-speed operation, or where the wave form can be adjusted to produce the proper nugget size and spacing at the available welding speed. Interrupted current is used for most seam welding operations, and offers the following advantages:

1. Better control of heat
2. Provision of time between each spot weld in the seam for cooling of each nugget under pressure
3. Less distortion of workpieces resulting from overheating of metal adjacent to the weld
4. More-uniform welds with fewer surface defects.

Welding current is selected by trial-and-error in relation to the other operating variables in developing a welding schedule (see list under "Setting up Welding Schedules" on page 428). With shorter heat times, or with faster welding speeds, more current is required and the probability of electrode pickup is greater. Currents higher than those used for spot welding are required for seam welding, because of the continuous shunting of the current through the preceding welds.

Effect of Electrode Force

The amount of heat generated in the weld can be controlled by varying the welding current, or to a lesser degree by varying the electrode force, which affects contact resistance. The selection of the proper electrode force limits the range of welding-current values that will produce satisfactory joints, and with low electrode forces, small variations in welding current have considerable influence on weld quality. Therefore, electrode force should be high enough to permit a wide variation in current values.

Up to a certain point, increasing the electrode force causes a slight increase in nugget penetration and nugget width, but beyond that point nugget penetration decreases while nugget width increases more rapidly. With increased electrode force, the welding current is more concentrated at the center of the weld because of the crowned electrode surfaces, but is distributed over a wider surface because of indentation. Thus, as nugget width increases, nugget penetration decreases.

The effect of the electrode force on nugget penetration in seam welding 0.078-in.-thick 1010 steel using three

different values of welding current is shown in Fig. 7. Heating time was 6 cycles, cooling time 5 cycles and welding speed 55 in. per minute. The effect of the electrode force on nugget width under the same welding conditions is shown in Fig. 8.

Electrode force must be sufficient to provide good electrical contact and thus permit flow of current through the circuit. To avoid low-quality welds in workpieces that do not fit-up properly, sufficient total force must be applied to bring the workpieces into contact and to maintain the force needed for welding. If the applied force is constant, variations in the force needed to bring the workpieces into contact will cause variations in the welding force, thereby affecting weld quality. Excessive electrode force results in severe indentation of the workpieces, rapid mushrooming of the electrodes, and large reduction of contact resistance, which requires an increase in current.

Insufficient electrode force results in improperly forged welds and in excessive contact resistance between the electrodes and the work, causing burning, and therefore short life, of the electrodes. It can also permit the expulsion of molten metal at the interface, thus (like excessive electrode force) resulting in surface indentation at the welded seam.

The pressure at the weld is constantly changing because of the rapidly changing temperature and strength of the metal in the heated area. For best results, the welding machine should be designed with a low-inertia follow-up system, which applies reactive force to the welding head to maintain the proper distance between the electrodes, and to avoid low pressure, high contact resistance, and expulsion of metal from the weld zone.

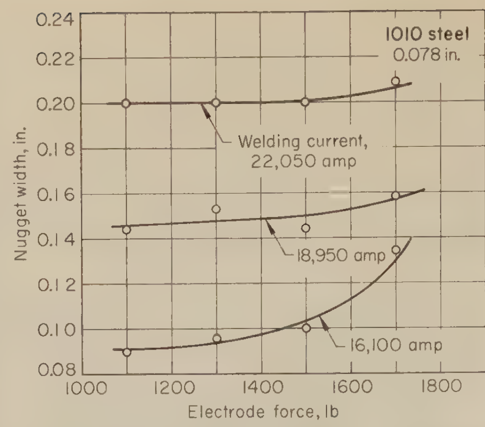
Effect of Heat Time and Cool Time

The nugget size is controlled principally by the heat time, and nugget overlap, by the cool time. For lower welding speeds, the ratio of heat time to cool time should be between 1.25 to 1 and 2 to 1 for best results. As welding speed increases, the spacing of the spot welds increases so that they do not overlap unless the ratio of heat time to cool time is increased: for example, at higher welding speed, a ratio of heat time to cool time of 3 to 1 or higher is needed.

To obtain the largest number of nuggets per inch that will yield leak-tight joints at a given welding speed, the heat time should be adjusted to produce the required nugget properties, and the cool time should be short enough to provide the required nugget overlap. The reductions in nugget penetration and nugget overlap that occur with increasing cool time in resistance seam welding of 0.078-in.-thick 1010 steel are shown in Fig. 9.

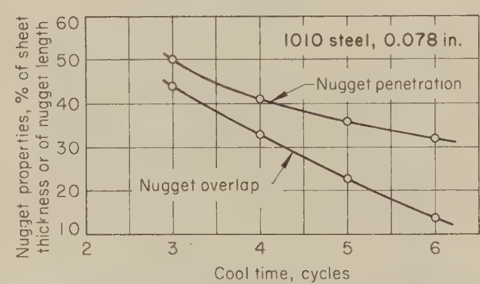
Effect of Welding Speed

The speed at which low-carbon steel can be seam welded depends on the desired weld quality and on the



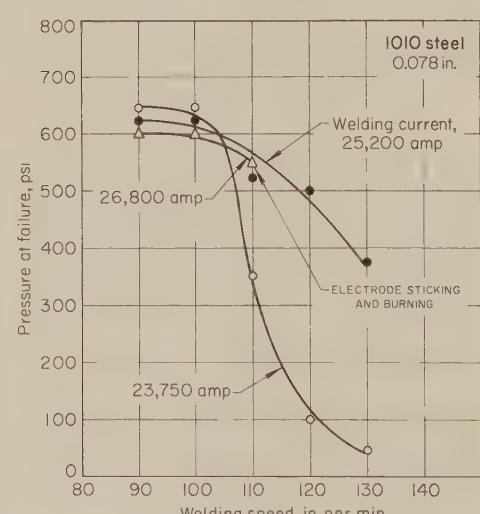
Welding conditions: heat time, 6 cycles; cool time, 5 cycles; welding speed, 55 in. per minute. (Source: Same as Fig. 6)

Fig. 8. Effects of welding current and electrode force on nugget width in seam welding 0.078-in.-thick 1010 steel



Welding conditions: heat time, 6 cycles; electrode force, 1500 lb; welding current, 18,950 amp; and welding speed, 55 in. per minute. (Source: Same as Fig. 6)

Fig. 9. Effects of cool time on nugget penetration and nugget overlap in seam welding 0.078-in.-thick 1010 steel



Welding conditions: heat time, 2 cycles; cool time, 1 cycle; electrode force, 1500 lb. Pillow-type samples were seam welded, at three welding-current values, then were inflated with air until failure occurred. (Source: Same as Fig. 6)

Fig. 10. Effect of welding speed on joint strength in seam welding 0.078-in.-thick 1010 steel at three levels of current

design, thickness and surface condition of the workpieces. The use of excessive welding speed causes a rapid reduction in weld strength, even with higher welding currents. As welding speed is increased, the welding current must be increased in order to develop sufficient heat in the work metal. Increased welding current causes surface burning of the work metal and electrode pickup, and thus, even with flood cooling, welding speed is limited.

The effect of welding speed on joint strength in welding 0.078-in.-thick 1010 steel at three different levels of welding current is shown in Fig. 10. Heat time was 2 cycles, cool time was 1 cycle and electrode force was 1500 lb. The values were obtained in pillow tests (see AWS C1.1-66, Section V) in which pillow-type specimens were seam welded at the three levels of current and then were inflated with air until rupture or leakage occurred.

Effect of Workpiece Design on Electrode Shape

Design of workpieces can affect the shape of the electrode face and the contour of the electrode wheel. A small-width seam can be made in a narrow flange by reducing the thickness of the wheel at the circumference, as in Example 429 in the article on Resistance Welding of Copper Alloys. To weld the dish-shape front of a clothes drier in Example 384 in the present article required the electrode wheel to be set at an angle, which in turn necessitated the face of the electrode to be machined at an angle to the side of the wheel (see Fig. 12). Sheets having stiffeners that cross the path of a seam weld require electrodes with notches, as shown in Fig. 3, if the welds are to be made without lifting the electrode from the sheet. Starting a seam weld close to the flange or sidewall of components that cross the path of a seam weld can be done by using segments of an electrode wheel, as was done in the example that follows.

Example 383. Use of a Segmented Electrode Wheel To Seam Weld Close to the Flange of a Stiffener (Fig. 11)

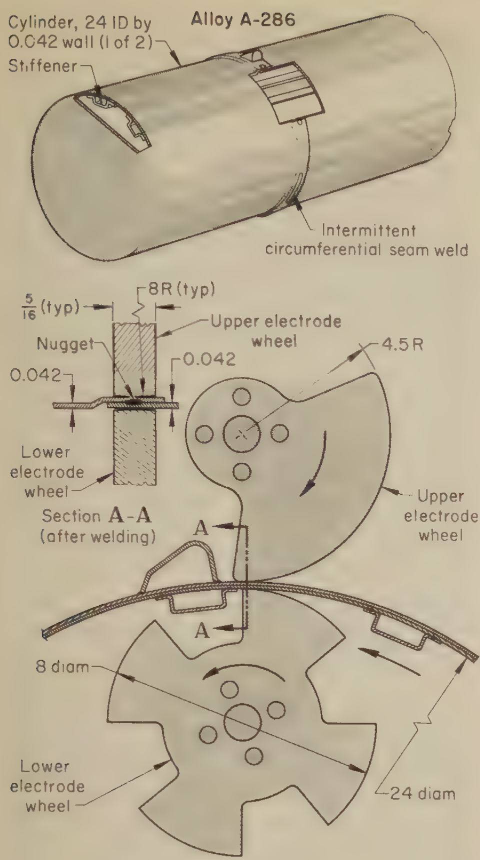
A cylindrical tank was made by resistance seam welding two sections of 0.042-in.-thick A-286 iron-base heat-resisting alloy. Components contained on both the inner and outer surfaces of the tank made it necessary to use segmented upper and lower electrode wheels to produce a leak-proof circumferential seam originating close to the flanges of the components. Both the upper and lower electrode wheels were shaped so that initial contact with the workpieces occurred at the edge of the segments (see Fig. 11).

Electrode motion was intermittent and the welding heat was supplied by three impulses from a three-phase alternating-current welding machine. A dual electrode force, consisting of a weld force and a forge force, was used to produce sound weld nuggets.

Equipment details and resistance seam welding conditions are given in the table that accompanies Fig. 11.

Width of Joint Overlap

The width of overlap at the joint (contacting overlap) must be sufficient to prevent collapse of the work metal at the edge adjacent to the seam. Table 3 lists recommended minimum widths of contacting overlap for resistance seam welding of low-carbon steel ranging in thickness from 0.010 to 0.125 in.



Setup for making intermittent circumferential seam weld

Equipment Details

Power supply	440 v, three phase
Welding machine	Semiautomatic, circular
Rating at 50% duty cycle	125 kva
Heat control	Phase shift
Upper electrode	5/16 in. wide by 9-in. diam; 8-in. face radius; segmented
Lower electrode	5/16 in. wide by 8-in. diam; 8-in. face radius; notched
Electrode material	RWMA class 3

Welding Conditions

Heat-control setting	70%
Heat time	5 cycles
Cool time	0.5 cycle
Heating impulses	3
Electrode force:	
Welding	1500 lb
Forging	2000 lb
Spot spacing	13 per inch
Welding speed	11 ipm

Fig. 11. Setup for resistance seam welding close to the flanges of stiffeners, using segmented electrode wheels (Example 383)

Excessive width of unwelded overlap between parts of seam welded assemblies can result in entrapment of dirt and moisture, which can present problems in subsequent manufacturing operations or in service. By use of the proper electrode force, welding current, heat and cool time, and electrode shape, the width of the weld nugget can be adjusted to minimize unwelded overlap, as in the following example.

Example 384. Automatic Circular Seam Welding in Which Unwelded Overlap Was Minimized To Avoid Moisture Traps (Fig. 12)

A drum for a clothes drier was made by resistance seam welding a 0.024-in.-thick wrapper to the flange of a round drum back 0.042 in. thick (Fig. 12a) and the flange of a round drum front 0.024 in. thick (Fig. 12b). All three components were of enameling iron (low-carbon steel). In each of the two circular seams to be welded, the total overlap was 7/16 in., as shown in Fig. 12. The three pieces were spot welded in position; then the wrapper was resistance seam welded to the drum back, and then to the drum front, producing two circular gastight seams.

In seam welding, it was important to ensure a minimum of unwelded overlap, and thereby to avoid moisture traps that could cause defects in a subsequently applied porcelain enamel coating. This was done (*a*) by adjusting the welding current, the heat-and-cool cycle, the welding speed and the electrode force so that a weld nugget was produced that was nearly as wide as the overlap of the flanges; and (*b*) by selection of electrode shape, dimensions and arrangement so that the full width of the drum-back flange (Fig. 12a) and nearly all of the width of the drum-front flange (Fig. 12b) were kept in contact with each lower electrode wheel.

The drum was welded in two automatic seam welding machines that differed only in rating. As shown in Fig. 12, both upper electrode wheels, and the lower wheel for the drum back, were mounted on horizontal axes; the axis of the lower electrode wheel for the drum front was mounted 18° from horizontal, to clear the dish-shape front.

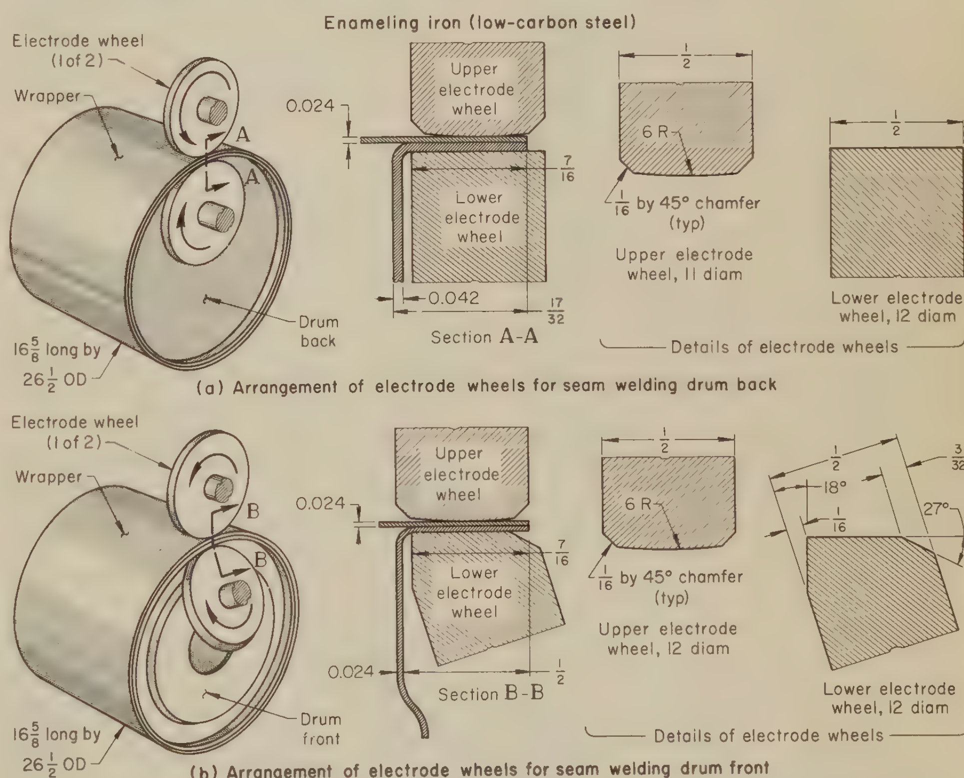
The face of each upper electrode wheel had a crown with a 6-in. radius, and had edges chamfered 1/16 in. by 45°. The faces of the lower electrode wheels were flat and were parallel to the work surface. This combination of electrode-face contours allowed the joint to be guided by a fixture on the welding machine, without attention from the operator once the weld had been started. The electrode material for both welds was RWMA class 2. The two lower electrode wheels and the upper wheel for the drum front were 12 in. in diameter. The diameter of the upper wheel for the drum back was 11 in.

In both welding machines, the upper electrode wheels were shaft driven through gears, and the lower wheels were idlers. The rotation of the powered upper wheels maintained a welding speed of 122 in. per minute. All shafts of the electrode wheels ran in tapered roller bearings. Brushes carried the welding current to the electrode wheels, and the bearings were insulated so that no current would pass through them. In each of the two welding operations, a timer stopped the machine after a preset interval, allowing only enough running time to complete the circular seam.

Re-dressing of the electrode wheels, in which about 1/16 in. of metal was removed, was done after welding about 1600 drums. Because of the reduction in wheel diameter resulting from each dressing of the electrode wheels, the speed of the gear-driven upper electrodes had to be adjusted to maintain the welding speed at 122 in. per minute. Additional equipment details and welding conditions are given in the table that accompanies Fig. 12.

Types of Seam Welds

Several types of resistance seam welds can be made, including lap seam welds joining flat sheets; flange-joint lap seam welds, in which at least one member has a flange that overlaps the mating piece; and mash seam welds, in which the work metal is compressed at the joint to reduce the joint thickness. Two other types of resistance seam



Equipment Details

Power supply	460 v, single phase
Welding machines (2)	Automatic, circular
Rating at 50% duty cycle	200 kva for welding drum back; 150 kva for welding drum front
Heat control	Phase shift

welds, made with the use of special techniques, are butt seam welds and foil butt seam welds.

In addition, both low-frequency and high-frequency induction and resistance welding are used for butt welding strip stock into tubes and other shapes.

Lap Seam Welds. The most common type of seam weld is a simple lap seam, in which the pieces to be welded are lapped sufficiently to prevent expulsion of weld metal. Applications include sealing of cans, water tanks and mufflers, in which watertight or gastight joints are needed.

In the following example, a drawn sump with flanges was seam welded to a cylindrical tub to make a watertight joint. The two components of the workpiece were designed to facilitate seam welding.

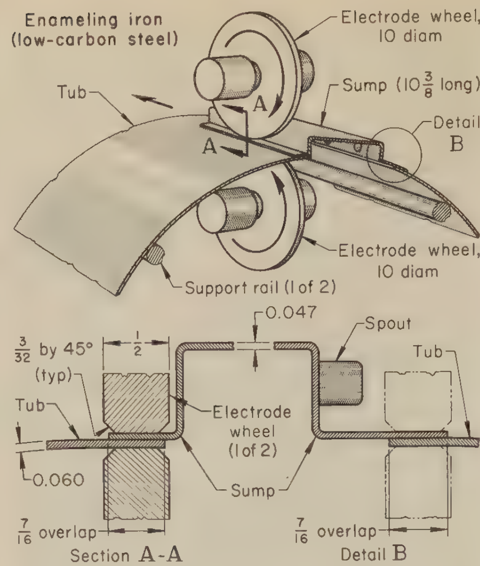
Example 385. Semiautomatic Straight Lap Seam Welding (Fig. 13)

The flanged sides of a drawn sump were lap seam welded to a cylindrical washer tub, as shown in Fig. 13, to make two straight watertight seams, 10⅜ in. long and parallel to the axis of the tub. Both components were of enameling iron (low-carbon steel); the sump was 0.047 in. thick, and the tub 0.060 in. thick.

To allow the upper electrode wheel to clear hose-connection spouts that were welded to one side of the sump, the flange on that side was made wider than the flange on the other side; the matching hole in the tub was made correspondingly large, to maintain a uniform overlap of 7⁄16 in. (see section A-A and detail B in Fig. 13). The nugget was made wide enough to avoid difficulties from unwelded overlap in subsequent porcelain enameling.

The welds were made in a semiautomatic longitudinal resistance seam welding machine that had two rails for supporting the tub, as shown in Fig. 13. The sump had previously been spot welded to the tub to hold the components in proper relation, and to simplify the resistance seam welding operation.

The workpieces were moved by the force and rotation of two knurl-driven electrode wheels, and were guided by the operator. The knurl drive continuously dressed the electrode wheels, which had double-bevel flat faces. The electrode faces were redressed after welding about 1600 tubs. Additional equipment details and welding conditions are given in the table that accompanies Fig. 13.



Equipment Details

Power supply	460 v, single phase
Welding machine	Semiautomatic, longitudinal
Rating at 50% duty cycle	200 kva
Heat control	Phase shift
Electrode-ram operation	Air cylinder
Electrode material	RWMA class 2

Welding Conditions

Heat-control setting	90%
Heat time	4 cycles
Cool time	4 cycles
Electrode force	1025 lb
Welding speed	65 ipm
Electrodes	½ in. wide by 10-in. diam; double bevel; 5⁄16-in.-wide flat face
Production rate	60 tubs per hour

Fig. 13. Setup for resistance lap seam welding of a flanged sump to a washer tub (Example 385)

Flange-joint lap seam welds are used in joining assemblies having one straight member and one outward-flanged member at the joint to be welded, such as the duct shown in Fig. 14(a), or assemblies with two outward-flanged members, such as automotive gasoline tanks, as shown in Fig. 14(b). Common applications include containers with outturned bottoms or tops, and ducts or structural parts with outturned sides. Unless the workpiece length is less than the usable throat depth of a longitudinal machine, seam welds of this type are made on a circular machine.

Often the container ends, such as the drum front in Example 384 (Fig. 12), are dished for added strength, and one or both electrode wheels must be mounted at an angle to clear the workpiece. Wheel-diameter limitations may also necessitate setting a wheel at an angle, as in the view at right in Fig. 14(a).

Flange-joint seam welds can also be used for welding assemblies in which the flanges face inward at the joint (see Fig. 14c); however, to reduce overhang of the arm supporting the lower electrode, or the required throat depth of the machine, the length of the workpiece should be kept to a minimum. If the lower-electrode support is small, too much overhang can result in excessive deflection of the support, and thus cause inconsistent weld quality and unacceptable welds due to reduced electrode pressure.

In the following example, three thicknesses of metal were welded together in a gastight flange joint. A resistance seam weld nugget prevented the piece of metal at the center of the joint from melting faster than the two outer pieces in gas tungsten-arc seal welding the edges of the workpiece.

Example 386. Use of Resistance Seam Welding and Gas Tungsten-Arc Welding To Produce a Gastight Joint (Fig. 15)

A 10-in.-ID bellows assembly for a fuel duct for a rocket motor, shown in Fig. 15, consisted of a straight section of a 0.020-in.-thick bellows wall sandwiched between two 0.040-in.-thick rings, all made of nickel alloy 718. Originally, the joint was made by edge-flange welding using the gas tungsten-arc process. When the joint was tested hydrostatically under an internal pressure of 160 psi, the joint did not leak; but when it was tested with a helium mass spectrometer under an internal vacuum, significant leakage was detected.

An investigation revealed that during gas tungsten-arc welding, the bellows wall melted back faster than the rings, so that weld metal was deposited at the edges of the rings only — which provided a leak path around the unwelded edge of the bellows. (See detail A, original method, in Fig. 6 for Example 276, on page 284.)

The problem was solved by first resistance seam welding the three workpieces together (see operation 1 in Fig. 15), then machining the edges back to the edge of the seam weld. A gas tungsten-arc weld was then deposited as before to ensure a gastight joint (see operation 2 in Fig. 15). The completed seam and arc welded joint was gastight under test conditions.

Before welding, the workpieces were cleaned by immersing them for 15 minutes in a solution of 30 to 40% nitric acid and 2 to 5% hydrofluoric acid that was at room temperature. The inner and outer rings were completely immersed; the bellows was immersed only to the first convolution.

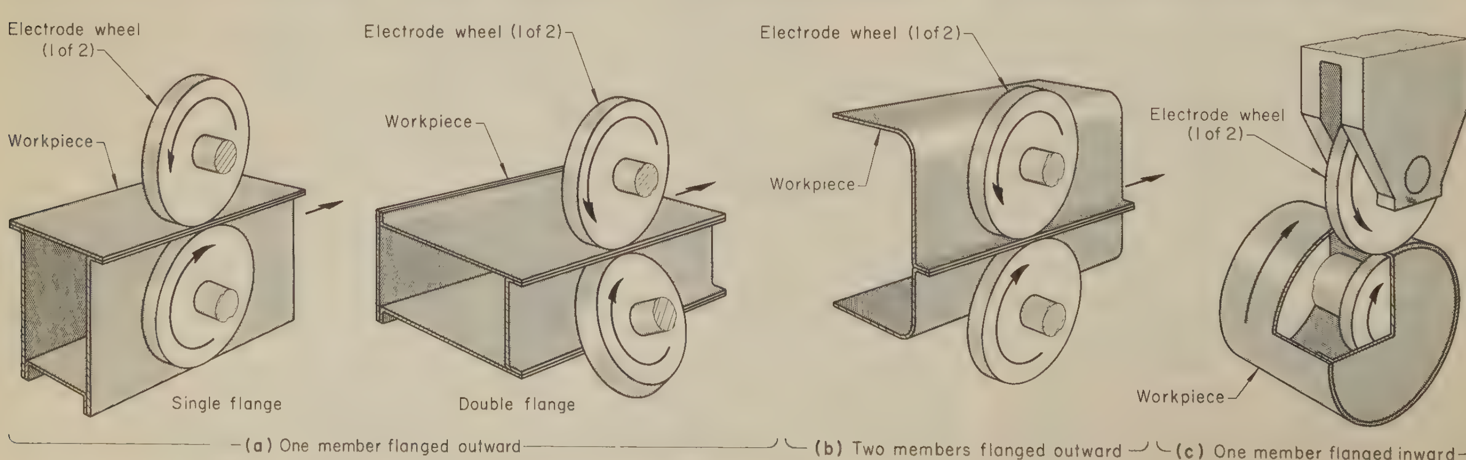


Fig. 14. Typical arrangements of electrode wheels for making various types of flange-joint lap seam welds

Equipment details and welding conditions for resistance seam welding are given in the table that accompanies Fig. 15. Conditions for gas tungsten-arc welding are given in Example 276, in the article on Arc Welding of Heat-Resisting Alloys.

Mash seam welds are produced by overlapping two sheets by an amount ranging from 1 to 1½ times the sheet thickness and applying a high electrode force and a high continuous welding current. The resulting weld thickness is 10 to 25% greater than the sheet thickness. Flat electrodes are used that are wide enough to control the weld thickness. The electrode force, welding current, welding speed, weld thickness and amount of overlap are all interrelated and must be accurately controlled to ensure consistent results. Mash seam welds require higher electrode force, welding current and welding speeds than are used in conventional seam welding.

The sheet overlap determines the amount of metal to be redistributed, and thus affects weld thickness. Therefore, the workpieces must be rigidly and accurately clamped or tack welded to prevent lateral motion during the welding operation. In applications where the mashed surface must be as flat as possible to facilitate porcelain enameling and to present a good appearance, a bar-type electrode is used against the surface to be enameled, and an electrode wheel is used against the other surface. When the finished appearance is important, the weld can be ground or roll planished to remove surface defects.

The most satisfactory mash seam welds are made in low-carbon steel. The maximum stock thickness that can be successfully mash seam welded is about 0.060 in. Stainless steel has been mash seam welded in some applications. Because of their narrow plastic range, nonferrous metals generally cannot be mash seam welded. This process is widely used in the manufacture of refrigerator cabinets, stoves, laundry equipment and other products that receive porcelain enamel coatings.

Butt seam welds are made by a special resistance seam welding technique in which the two abutting edges are heated and lightly forged together. There is a slight depression where the electrode wheels compress the plastic metal. This type of weld usually has low strength.

High-quality butt seam welds can be made in tubing by resistance heating the edges of roll-formed strip stock and forging them together with squeeze rolls. The welded tube has a small upset area on each side of the joint, which is continuously removed by scarfing tools.

This technique differs from upset butt welding in that the entire joint is not forged together simultaneously, but rather is forged together progressively as the electrode wheels traverse the seam.

Foil Butt Seam Welds. The strength of a butt seam weld can be increased by adding metal to the surfaces perpendicular and adjacent to the abutting edges of the joint. This technique is called foil butt seam welding. A thin, narrow strip of metal, usually 0.010 in. thick and ⅛ to 5⁄32 in. wide, is introduced on one or both surfaces adjacent to the joint as the workpiece is passed between conventional seam welding electrodes. This technique produces a smooth, nonoverlapping seam that is high in strength and neat in appearance. Highest-quality foil butt seam welds show nugget penetration to the foil-workpiece interface, complete foil bonding, and smooth, regular surface contours. The only edge preparation required is to ensure that the sheared edges are clean and straight without excessive burr or gap when they are butted together.

The thin strip or foil acts as a bridge to distribute the welding current evenly to both sheets, concentrates the current in the joint, helps contain the molten nugget as it grows and then cools, and provides metal for a slightly raised bead.

The variables having the greatest effect on the tensile strength of foil butt seam welds are welding current, welding speed, size of the gap between the edges of the butted workpieces, and thickness of the work metal. For the commonly used thicknesses of low-carbon steel, welding speeds similar to those used in conventional seam welding are permissible, provided that the gap is no wider than 0.015 in. Interrupted current and partial-wave continuous current both are used for foil butt seam welding.

Foil butt seam welded assemblies are ordinarily used in the as-welded condition. In those applications requiring at least one side of the weld to be finished flush to provide a smooth, blemish-free surface, removing some of the foil reduces the strength or reinforcement that the foil may have contributed to the weld.

In the following example, foil butt seam welding was used to make a smooth joint in a furniture component.

Example 387. Foil Butt Seam Welding a Table Leg To Avoid a Finishing Operation (Fig. 16)

Figure 16(a) shows a tapered table leg that was foil butt seam welded from 0.047-in.-thick low-carbon steel. If welded by other methods, this leg would have required a finishing operation before being painted, which would have added to the total cost. Foil butt seam welding slightly increased the thickness of the welded joint, but the edges of the foil blended into the base metal and made a smooth seam (see section A-A in Fig. 16).

The leg was welded in a 300-kva automatic longitudinal resistance seam welding machine that had an electrode wheel mounted on a movable carriage. An air-operated ram raised and lowered the electrode wheel, and forced it against the workpiece during welding. The lower electrode was a bar electrode mounted in a mandrel that was fastened to the stationary frame. The mandrel and electrode conformed to the shape of the leg, as shown in Fig. 16(b).

In operation, the table leg was placed over the mandrel and clamped in place, with the edges of the joint tightly butted. The electrode wheel was automatically moved into position above the workpiece, low-carbon steel foil (0.010 in. thick by 5⁄32 in. wide) was automatically fed over the joint, the wheel was lowered and welding force was applied. As the welding current passed from the upper electrode wheel through the foil and the abutting edges of the table leg to the lower electrode, the carriage advanced the wheel along the seam to produce a resistance welded joint. Because foil was used on one side only, weld penetration was 80 to 90% of stock thickness.

The welding speed was 20 ft per minute. Production rate was 220 table legs per hour. The electrodes were made of RWMA class 2 material. The upper electrode was continuously cleaned using a scraper-type wheel dresser. The scraper needed resharpening after each four to five hours of operation. The electrode force was 1200 lb.

For 1000 legs, the cost of foil was $6.36, and allowance for wear of the electrode wheel was $1.60. Additional details with regard to the equipment and welding conditions are given in the table that accompanies Fig. 16.

Seam Welding of Coated Steel

Resistance seam welding of low-carbon steel that has a thin coating of zinc, aluminum or terneplate can be done satisfactorily by proper selection of welding conditions. The metal coating increases the contact resistance, and thus welding of coated steel requires higher welding current and electrode force than are needed for welding similar thicknesses of uncoated steel. The welding speed must be limited to avoid excessive heating of the electrode and arcing at the workpiece interface, and immersion or flood cooling is recommended to permit a higher welding speed to be used, as well as to improve electrode life. In addition, a jet of water can be directed onto the work at the point where the work leaves the electrode wheels.

The RWMA class 2 copper alloy materials are best for electrodes used in seam welding of coated steel. Electrode life is shorter than in welding uncoated steel because of electrode pickup and higher welding currents. Because electrode pickup is considerable, the welding machine should be equipped with a knurl drive to break up and remove the pickup and to maintain the face width of the electrode. A scraper blade may be needed also for proper electrode maintenance.

For additional information, the reader is referred to the sections that discuss resistance spot welding of steel with various types of coatings, on pages 420 to 422 in this volume.

Other Examples of Resistance Seam Welding

Table 4 lists examples of resistance seam welding presented elsewhere in this volume. These deal with application of the process to stainless steel, aluminum alloys, and copper alloys.

Projection Welding

*By the ASM Committee on Resistance Welding of Steel**

PROJECTION WELDING is a resistance welding process in which current flow and heating are localized at a point or points predetermined by the design or configuration of one or both of two parts to be welded. The process is closely related to resistance spot welding, in which current flow and heating are localized by one or both electrode contact faces, which determine the location, size and shape of the weld produced.

This article is concerned primarily with projection welding of low-carbon and low-alloy steels, although much of the information presented is applicable also to other work metals. Projection welding of stainless steel, aluminum alloys and copper alloys is described in the next three articles in this volume.

In the usual application of projection welding, a projection, specially designed and formed on one of two conforming workpieces, is used to concentrate current flow and heating at the point where the weld is to be made.

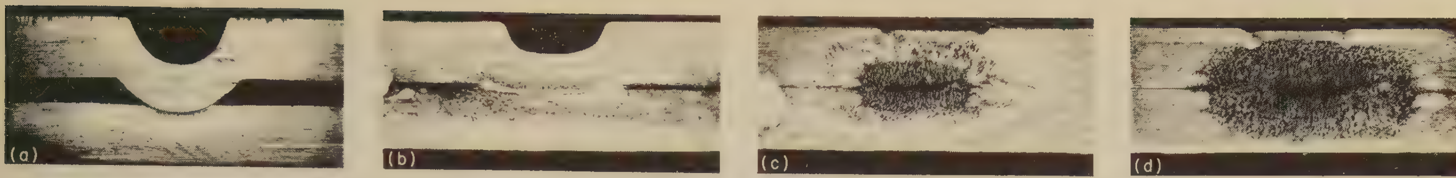
Projections may be of any practical shape that can properly concentrate the welding current. In cross-wire projection welding, the curved surfaces of two intersecting wires perform the function of a projection. The shapes of parts also take the place of conventional projections in projection welding other special types of joints.

Electrodes or welding dies are used to conduct current to the workpieces, and to apply the welding force. Force is always applied before, during and after the application of current to ensure a continuous electrical circuit and to forge the heated workpieces together. Welding dies may also hold and clamp the workpieces in proper relation to each other before and during the welding operation.

Formation of Weld. The formation of a projection weld nugget, which depends on the design of the projection, the selection of welding conditions, and the adequacy of the resistance welding equipment, is shown in stages in Fig. 1, which is based on projection welding of 0.092-in.-thick low-carbon steel using embossed spherical projections and a weld time of 20 cycles (⅓ second).

At first, as shown in Fig. 1(a), the workpieces are brought together under pressure without application of welding current, and the projection may be slightly compressed and indented into the surface of the mating workpiece. Figures 1(b), (c) and (d) show the stages of formation of a typical weld at 20%, 60 to 70%, and 100% of the weld time (or "heat time").

*For committee list, see page 401. Most of the examples in this article were contributed by members of other Metals Handbook welding committees. Additional examples on projection welding that appear in other articles in this volume are listed in Table 8, page 455.



(a) Components are brought together between electrodes, without application of current. Projection on upper component is pressed against lower component by electrode force. (b) At 20% of weld time (or "heat time"), collapse of projection is nearly complete, and a pressure weld is formed. (c) At 60 to 70% of weld time, fused weld nugget has developed about half its final thickness and diameter, sheet separation is zero, and upper surface is flat against the upper electrode. (d) At end of weld time, nugget has reached full thickness (penetration) and diameter. (Adapted from: J. F. Harris and J. J. Riley, "Projection Welding Low-Carbon Steel Using Embossed Projections", *Welding Journal*, Apr 1961)

Fig. 1. Four stages in the development of a weld nugget in 0.092-in.-thick low-carbon steel during projection welding, using embossed spherical projections 0.050 in. high and a weld time of 20 cycles

At about 20% of weld time (Fig. 1b), collapse of the projection is nearly complete, and a pressure weld is formed. A nugget of fused weld metal does not begin to form until about 50% of the weld time has elapsed.

At about 60 to 70% of weld time, as shown in Fig. 1(c), fusion has progressed a sufficient distance from the interface to produce a well-defined weld nugget that has about half its final thickness (penetration) and diameter. Sheet separation adjacent to the weld nugget has been reduced to zero, and the softened metal above the nugget has been flattened against the face of the upper electrode (compare with Fig. 1b). Nugget diameter, penetration and shear strength continue to increase as weld time progresses. Figure 1(d) shows the fully developed weld nugget.

Applicability of Process

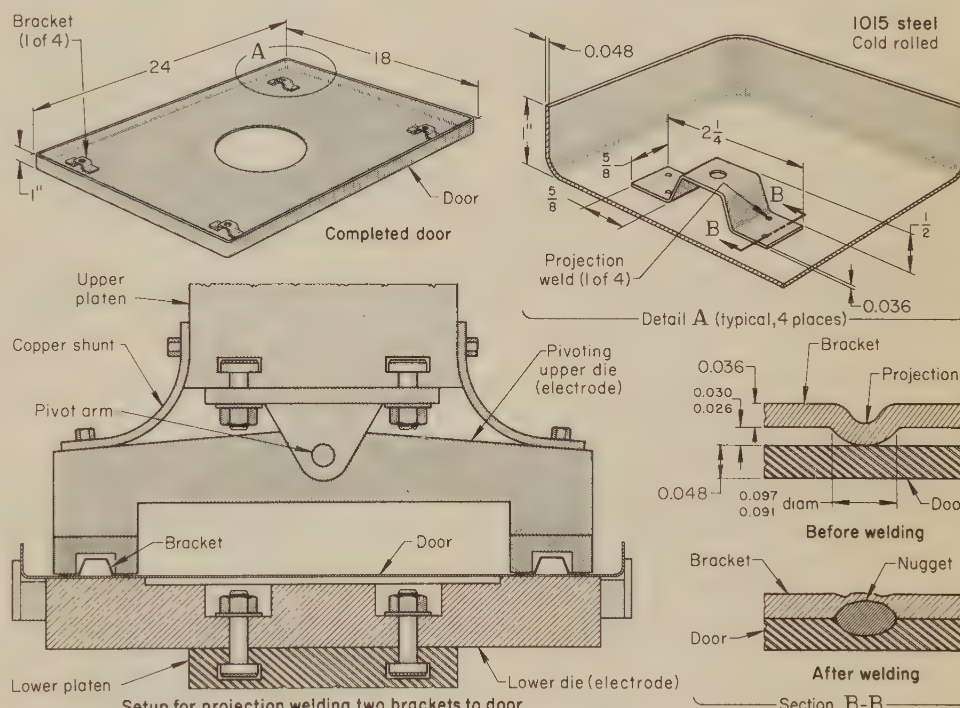
The principal application of projection welding is the joining of stamped low-carbon and low-alloy steel parts (punched, drawn or formed) on one of which a projection has been formed during the stamping operation. Projection welding is also used for joining screw-machine parts to stamped parts; the projection is machined or coined on the end of the screw-machine part. Fasteners or mounting devices, such as nuts, screws, brackets, pins, bosses, handles and clips, can be attached to various products by projection welding. This technique is of special value in mounting attachments to surfaces of which the back side is inaccessible to a welding operator, and in applications where the mounting surface must be leakproof at the weld joint.

Projection welding is most successful in workpieces 0.022 to 0.135 in. thick. Stock 0.010 in. thick has been projection welded; however, projection design is critical and machines with low-inertia heads and fast follow-up are needed. Sections less than 0.010 in. thick are more adaptable to spot welding.

Projection welding of crossed wires is used for making such diverse items as stove and refrigerator racks, soap dishes, lampshade frames, gratings, grills, and electrical connector networks for electronic applications.

Advantages. The principal advantages of projection welding are:

1. The number of welds that can be made simultaneously with one operation of the welding machine is limited only by the ability of the controls to regulate current and force.
2. Because of greater current concentration at the weld, and thus less chance of shunting, narrower flanges can be welded, and welds can be spaced closer together, by projection welding than by spot welding.
3. Electrodes used in projection welding have faces larger than the projection or pattern of projections, and larger than faces of electrodes used for making spot welds of comparable nugget diameter, and thus, because of lower current density, require less maintenance than do spot welding electrodes.
4. Tooling construction for projection welding usually combines welding dies, or electrodes and electrode holders, with workpiece locators in one assembly, which frequently can be designed for welding two or more small workpieces to one larger one.
5. Projection welds can be made in metal that is too thick to be joined by resistance spot welding.
6. Flexibility in the selection of projection size and location allows welding of workpieces in thickness ratios of 6 (or more) to 1. Workpieces in thickness ratios greater than about 3 to 1 sometimes are difficult to spot weld.
7. Weldments requiring a minimum of surface marking on one side can be produced by embossing projections on the component with less-critical appearance requirements. The slight bump raised in welding (if objectionable) can be removed in a simple mechanical finishing operation.
8. Projection welds can be located more accurately, and are more consistent in



Comparison of Costs for Spot Welding vs Projection Welding

Item	Spot welding	Projection welding
Production rate, doors per hour	75	210
Welding cost per 100 doors	$5.60	$2.01
Finishing cost per 100 doors	$3.92	$3.16
Total cost per 100 doors (labor plus overhead)	$9.52	$5.17
Saving per 100 doors		$4.35
Annual saving (750,000 doors produced per year)		$32,625.00

Equipment Details for Projection Welding

Welding machine	Press type, RWMA No. 2
Rating at 50% duty cycle	100 kva
Current, max	46,000 amp
Electrode material	RWMA class 2
Electrode force, max	1800 lb

Conditions for Projection Welding

Welding current	32,000 amp
Heat-control setting	90%
Electrode force	1200 lb
Squeeze and hold times	10 cycles each
Weld time	6 cycles

Projection welding replaced spot welding, in which the 16 welds (four per bracket) had to be made one at a time because of close spacing. As shown in the table, the change of process resulted in a 180% increase in production rate and a 46% saving in costs.

Fig. 2. Setup for joining four brackets, two at a time, to a clothes-drier door (Example 388)

diameter and thickness (penetration), than spot welds (and thus, for a given strength, can be smaller in average size than spot welds).
9 Oil, rust, scale, plating and other work-metal coatings interfere less with projection welding than with spot welding.

In spite of the additional cost of embossing or otherwise providing projections, projection welding often is more economical than spot welding. A greater number of welds can be made simultaneously, surface finish can be better preserved, and handling sometimes can be reduced, as in the application described in the example that follows.

Example 388. Change From Resistance Spot Welding to Projection Welding That Increased Production and Reduced Costs (Fig. 2)

Originally, spot welding was used for attaching four brackets to the low-carbon steel door of a clothes drier (Fig. 2, upper left). The 16 spot welds (four per bracket) were made one at a time.

Production rate was increased by 180% and costs were reduced by 46% when spot welding was replaced by projection welding for attaching the brackets. With the setup shown at lower left in Fig. 2, projection welds were made eight at a time, attaching two brackets to the door simultaneously, and loading of parts into the welding machine was faster than with the fixture used for spot welding.

The upper die (electrode) was pivoted to equalize the welding force on each of the brackets. A means was provided in the upper die for locating and holding the brackets for welding, and the lower die incorporated gages for positioning the door.

Surface finishing was done in less time after projection welding than after spot welding. Equipment details and conditions for projection welding, along with a comparison of production rates and costs for the original and improved methods, are given in the table that accompanies Fig. 2. Yearly production was 750,000 doors.

In the following example, projection welding was selected over arc welding or resistance spot welding for greater productivity at lower cost (including the cost of electrode maintenance).

Example 389. Projection Welding of Mounting Brackets to a Panel (Fig. 3)

Four press formed right-angle mounting brackets, 2 in. long and 0.156 in. thick, were projection welded to a panel 0.090 in. thick, as shown in Fig. 3. The brackets and the panel were made of 1010 steel. Each bracket, on which three spherical projections, 0.056 in. high by 0.250 in. in diameter, had been produced during press forming, was welded in one operation in a press-type projection welding machine. Equipment details and welding conditions are given in the table with Fig. 3.

The three-weld joint in each bracket was required to withstand a shear load of 2000 lb, and when peel tested, was considered sound if buttons of metal were pulled from the panel.

The electrode faces were flat and were longer than the brackets, as shown at lower right in Fig. 3. The lower electrode had to be dressed after 60 to 80 hours of welding, and the upper electrode, after 30 to 40 hours.

The welding machine and controls cost $6300. The yearly cost for maintenance of electrodes (labor at $4.08 per hour) and for purchase of replacement electrodes was $185. Annual production was 20,000 panels.

Projection welding was selected because it could provide greater productivity, at lower cost, than could arc welding or resistance spot welding. Production rate was 100 panels per hour for projection welding, compared to estimates of 15 per hour for arc welding and 50 per hour for spot welding. Cost per panel was $0.08 for projection welding, compared to estimates of $0.50 for arc welding and $0.16 for spot welding. Cost of electrode maintenance was lower for projection than for spot welding.

Because of its speed and adaptability to automatic control, projection welding is readily integrated with high-speed forming, trimming and other press operations in automatic multiple-station machines, as in the welding of electrical contacts described in the following example.

Example 390. Projection Welding Combined With Cutoff, Coining and Trimming in an Eight-Station Automatic Machine (Fig. 4)

The mercury-switch contact assembly shown in Fig. 4, which consisted of a platinum-nickel wire, 0.0038 in. thick by 0.0105 in. wide, and a nickel-iron pole piece, originally was projection welded manually in a separate operation. To increase production and reduce costs, projection welding was done automatically and was combined with cutoff, coining and trimming in an eight-station automatic machine. After welding, the wire was coined to form three contact surfaces 0.004 in. wide by 0.006 in. high by 0.010 in. long, as shown in Fig. 4.

Details of Improved Method. The assembly was made at the rate of 800 pieces per hour. The operations were performed on a cam-operated eight-station rotary-indexing table as follows:

1 Manually load pole piece into the lower die (the lower welding electrode, which also served as a support during coining and trimming).
2 Automatically align pole piece and apply a drop of alcohol for cleaning and to provide cooling during welding.
3 Feed and cut off platinum-nickel wire, and projection weld to pole piece (Fig. 4, section B-B).
4 Idle.
5 Coin three contacts on wire, and partly trim excess wire (Fig. 4, section C-C).
6 Remove excess wire (Fig. 4, section C-C).
7 Eject finished weldment.
8 Idle.

Prior to assembly, the nickel-iron pole piece was degassed in a hydrogen atmosphere. In station 3, after the pole piece was located in the lower die, the upper die was lowered to within 0.002 in. of the welding position. The rectangular-section wire was fed from a spool and was guided across the pole piece by a slot in the upper die. The wire was cut off and the upper die was lowered to make the weld.

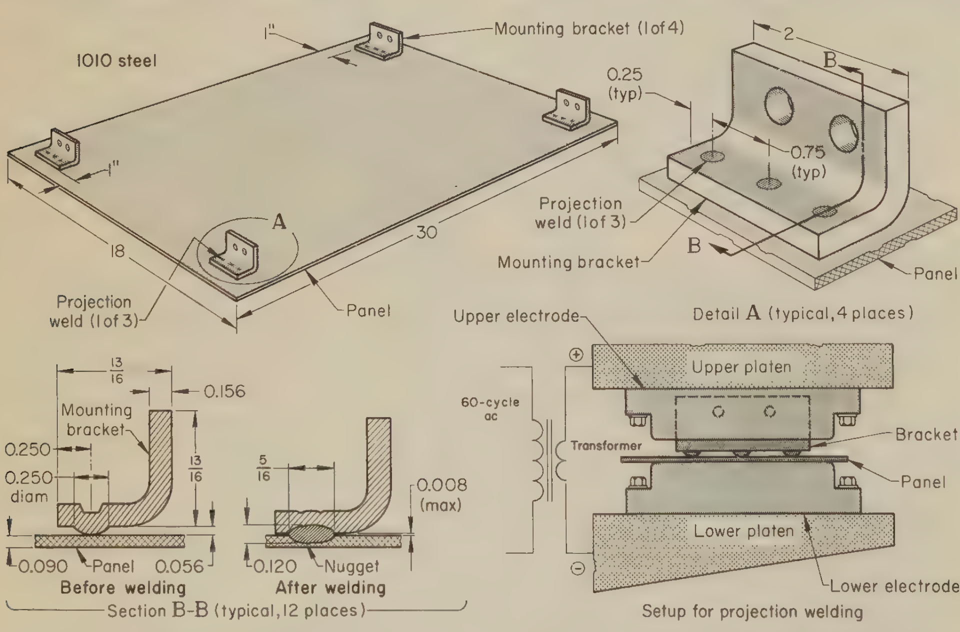
Comparison With Original Method. Previously, the same basic operations had been performed manually. The improved (automatic) process required greater care in aligning the workpieces and the dies. The machine cost $15,950, but production per man-hour was more than quadrupled over the original method, as shown in the table with Fig. 4, and there were fewer rejections. The resulting decrease in production costs allowed amortization of the cost of the machine in 147 working days, or after welding of 938,000 assemblies.

Quality Control. Five assemblies were inspected every 15 minutes. First they were dimensionally inspected in an optical comparator at a magnification of 50 diameters. Then they were tested destructively by applying force to the faces of the three coined contacts. The weld was required to hold until the contacts had been bent 90°.

Conditions for projection welding by the improved method, and a comparison of labor costs for cutoff, coining, welding and trimming by the original and improved methods, are given in the table with Fig. 4.

Limitations of projection welding include the following:

1 Forming of one or more projections on one of the workpieces may require extra operations.
2 When several welds are made at once with the same electrode, alignment of the work and dimensions (particularly height) of the projections must be held to close tolerances to obtain consistent weld quality.
3 In any one operation, welding is limited to joining two thicknesses of metal and, as in spot welding, the



Equipment Details

shape of the work and location of the projections must be compatible with application of the electrode force.

4 Nugget size is limited by the size of the projection.

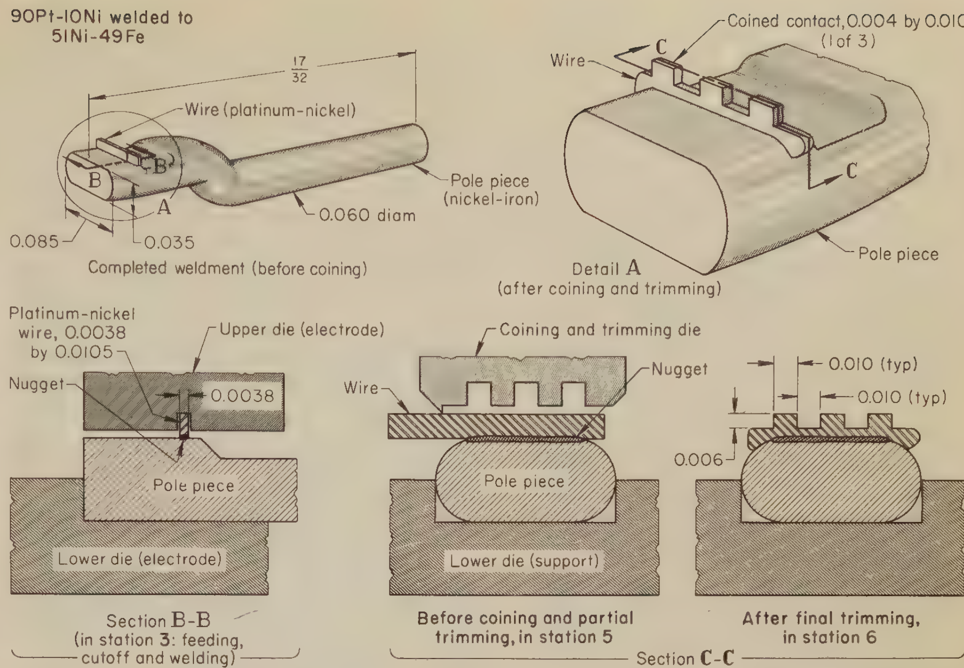
Welding Machines

Press-type machines, with either single-phase or three-phase transformers, are used for projection welding. The welding head in these machines is guided by bearings or ways and moves in a straight line. Platens with T-slots or tapped holes are used for mounting the welding dies or electrodes. Rocker-arm machines generally are not used for projection welding because the electrode moves in an arc that can cause slippage between the components as the projection collapses.

The welding head can be hydraulic, spring, magnetic or air actuated. Many machines have a low-inertia welding head, or a means of uncoupling the electrode holder, to provide fast follow-up as the projection collapses. A schematic arrangement of a low-inertia welding head is shown in Fig. 5.

At the start of the welding stroke (Fig. 5a), equal air pressure is applied to the top of the piston and to the diaphragm. By the time the piston has completed its travel, the diaphragm has been compressed by the retraction of the internal shaft. Retraction of the internal shaft simultaneously compresses the diaphragm and closes the welding-current switch; control lever for the switch rides in the shaft collar.

At the instant the welding current is initiated (Fig. 5b), the only remaining mass to be moved is the internal shaft and its attached electrode. Air pressure acting on the diaphragm and the force of the compressed spring between the inner and outer shaft easily overcome the low inertia of the system and move the upper electrode downward as the projection collapses. Thus the workpieces are kept in close contact under partial electrode force until the welding head follows and forges the weld region with the full electrode force (Fig. 5c). A welding head like that shown in Fig. 5 was used in Example 393.



Item	Original method (manual)	Improved method (automatic)
Comparison of Labor Costs(a)		
Assemblies per man-hr	180	800
Number of operators	2	1
Cost per assembly at $4 per man-hr	$0.022	$0.005
Saving per assembly	...	$0.017

Conditions for Automatic Projection Welding

Transformer rating at 50% duty cycle ....5 kva
Electrode material ......RWMA class 10 (Cu-W)
Welding voltage ....1.5 v
Electrode force ....0.6 lb

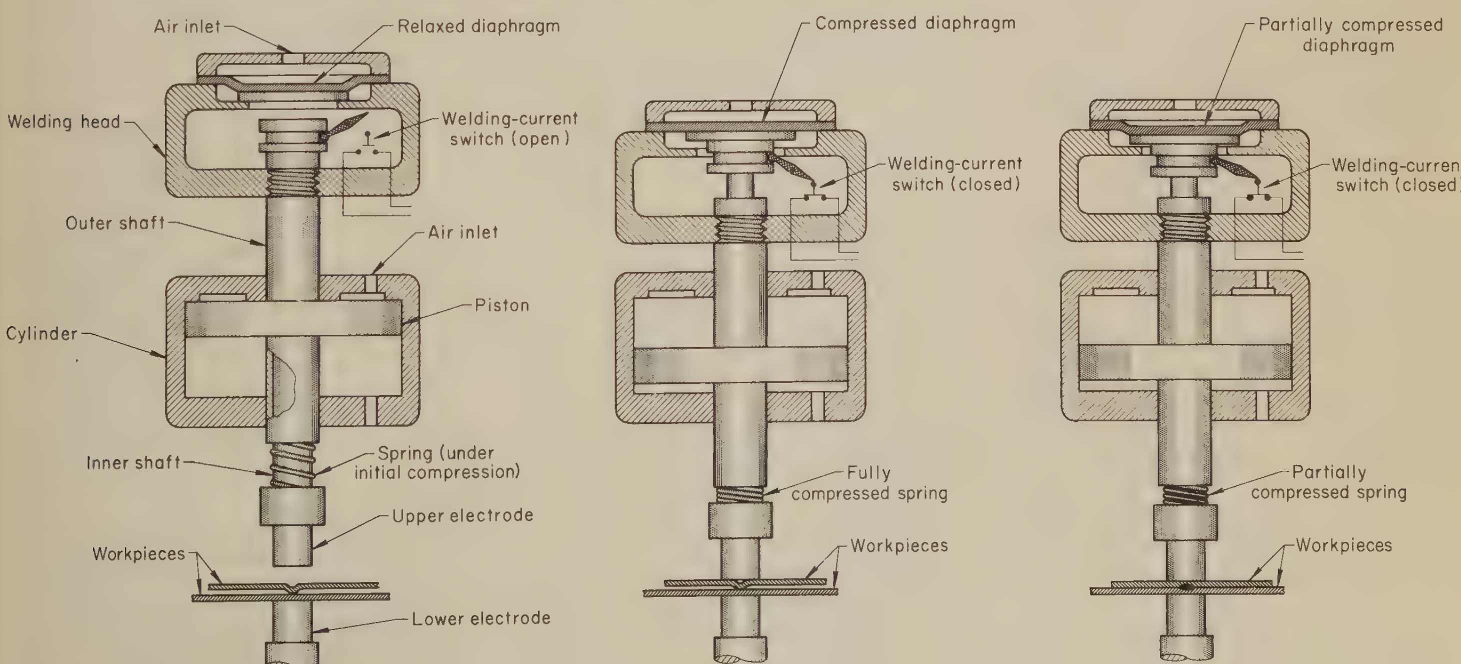
Weld time ....2 cycles

(a) For cutoff, projection welding, coining and trimming

Fig. 4. Mercury-switch contact assembly for which projection welding was combined with cutoff, coining and trimming in an eight-station automatic machine (three stations shown), to increase production and reduce costs compared with original method (Example 390)



(a) Welding head in open position

(b) Welding head in position for squeezing and heating projection

(c) Welding head at instant of projection collapse and start of nugget formation

Air pressure on the diaphragm and the force of the compressed spring overcome the low inertia and move the upper electrode downward as the projection collapses, keeping the workpieces in contact. The welding head follows, to forge the weld region with the full electrode force.

Fig. 5. Low-inertia welding head for a projection welding machine

Welding-machine controls are usually of the synchronous type. Phase shift and pulsation timing are often included on single-phase or three-phase machines, to regulate welding current. Pulsation timing may be helpful when welding thick metal or unequal thicknesses, and to compensate partly for slow follow-up. On single-phase machines, slope control is sometimes used in special applications, generally for the same purposes as are served by pulsation timing.

For additional information on resistance welding machines and controls, see the article on Resistance Spot Welding, which begins on page 401.

Metals Welded

The metal that can be projection welded most satisfactorily is low-carbon steel (0.20% C max). Naval brass, Monel (nickel-copper) alloys and austenitic stainless steels have also been projection welded. Any two of these metals can be projection welded.

Coated metals, such as galvanized steel, terneplate, tin plate and aluminized steel, are successfully welded, but considerable electrode maintenance is usually needed. (See "Projection Welding of Coated Steel", page 450.)

Not all metals can be projection welded, because some are not strong enough to support projections; some brasses cannot be projection welded because the projections collapse too rapidly under pressure. Aluminum has been projection welded only to a limited extent, and best results are obtained with extruded parts, using conventional projections. Thin steel (less than 0.010 in. thick) usually is more easily spot welded than projection welded because of the difficulty of forming projections that will not collapse before reaching the welding temperature. Free-machining steel sometimes can be projection welded using specially designed joints and electrodes (see Example 396), but generally is difficult because sulfur and phosphorus segregation causes brittle welds.

Metallurgical Effects of Projection Welding

The rate of quenching projection welds is extremely rapid in thin members, because of the closeness of the water-cooled electrodes to the weld nugget. Although the total amount of heat is low because of the short weld times and the small amount of metal heated, severe solid-metal quenching is obtained. Under some conditions, quench rates for projection welds may be so severe that the fully hardened condition is achieved even in low-carbon steels. Therefore, recommended practice limits the carbon content of carbon steels to 0.20% max, unless special techniques are employed.

Cleaning of Workpieces

Optimum welds on all metals are obtained when surfaces are clean and without scale, oxide, excessive oil and grease, or other foreign material. A thin coating of oil normally does not cause poor results, but if optimum-quality welds are required, the material should be degreased before welding. Unclean surface conditions result not only in lack of weld uniformity but also in gas and inclusions in the weld nugget, which reduce weld strength.

Surfaces coated with scale, oxide, oil or other surface films can be more readily projection welded than spot welded. For projection welding on such surfaces, the concentration of the electrode force on the tip of the projection must be sufficient to break through the coating and get the weld started. The heat from this start can then melt and vaporize volatile surface contaminants; other foreign matter is broken up and at least partially expelled during collapse of the projection.

Thin surface films that have low and uniform electrical resistance have the smallest effect on welding. Steel that is coated with extremely thick and nonuniform mill scale may not be weldable on a practical production basis unless the scale is removed prior to welding. (See the section on Surface Preparation on page 415 in the article on Resistance Spot Welding for more detailed information on the effect of surface coatings on welding.)

As workpieces are prepared for projection welding, burrs around sheared edges of the components and around pierced holes in the components should be removed. As the projection collapses, these burrs, if not removed, form shunting paths for both current and electrode force. Uncontrolled shunting makes it difficult to obtain consistently high weld quality.

Process Variables

The major variables that affect projection welding are welding current, electrode force, and weld time. Other factors are heat balance, number and placement of projections, and other aspects of projection and joint design.

Variations in weld quality are minimized when electrode force, welding current, and weld time are maintained at constant values, and when the electrodes are kept clean and in good condition. Other factors that affect the flow of welding current across the weld interface include: quality of power regulation on the high-voltage lines that supply the welding machines, adequacy of low-impedance substation transformers, capacity of bus lines to the welding machines, the use of suitable current or voltage regulators on the welding machines, and proper allowance for the introduction of magnetic metals into the secondary loop of the machine. In addition, accurate fit-up of the workpieces and uniform height of the projections are necessary.

Schedules for projection welding of low-carbon steel from 0.014 to 0.125 in. thick are given in Table 1. These data are intended to serve as starting points, and should be adjusted to suit the specific application and the equipment being used.

Welding current required for projection welding, although slightly less per weld than that needed for spot welding, must be high enough to cause fusion before the projection is completely flattened. The recommended current is the highest current that, when used with the correct electrode pressure, does not cause excessive expulsion of metal. For a specific projection size, expulsion of metal increases as welding current increases, because the current must flow through a small contact area. Slope control sometimes can be used to minimize expulsion.

The rigidity of a projection against collapse, which is a function of work-metal properties and thickness, has an effect on selection of the welding current. For welding thin metal (less than 0.020 in. thick), the ranges of welding current and weld time are narrow.

During a production run, it may not always be feasible (although it is preferred practice) to hold all workpiece variables constant and to avoid heat buildup in the work, electrodes, fixtures and equipment. Therefore, it may be necessary to change the heat-control settings at intervals during the run to produce the desired heat at each weld. (Alternatively, the weld time and the squeeze time can be changed, if more convenient or effective.)

Progressive heat buildup can also be a problem when a number of projection welds are made in sequence on a single part — even though the size and spacing of the projections and the thickness and width of the work metal are the same for all of the welds. Heat buildup can be compensated for by changing the heat-control settings, or otherwise adjusting the current, for some of the welds. In addition, shunting effects may vary after the first weld is made, and heat-sink behavior may differ for some of the welds, which further affect the heat input from weld to weld.

To compensate for such effects in making a number of welds on a single part, suitable changes in heat-control settings can be made manually or can be programed into automatic control equipment for high-production applications, as in the example that follows.

Example 391. Use of Programed Changes in Welding Current To Compensate for Changes in Shunting Behavior and Heat Buildup in High-Speed Projection Welding (Fig. 6)

The brake-shoe assembly shown in Fig. 6 was manufactured by roll forming a rim and a web and joining them with nine projection welds. To compensate for heat buildup and for changes in shunting behavior and thus to provide the desired heat input for each weld, the welding current was increased automatically for successive welds or groups of welds by programed changes in the heat-control setting, as shown in the table with Fig. 6. The machine was equipped with four heat-control units, which were preset at different current levels and were selectively activated by a timer to provide the desired current for each weld.

The web, which had four locating tabs for engagement with slots in the rim, was sheared to shape. The flat rim had, in addition to the four slots, nine weld projections for attachment to the web. Figure 6 shows the detail of the first projection to be welded (Projection A) at the lower left, and the detail of the remaining eight projections (of which Projection B is typical) at the lower right.

Sequence of Operations. The webs and rims were stored in magazines and were fed automatically to the forming and welding machine. In the view at upper right in Fig. 6, the two components are shown in

position at the start of the operation. The electrode wheels (which also served as forming rolls) revolved continuously, and the welding current was initiated by a cam as each projection on the rim came into welding position. The driven electrode wheel had nests for two webs (see Fig. 6), and thus two brake-shoe assemblies were formed and welded at each revolution of the wheel. The web was fed and hydraulically clamped against the driven electrode wheel. Simultaneously, the rim was fed from the second magazine through guides and was advanced until the first slot engaged the first locating tab on the web. The wheel rotated, and as the first projection came into welding position between the electrode wheels and made contact with the web, the welding current was initiated to make the first weld.

As the electrodes revolved and the projections were fed into position against the web, the welds were made in sequence as the rim was formed to the semicircular contour of the web. All movements of the machine were mechanically synchronized; limit switches, closed by cams, initiated the weld timer to make the welds. On completion of the last weld, the assembly was ejected onto a conveyor.

Heat Control and Welding Current. Typical heat-control settings and welding currents for the nine projection welds are shown in the table with Fig. 6. As each weld after the first was made, there was some shunting of current through the preceding weld or welds, making necessary the successive increases in heat-control setting and current. Also, there was a gradual buildup of heat in the work as successive welds were made, which increased the electrical resistance of the work metal and contributed to the need for higher heat-control settings as welding progressed.

The combined effects of shunting and heat buildup were such that a separate heat-control setting was needed for the ninth weld, for which soundness was critical because of its position at an end of the part. At the other extreme, the current at the first projection (which was cool and not subject to shunting) was much lower than for any of the remaining welds, in spite of the fact that the projection for the first weld was more than twice as large in area as the other projections.

Quality Control. Weld quality was checked in three ways: (*a*) the operator peel tested a set of two brake shoes twice during each shift, (*b*) the operator visually spot checked the welds at random intervals during the shift, and (*c*) the quality-control floor inspector visually checked the welds at random intervals during the shift. Welds were acceptable if, when the rim was peeled from the web, a button from the rim remained attached to the web at each weld spot.

The electrode wheels, which were 1¼ in. thick, were removed from the machine and dressed after welding about 6200 assemblies. Equipment details and welding conditions are given in the table with Fig. 6. The procedures described here were used to make other brake-shoe assemblies ranging in diameter from 6½ to 12 in., with rim widths from 1¼ to 2¾ in.

Electrode force used in projection welding depends on the work metal, the size and design of the projection, and the welding machine. Excessive force causes the projection to collapse before the weld area has reached the proper temperature, which results in the formation of ring welds, in which fusion occurs around the periphery of the projection but is incomplete at the center. For best appearance of welds, the electrode force should be such that the projection is flattened completely after the metal has reached welding temperature. Also, force must be sufficient to produce a sound weld with minimum separation of the workpieces.

If the projection is high, a welding machine having heavy, slowly moving parts should not be used, or provision must be made for quick follow-up as the projection is melted. Slow follow-up permits expulsion of molten metal before the pieces can be brought together and welded.

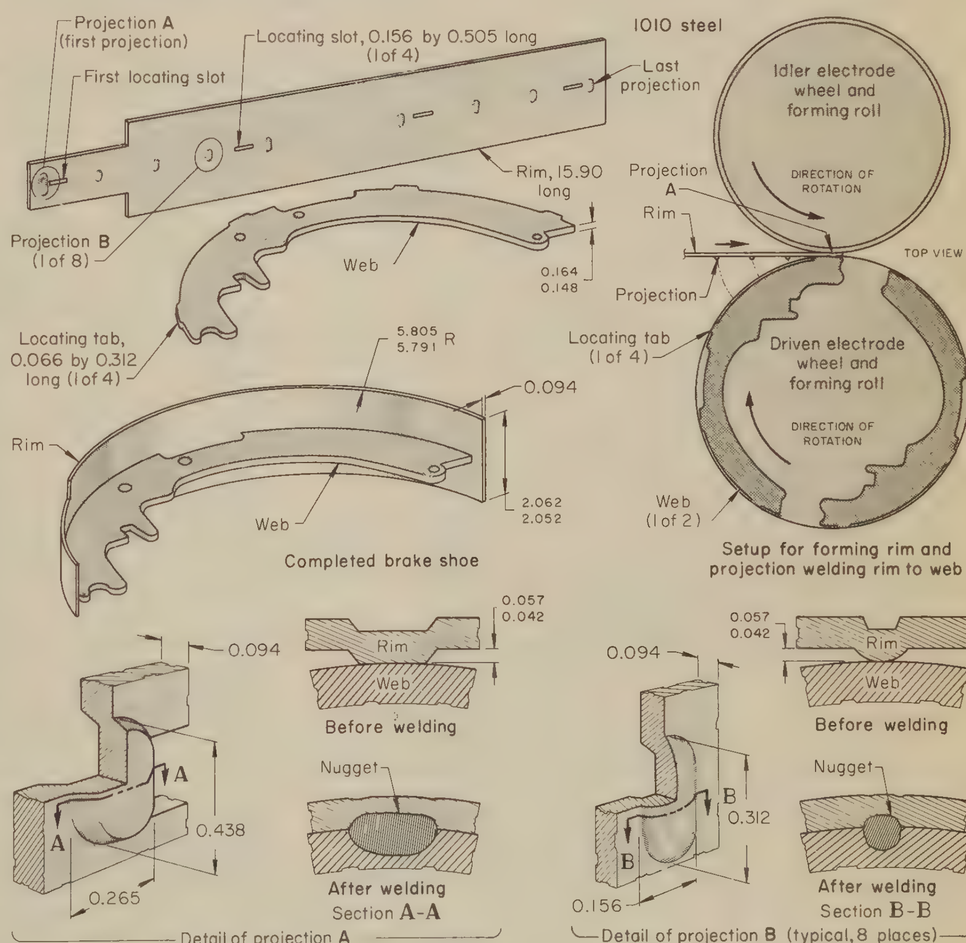
Application of an initial force high enough to cause a definite indentation of the lower workpiece by the projection is sometimes used to help prevent expulsion of molten weld metal when follow-up is too slow or follow-up force is insufficient.

Electrode force influences development of porosity in the weld nugget. The force must be low enough to provide properly timed projection collapse, and yet high enough to produce sound welds. Sometimes, especially in welding thick workpieces, a weld force is used to make the welds, and a forging force is applied after current flow has stopped, to minimize porosity.

Weld time for a given type and thickness of work metal depends on welding current and rigidity of the projection. Weld time is less important than electrode force in projection welding low-carbon and low-alloy steel, provided the time is sufficient to produce a nugget of adequate size at the chosen welding current. A shorter weld time results in higher production efficiency, and in less discoloration and distortion of the workpiece. After the proper electrode force and welding current are determined, the weld time is adjusted to make the desired weld.

Projection welds made in the shortest times are not necessarily of the best quality. A short weld time requires a correspondingly high welding current, which initially must pass through a small contact area, increasing the current density and the possibility of metal expulsion.

When several projection welds are made at once, using the same electrode (multiple-projection welding), it is helpful to use pulsation timing and somewhat longer weld times than for comparable single welds. Variation in height of projections has an effect on timing of initial contact, and the use of slope control provides slow initial heating and allows enough time for all of the projections to make contact with the mating workpiece before the



Equipment Details

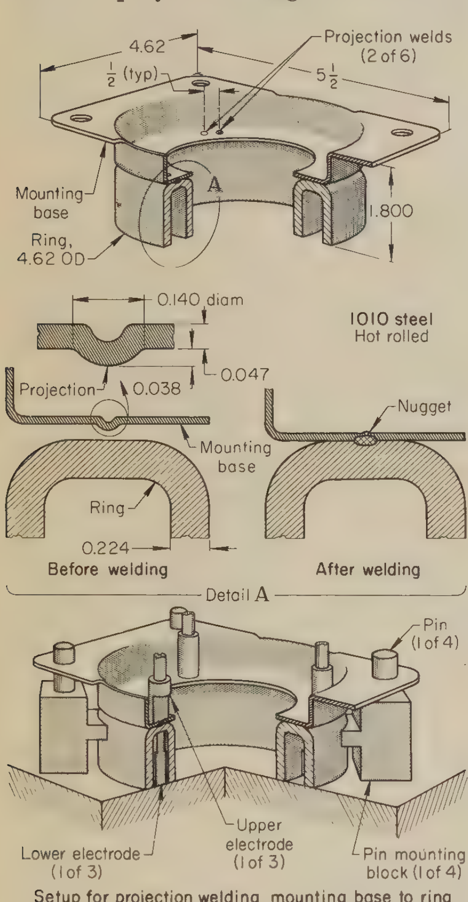
high welding current is applied, thus producing more uniform welds and minimizing expulsion.

Heat Balance. Maintaining the proper heat balance between workpieces sometimes is difficult in projection welding. If heat balance is incorrect, the projection can be melted away before the mating surface is brought to welding temperature.

The factors that affect heat balance are: (*a*) design of the projection, (*b*) electrode material, (*c*) thickness of the workpieces and thermal and electrical conductivity and other properties of the work metals, and (*d*) heating rate.

Projections must be designed to withstand the initial electrode force needed for the proper flow of current, yet collapse fully at welding temperature so as to produce a sound weld with minimum or no sheet separation. When multiple projections in groups of four or more are welded, slight variations in projection height can affect heat balance in all the projections and can make it difficult to obtain simultaneous collapse of the projections.

A water-cooled electrode made of RWMA class 2 or class 3 electrode material may prevent a thin sheet from heating sufficiently if the projection is on a thicker component. This can be avoided by the use of a hard material of low electrical and thermal conductivity, such as RWMA class 10, 11 or 12, in contact with the thinner sheet.



Equipment Details

(a) Steel to be welded should be free from scale, oxides, paint, grease and oil. (b) Data based on thickness of thinner sheet, and for two thicknesses only. Maximum ratio between two thicknesses, 3 to 1. (c) Face diameter equals twice the diameter of the projection. (d) Approximate current at electrodes, using 60-cycle ac.

As discussed in the section on Metals Welded, page 438, not all metals can be projection welded, because in some, projections collapse too rapidly under pressure. Also, the thermal conductivity of some metals is such that heat is dissipated away from the projections too quickly for them to reach welding temperature. When dissimilar metals are welded, projections should be formed on the metal of higher electrical and thermal conductivity to more nearly equalize the rate of heating in the two workpieces. Rate of heating is important because the two mating surfaces must be brought to welding temperature at the same time.

When similar metals of equal thickness are welded, projections can be formed on the component that is easier to handle or that has the less critical requirements for surface appearance. In welding workpieces of unequal thickness, projections should preferably be formed on the thicker workpiece to ensure that both of the mating surfaces reach welding temperature at the same time. Projections on the thinner workpiece can melt off before the thicker workpiece reaches welding temperature, unless tooling and welding procedure are specially developed and carefully maintained and controlled to overcome this problem.

However, with suitable precautions, good results can be obtained using projections formed on the thinner workpiece — even when the workpiece-thickness ratio is as great as 5 to

SOURCE: "Recommended Practices for Resistance Welding", AWS C1.1; also, "Welding Handbook", 6th Ed., Section 2, American Welding Society, 1969. Published here by permission.

(a) Welding conditions in table are for 1010 steel, and for types 309, 310, 316, 317, 321 and 347 stainless steel. Surface of steel to be welded should be free from scale, oxides, paint, grease and oil. (b) Size of projection is normally determined by thickness of thinner piece, and projection should be on thicker piece where possible. Data are based on thickness of thinner sheet, and for two thicknesses only. (c) Projection should be made on workpiece of higher conductivity when dissimilar metals are welded. For diameter of projection *D*, a tolerance of ±0.003 in. in material up to and including 0.050 in. in thickness and ±0.007 in. in material over 0.050 in. in thickness may be allowed. (d) For height of projection *h*, a tolerance of ±0.002 in. in material up to and including 0.050 in. in thickness and ±0.005 in. in material over 0.050 in. in thickness may be allowed. (e) Contacting overlap *l* does not include any radii from forming. Weld should be located in center of overlap.

1, as in the following example, in which forming of projections on the thicker workpiece was too difficult.

Example 392. Projection Welding of a Steel Assembly in Which the Projections Were Formed on the Thinner Workpiece (Fig. 7)

The clutch mount for the compressor in an automobile air conditioner was made by projection welding a drawn ring with a 0.224-in.-thick wall to a mounting base 0.047 in. thick (see Fig. 7). Both components were made of 1010 steel. In the original design of the assembly, the projections were on the thicker (ring) section, as conventionally recommended. However, these projections were difficult to form, and the assembly was redesigned with the projections on the thinner (base) section. With the new design, satisfactory welds were made without burning the thin mounting base. Equipment details and welding conditions are given in the table with Fig. 7.

The projections were formed in pairs 120° apart on the contact surface of the mounting base. The projections in each pair were ½ in. apart.

The outside diameter of the ring was required to be concentric with the bolt circle on the mounting base within 0.010 in. TIR. This requirement was met by use of the fixture shown in Fig. 7. Four pins that extended upward from mounting blocks positioned on the base of the fixture passed through locating holes in the mounting base, while machined inner faces on the pin-mounting blocks located the outside diameter of the ring. To maintain the specified tolerances on the assembly, the outside diameter of the ring had to be held within ±0.005 in. in the forming operation. The diameter of the locating holes was held to +0.002, −0.001 in., and the diameter of the bolt circle was held to ±0.001 in.

The three upper electrodes were lowered to make the six welds simultaneously.

The finished assemblies were visually examined for weld nuggets. Destructive tests were made on two assemblies per hundred. For acceptance, five welds on each assembly tested had to pull buttons. The rejection rate due to weld failures was negligible. Assemblies were inspected for compliance with the concentricity requirement in a rotating fixture using a dial indicator. Samples were inspected on the basis of a 5% acceptable quality level. The welded assemblies consistently remained within tolerance, provided the components were within their assigned manufacturing tolerances.

Welding Schedules. Practice in setting up welding schedules for projection welding of work for which previous experience is lacking is generally the same as for resistance spot welding. A typical sequence of steps is described on page 417 in the article on Resistance Spot Welding.

Tables 1 to 7 in the present article give data on recommended practices for projection welding of low-carbon steel, which are intended to serve as starting points. (Table 2, which gives details of projection design, applies also to austenitic stainless steel.)

Electrodes, Welding Dies and Fixtures

An electrode designed for resistance spot welding can be used for projection welding if the electrode face is large enough to cover the projection being welded, or the pattern of projections being welded simultaneously, by the electrode. To minimize marking and indentation of workpieces, recommended electrode-face diameter for making a single projection weld usually is two or more times the diameter of the projection; in multiple-projection welding, the electrode face should be large enough to extend beyond the boundaries of the pattern of projections by approximately the diameter of one projection.

Table 3. Conditions and Joint Strength for Projection Welding Thin 1010 Steel Sheets of Equal Thickness, Using Annular Projections (a)

SOURCE: J. F. Harris and J. J. Riley, "Projection Welding Low-Carbon Steel Using Embossed Projections", *Welding Journal*, Apr 1961; reprinted as RWMA Bulletin No. 31

Simultaneous welding of a number of projections that are far apart requires a rigid electrode large enough to cover the projections and shaped so as not to deform tabs, flanges or other features of the component being welded. The use of a pivoted electrode that is properly designed and insulated to avoid excessive shunting may be helpful in some applications, as in Example 388. With proper fixturing, the accuracy attainable with projection welding is equal to that obtained with any other joining process.

Electrode Materials. Flat electrodes or local contact-surface electrodes usually have acceptable life when made from RWMA class 2, 3 or 4 materials. (See Tables 2 and 3, page 409, in the article on Resistance Spot Welding, for identification of electrode materials.) RWMA class 2 electrode materials are generally preferred because they provide the best compromise among electrical conductivity, strength, hardness, and temperature resistance.

If a harder electrode material or a material with lower electrical conductivity is needed, an economical solution is to use a composite electrode with copper backing and a copper-tungsten alloy facing. The facing material usually is RWMA class 10, 11 or 12. Classes 11 and 12 have lower electrical conductivity and higher hardness and strength than does class 10.

The ideal electrode material is one that is as hard as possible and that does not crack or cause surface burning on the weldment. If cracking or surface burning is encountered, a softer alloy with higher conductivity and ductility should be used.

In the examples in this article for which electrode materials are given, class 2 material was used in eleven applications, class 3 in six, class 11 in four and class 10 in one. (In some applications, upper and lower electrodes or inserts were of different materials.)

(a) For welding two equal thicknesses of metal. As thickness ratio increases, welding current and weld time are increased to obtain a sufficiently large nugget diameter and adequate penetration, and to minimize sheet separation. (b) Approximate shear strength of joint for each projection weld; shear strength varies with joint design. (SOURCE: Same as for Table 4)

Electrode Design. There are three basic types of electrodes used in projection welding:

1 Round, flat-face electrodes of the type used for spot welding
2 Large, flat-face electrodes of bar stock
3 Bar-type electrodes, in which a series of local-contact surfaces are made by relieving the bar between intended contact locations, or by brazing or clamping contact inserts of hard copper alloy to the bar. (Figures 2, 18 and 20 show electrodes of this type.)

Fig. 8. Setup for automatic projection welding of one or two arms to a base in the manufacture of relay armatures (Example 393)

Standard spot welding electrodes are used to weld single projections; electrode diameter is usually at least twice that of the projection.

Large flat-face electrodes are used for welding a few projections in a localized area, but they are not recommended for welding components that may be distorted from the projection-forming operation.

Bar-type electrodes usually can equalize current and force regardless of slight distortion or other variations in the workpieces, and are recommended for all multiple-projection welding, especially in applications that involve four or more projections.

Welding Dies and Fixtures. Welding dies hold and clamp the workpieces in correct alignment for welding, and also serve as electrodes or as holders for inserted electrodes or electrode buttons. Fixtures are auxiliary positioning devices that do not conduct current.

Welding dies and fixtures should be designed to meet these requirements:

1 Accurately position the workpieces.
2 Permit rapid loading and unloading. Air jets, levers or mechanical loading and unloading devices can be used. A combination of manual loading and automatic unloading is employed in many applications.
3 Allow initial workpiece contact at or near the weld, to provide the shortest possible current path between the electrodes, and to avoid energy losses from unnecessary resistive heating of thin sections of work metal in the current path.

Steel or other magnetic materials should not be used in fixtures for welding with alternating current, because they reduce the electrical capacity of the machine and heat up when within the secondary loop. Nonmetallic materials that have good strength and are electrical insulators, such as filled phenolics, help to avoid unintentional shunting of current, and are often used in fixturing for small parts.

Small parts can be located by the lower die, and larger parts by stops, pins or other types of locators. When a small part is to be located on top of a larger part, a removable gage can be used that locates the parts while the upper die makes the weld. Parts also can be held in the upper die by spring clips, plungers or vacuum.

Projection welding of assemblies that have long, thin components may demand special care in the design of fixtures. Heating must be concentrated at the weld interface, and to avoid waste of energy and overheating of workpieces, fixtures should be designed to provide electrode contact to the long, thin component as close as possible to the joint, as in the following example.

Example 393. High-Production Welding of a Relay Armature in Which Electrical Contact Was Made Near the Joint Surface To Prevent Overheating of Long, Thin Arms (Fig. 8)

The relay armature shown at upper left in Fig. 8 was made by projection welding the two arms to the formed base. Some of these armatures required only one arm, on either the left or the right side.

Fixtures for locating and clamping the components in proper relation were mounted on a rotary-indexing table (see view at right in Fig. 8), and an automatic welding

machine was designed that was capable of projection welding either or both arms to the armature base at a rate of 1500 assemblies per hour. The sequence of operations performed by the machine was as follows:

1 Load a left arm, a right arm or both arms into the fixture.
2 Detect presence of arm or arms.
3 Load base into fixture.
4 Detect presence of base.
5 Clamp components in fixture and weld.
6 Unload welded assembly.

During welding, air-actuated side clamps held the arms against the lower electrode, which was ¼ in. thick. Below this electrode, the fixture was recessed to restrict the current flow to the joint end of the arms. The cross-sectional area of the lower portions of the arms was not large enough to carry the welding current, and this arrangement minimized heat losses.

The upper electrode, shaped as shown in Fig. 8, was attached to the lower end of a spring-loaded inner shaft of an air-actuated ram on the welding machine. This low-inertia, fast-follow-up welding head, similar to that shown in Fig. 5, provided a precisely timed follow-up to complete the weld, and avoided undesirable arcing.

To help concentrate the welding current at the joint, an elongated projection was formed on the base in the area where each arm was to be attached (see sections B-B and C-C in Fig. 8). The sheared edges on the arm assisted in making a good weld.

The dimensions of the assemblies were checked after each lot of 500 had been welded. The welds were tested by bending the arms to the side or by twisting them; other destructive tests were made after each lot of 500 assemblies to determine tensile strength. Minimum breaking load was specified at 150 lb for each weld. The joints were tested to a load of 300 lb. If a weld failed in the range of 150 to 300 lb, the nugget was required to pull base metal over at least 50% of its area.

Equipment details, and conditions for welding single-arm and double-arm assemblies, are given in the table that accompanies Fig. 8. The electrode force, current and weld time were established to produce a weld nugget with a strength of 200 lb. The upper electrode was changed after welding each lot of 5000 assemblies.

Electrode Holders. In projection welding, electrodes are placed in holders similar to those used in resistance spot welding. The holders are for single electrodes, or for two or more electrodes. Holders for single electrodes can be used for both the upper and lower electrodes. Multiple-electrode holders, of either standard or special design, are generally used for the upper electrodes; electrode forces are equalized by springs, mechanical devices or hydraulic equalizers.

Hydraulic equalizers will transmit high forces equally to electrodes that are spaced closer than is permissible with mechanical linkage or spring-type balancers. The amount of electrode force that can be transmitted through mechanical or spring-type equalizers generally is low. Also, it is difficult to adjust spring-type equalizers so that the same force is exerted on the workpiece through each electrode. When electrode forces greater than about

Fig. 9. Projection welding of an automobile-jack base, in which a specially designed hydraulic-equalizing multiple-electrode holder was used to make four closely spaced welds simultaneously under high electrode force (Example 394)

1000 lb are used, the size of the spring and holder can limit the minimum center distance between the electrodes.

For the application in the next example, a special hydraulic-actuated multiple-electrode holder was designed that would equalize the high electrode force while making four closely spaced projection welds in thick workpieces.

Example 394. Use of a Specially Designed Multiple-Electrode Holder To Make Four Welds Simultaneously Under High Electrode Force (Fig. 9)

A base for an automobile jack was made as a projection weldment of two press-formed components: a base socket of 0.135-in.-thick 1008 steel, and a base of 0.105-in.-thick 1009 steel (see Fig. 9). Four projections were formed on a 3$\frac{9}{16}$-in.-diam circle on the lower side of the base socket.

Because the spacing of the projections was comparatively close for simultaneous welding with electrodes in separate holders, and because the thick work metal required use of high electrode force, a special welding machine with a hydraulic-equalizing upper-electrode holder that contained four electrodes was designed. Each of the electrodes was connected to a separate transformer, and all four welds were made simultaneously. The four transformers had a common ground attached to the lower-electrode assembly.

Force for all four upper electrodes was provided by a single air cylinder. The hydraulic equalizer consisted of a main chamber with four pistons arranged in a keystone-shape pattern coinciding with that of the four projections (approximately 2$\frac{3}{8}$ in. apart). Each piston was hardened and contained an O-ring and a leather backup washer. A hardened keeper-plate limited piston travel and prevented rotation of the piston due to pull from the inductive field created by the adjacent electrode feeder shunts. A flange on the end of each piston was used for attaching a copper alloy electrode holder. Fiber bushings and washers electrically isolated the electrode holder from the piston. The top contained a reservoir for the hydraulic fluid and was fastened to the piston rod of the air cylinder. The equalizing head was initially charged with molten petroleum jelly to facilitate bleed-off of entrapped air. Replacement of the petroleum jelly was done through a high-pressure grease fitting using a grease gun. A needle-type shutoff valve protected the grease fitting from the high operating pressure. Petroleum jelly was used as the hydraulic fluid because it was viscous enough to keep the piston from moving too far from working position between strokes but not viscous enough to extend unduly the time needed to balance the force during the working stroke.

The upper electrodes, made of RWMA class 2 material, were attached to the holders through adapters that provided for water cooling of the electrodes. The lower electrode was a large copper block with replaceable inserts of RWMA class 11 material (copper-tungsten alloy) under each weld location. The lower-electrode block had a locator for positioning the base socket. Although the components had matching tabs and holes for final location, the frame for an automatic unloading device was used as an approximate locator when the base was placed on top of the base socket.

The assembly was welded in the inverted position, as shown in Fig. 9. Equipment details and welding conditions are given in the table with Fig. 9. Production rate was 750 pieces per hour.

The welds were tested several times each hour by inserting a wedge between the welded surfaces with a hydraulic jack. The separated nuggets were required to be at least $\frac{1}{8}$ in. in diameter.

Assemblies per hour	200 (1000 welds)

Fig. 10. Projection welding of a can to a tube, in which cooling-water passage in lower-electrode support was enlarged to prevent overheating of lower electrode in continuous production (Example 395)

Current Path. Arrangement of work, projections, electrodes and fixtures so as to provide the shortest possible current path from one electrode through the work at the desired weld point to the other electrode, as in Example 395, is also important in the projection welding of bar stock to sheet metal, as shown in Examples 396, 397 and 407.

Cooling of Electrodes and Dies. Water cooling, either directly on or within the electrode or die, is used to avoid overheating of dies and workpieces. The water passages should be located as close as possible to the face of the electrode (or the die) without weakening this component.

In projection welding, the rate of operation of the equipment has an important bearing on the quality of the welds produced. If the equipment, especially welding dies and electrodes, does not have sufficient cooling time between welds, the quality of welds deteriorates as the equipment gets hotter. Equipment must be able to dissipate at least as much heat as is generated by the welding process. This can be arranged by the often undesirable expedient of slowing the production rate to increase the cooling part of the cycle. If the production rate must be maintained, the passages for cooling water in the electrodes can be enlarged, as long as adequate electrode strength is retained, as was done in the example that follows.

Example 395. Use of an Enlarged Cooling-Water Passage To Limit Heat Buildup in a Lower Electrode (Fig. 10)

Five projection welds were made simultaneously in joining a flanged tube and a deep drawn can, as shown in Fig. 10. Equipment details and welding conditions are given in the table that accompanies Fig. 10.

The current (32,000 amp) needed to make the five welds simultaneously produced more heat in the lower electrode than could be dissipated in continuous production at the required rate of 200 assemblies per hour, and the lower electrode burned out after making 400 to 500 assemblies, or in a little more than 2 hr. When time was taken to change electrodes, the production rate could not be maintained.

To prevent overheating, the cooling-water passage in the support for the lower electrode was enlarged.

The upper electrode was a simple cylinder of RWMA class 3 material, 1 in. in diameter and $\frac{5}{8}$ in. thick, and was attached to a swivel mounting. Both the lower electrode and the lower-electrode support, mounted on a fixture that could be rocked out on a hinge to change workpieces, were annular in shape to fit the space between the can and the tube. Insulation prevented contact between the lower-electrode assembly and the tube, and three insulated stainless steel wear shoes were used for locating the can. The insulated shoes were fastened to the lower-electrode support with nylon screws. Electrodes were removed and re-dressed after every 4000 assemblies, or after every 20 hours of operation, and were re-dressed two or three times before being replaced.

Each assembly was visually inspected for fusion at each projection. A full weld nugget was required on at least two of the five projections. No definite scrap rate was established because the rate was so low.

Projections

The size and shape of projections depend on the application and the required weld strength. Properly proportioned projections localize or concentrate the welding current, accurately control the location of welds, and ensure uniformity of weld nuggets. Projections often are spaced to give a three-point bearing. Three projections readily equalize themselves and give uniform contact with the mating workpiece if the electrodes are in reasonable alignment. For best results, the three projections usually are equally spaced and, on circular workpieces, are located radially, as far as possible from the axis of the workpiece.

Design of Projections. Proper projection design helps to provide consistent results and to reduce breakage of

forming tools. Following are some criteria for designing projections:

1 They should be easy to form without distorting the workpiece.
2 When projections are formed in sheet-metal parts, the metal in and around the projection must not be cracked or made markedly thinner.
3 The projection should be strong enough to support the initial electrode force before the current is applied.
4 The projection should collapse during welding without excessive expulsion of metal, leaving the two components in intimate contact.

Types of Projections. The five basic types of projections — spherical, elongated, annular, pyramidal and cross-wire — are shown in Fig. 11, along with two special types of projection welds for which conventional projections are not used. All types will produce strong welded joints if properly selected and applied.

Spherical projections are recommended for welding assemblies made of steel sheet and plate. They also can be coined or forged on the ends or faces of screws, nuts and similar fasteners. Several projections can be used, as in Fig. 11(b), or a single large, gently radiused projection can cover the entire face of the mating workpiece, as in Fig. 11(c). Details of size, overlap and strength of conventional spherical projections are given in Table 2. Recessed spherical projections are shown in the illustration accompanying Table 4, page 441, which gives dimensions for recessed projections used in welding steels of different thicknesses.

Elongated projections often are used instead of spherical projections where the shape of the parts makes an elongated weld more suitable, and where welds made with spherical projections will not meet strength requirements. For a given work-metal thickness, the height of an elongated projection should be approximately the same as the height of a spherical projection, the width should be approximately equal to the diameter of a spherical projection, and the length should be made to suit the application — usually two to three times the width.

Figure 11(d) shows an elongated projection that has been embossed in a sheet metal part. This type of projection was used in welding the flat base of a relay armature to the 0.083-by-0.22-in. end of the relay arm in Example 393, and in welding the rim of a brake-shoe assembly to the edge of a 5⁄32-in.-thick web in Example 391. The use of elongated projections on sheet metal that is to be welded to the sidewall of a tube or other cylindrical workpiece is described on page 447 and illustrated in Fig. 14. Elongated projections also can be coined or forged on fasteners, as in Fig. 11(e). Another type of elongated projection, of which the full width and height extend to the edge of a sheet metal part that is to be welded to the edge of a mating part, is shown in Fig. 11(f).

Annular projections are used for welding tubing to sheet metal, as shown in Fig. 11(g). (See Fig. 15, and the section on Projection Welding of Tube to Sheet Metal, page 447.) Annular projections are also used for joining sheet metal parts, particularly thin parts, where spherical projections may collapse prematurely during welding (Fig. 11h), and for making liquid-tight or gastight connections, as in attaching mounting studs to housings (Example 407). Accurate alignment of electrode faces is especially critical when annular projections are used.

In welding bar stock or screw-machine parts to sheet or plate in a joint such as the one shown in Fig. 11(j), the shape of the parts in the annular region of contact serves the function of a conventional projection.

Pyramidal projections coined or forged on the face of a nut are shown in Fig. 11(k) and (m).

Cross-wire welds (Fig. 11n) are used in making various wire products. No separate projection is formed; the shape of the wires produces point contact where the wires intersect, and functions as a projection. (See the discussion in the section on Cross-Wire Welding, page 448.) Round wire is welded to flat stock, using line contact.

In addition to cross-wire welds (as shown in Fig. 11n and Examples 398, 399, 403 and 404) and annular welds on pin-and-tenon joints (as shown in Fig. 11j and Examples 396 and 397), other types of joints also can be projection welded without the use of conventional projections. In Example 406, the curved outer surface of a steel tube functioned as a projection in welding the tube to the flat end of a cylindrical slug.

Spacing of Projections. The minimum spacing of projection welds can be somewhat less than that of spot welds because during projection welding the current is concentrated on a smaller area. The minimum spacing between projections is twice the projection diameter. A spacing substantially greater than the minimum is often used, to make embossing of the projections easier.

As shown in Tables 2 and 5, the recommended minimum contacting overlap for projection welding is from 2.3 to 2.8 times the projection diameter.

Projection Welding of Sheet Metal Parts

The principal uses of projection welding are those in which blanked, stamped and formed sheet metal parts are joined with the aid of projections that have been produced during the stamping or forming operation. Spherical and elongated projections are the types most commonly used for welding sheet metal parts; however, annular projections are used in welding parts less than 0.020 in. thick and in applications where gastight or liquid-tight connections are needed.

Thin workpieces, from 0.010 to 0.021 in. thick, can be projection welded using carefully designed projections and welding machines that have rapid

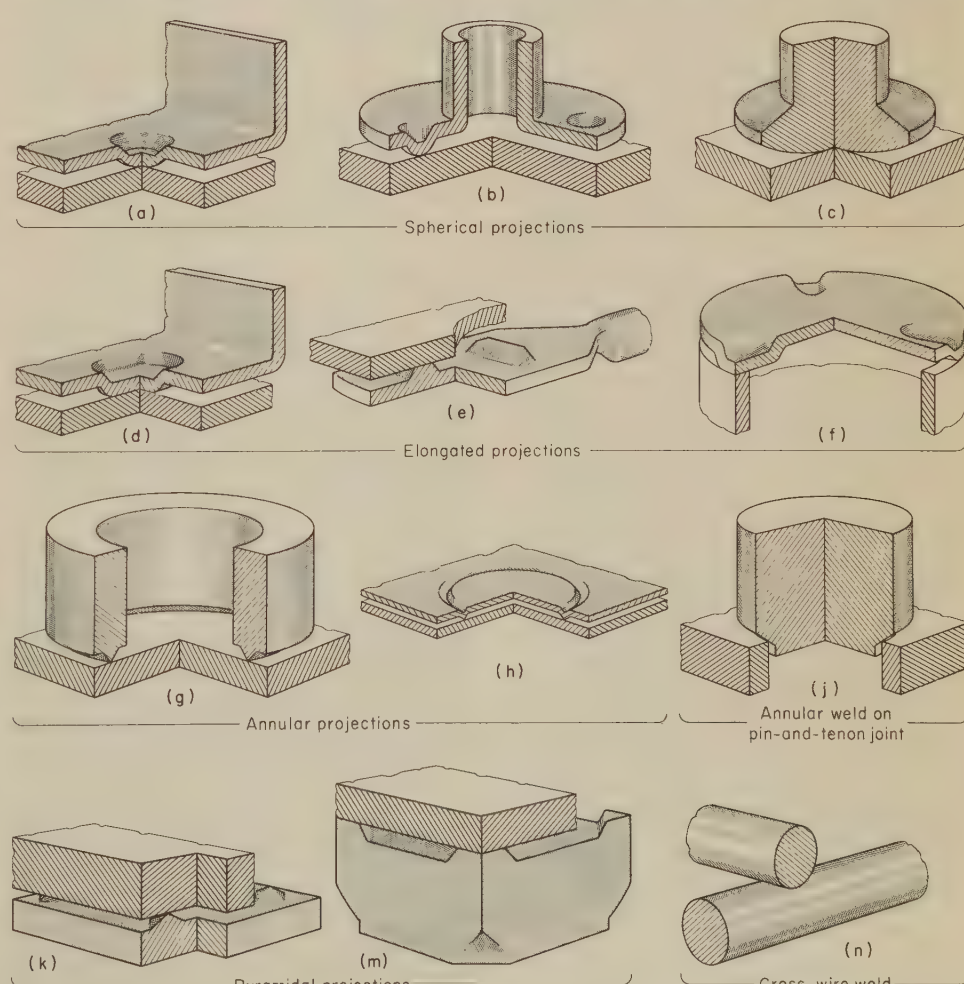

Fig. 11. Variations on basic types of projections. See text for discussion of application.

follow-up. The short time required to heat a spherical projection to welding temperature and the relatively small height of spherical projections necessitate extremely fast follow-up of the electrode. However, electrode force need not be as high as for welding thicker work metal. Lack of rigidity in the projection and lack of resistance to collapse before the welding current has been applied require careful adjustment of the initial electrode force.

The annular projection shown in the illustration with Table 3 has greater resistance to cold collapse, and can be used in place of a spherical projection for welding thin sheet metal parts. The welding conditions listed in Table 3 are for welding 1010 steel 0.0105 and 0.0179 in. thick using annular projections. The 6-cycle (0.1-sec) weld time shown allows latitude in selection of electrode force and welding current.

Intermediate-thickness workpieces, from 0.022 to 0.135 in. thick, are the most adaptable to projection welding. Workpieces up to 0.135 in. thick are more easily welded and more commonly used than workpieces greater than 0.135 in. in thickness. Table 1 gives recommended conditions for welding low-carbon and low-alloy steel in thicknesses up to 0.125 in. with one projection. For multiple-projection welding, electrode force and welding current are increased in direct proportion to the number of projections.

Thick Workpieces. Projection welding of workpieces 0.136 to 0.250 in. thick is limited because of the large equipment and the high power required. Welding in this thickness range generally results in an increase in weld porosity, an increase in sheet separation because of the difficulty of obtaining complete projection collapse, and an increase in expulsion of metal because the large machines needed usually have sluggish follow-up.

Weld porosity is difficult to eliminate, but can be minimized by using a lower electrode force during welding to reduce the current required and to prevent premature projection collapse, and by applying forge force immediately after the weld time. The use of pulsation timing may also be helpful.

Expulsion of metal resulting from sluggish ram movement can be compensated for by using upslope control to increase the current gradually during weld time. This procedure decreases the rate of follow-up needed to maintain proper welding force.

Sheet separation is minimized through the use of either forge force or a recessed type of projection. The illustration with Table 4 shows a recessed projection, and the table gives dimensions for recessed projections in low-carbon steel 0.123 to 0.245 in. thick. The tools needed for making recessed projections have short life, and because this type of projection is coined and not embossed, press capacity for making a projection in 0.250-in.-thick low-carbon steel must be about 30 tons.

Recessed projections limit weld strength. The metal that flows into the recess does not contribute appreciably to weld strength, but the recess permits complete collapse of the projection at lower electrode forces than are

Fig. 12. Platen-frame assembly projection welded using a pin-and-tenon joint to allow efficient handling in high production and to minimize penetration in free-machining 1213 steel pins (Example 396)

needed for collapsing conventional spherical projections.

Suggested projection size and welding conditions for projection welding two equal thicknesses of low-carbon steel from 0.153 to 0.245 in. thick using normal-size and small-size projections are given in Table 5. Dimensions given for normal-size projections are slightly different from those given in Table 2. The small-size projections can be used when two or more are needed, or to reduce the welding-machine size and the power requirements.

A special technique that is sometimes used in low-production projection welding of thick work metal is to insert a slug of metal between two flat workpieces to serve as a projection, thus avoiding the difficulties and cost of producing a conventional projection.

Workpieces of unequal thickness are projection welded about as often as are workpieces of equal thickness. Projections can be placed in either workpiece, although weld properties are less affected by variations in welding conditions if the projections are formed in the thicker component; this was done in Example 405, where the two components had a thickness ratio of 3 to 1. In welding workpieces in thickness ratios greater than 3 to 1, it may be more practical to place the projection in the thinner component, as was done for a clutch mount in Example 392.

The conditions listed in Tables 1 and 2 can be used for welding workpieces of unequal thickness. The welding current and weld time may have to be increased to obtain a sufficiently large nugget diameter and adequate penetration, and to minimize sheet separation. The added energy increases both the diameter of the nugget and the shear strength of the joint.

Projection Welding of Bar Stock to Sheet Metal

Projection welding of bar stock to sheet metal can be done easily if the parts and projections are correctly designed. Fasteners such as pins, studs and nuts are welded to sheet metal using spherical (Fig. 11a, b and c), pyramidal (Fig. 11k and m) and annular (Fig. 11g and h) projections, as an alternative to attaching them by stud welding or percussion welding.

Provision must be made for holding the component made of bar stock so that it can be welded at the correct angle with the mating part and so that the current path is as short as possible. Flow of current through a long slender shaft should be avoided, when possible, by applying the current to the shaft near the weld area.

In Example 407, in which a headed stud was welded to a sheet metal housing, an annular projection was formed on the underside of the head, and the shank of the stud was passed through a hole in the housing. Thus the upper electrode contacted the top of the head and provided a short path for the welding current.

In another type of joint design, as shown in Fig. 11(j), a tenon on the end of the pin acts as a pilot for inserting the pin into the hole in the sheet metal part, and an adjoining conical tapered section makes annular contact with the sharp edge of the hole, which localizes the current and heating. This joint design, which was used in Examples 396 and 397, facilitates fixturing and assembly, and is well suited to high-production welding in semiautomatic and automatic resistance welding machines.

In Example 396, three pins were projection welded at both ends to two platens 1.25 in. apart, making six welds at once, with the electrodes directly above and below each pin. In Example 397, in which a shaft was welded to a plate, a short current path was provided by resting the upper electrode on the plate and clamping the lower electrode to the shaft below the plate.

Besides being well suited to high-production welding, this type of joint permits the use of free-machining steel in the pin or shaft, because it allows close control of heating and a minimum of penetration into the pin or shaft, thus avoiding weakness and porosity that would result from segregation of sulfur or phosphorus in the free-machining steel during welding.

The use of this type of joint design (Fig. 11j) to allow high-production welding of free-machining steel is described in the next two examples.

Example 396. Use of Pin-and-Tenon Joint With a 45° Bevel To Allow High-Production Projection Welding of Free-Machining Steel to Low-Carbon Steel (Fig. 12)

The platen-frame assembly shown in Fig. 12 consisted of two end plates made of cold rolled low-carbon steel and three 5/16-in.-diam separating pins made of free-machining 1213 steel. Although 1213 steel generally is unsuitable for resistance welding, it was used for the pins because most of the molten metal for the welds was provided by the low-carbon steel plates, and because machining time was about half that for non-free-machining steel.

A 45° bevel on the pin between the 3/16-in.-diam tenon and the 5/16-in.-diam body of the pin was used to contact the sharp edge of the hole in the end plate, and thus the sharp edge acted as a projection and was melted to make the weld (see section A-A in Fig. 12). Penetration into the free-machining steel, inclusions in the weld nugget, and dilution of the low-carbon steel, which would destroy the bonding properties of the weld metal, were minimized.

The six welds were made simultaneously, using the equipment and welding conditions given in the table with Fig. 12. To make the six welds simultaneously, the lower electrodes were fixed in position while the vertical positions of the upper electrodes were hydraulically equalized to compensate for variations in pin length and electrode wear. The welding fixture included locating pins that fitted tightly into the two pairs of locating holes shown in Fig. 12 to maintain alignment of the two platens during welding.

One weldment from every hundred was checked by the operator in a go/no-go gage for dimensional accuracy. One of each 300 weldments was tested to destruction. Each of the broken welds was required to show evidence of torn metal.

Previously, these platen-frame assemblies had been joined by riveting over the ends of the pins. Riveting required 12.98 hr per 100 assemblies, whereas projection welding required only 2.38 hr. Because annual production was 30,000 assemblies, the change to projection welding resulted in a saving of 3180 hr per year.

Projection welding required the purchase of a new resistance welding machine ($10,000) and welding dies ($3000), but these expenditures were outweighed by the saving in time and also by a saving in material. The saving in material was obtained because the added strength and rigidity of the projection welded assembly allowed a reduction in the number of pins per assembly from four to three.

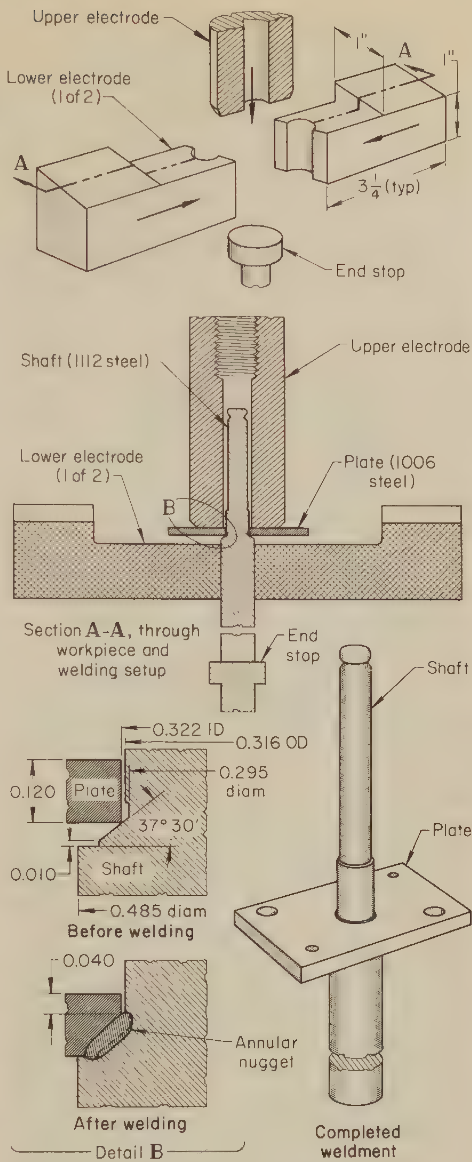
Example 397. High-Speed Automatic Projection Welding of a Free-Machining Steel Shaft to a 1006 Steel Plate, Using a Pin-and-Tenon Joint With a 37° Bevel (Fig. 13)

The plate-to-shaft assembly shown in Fig. 13 was made in an automatic resistance welding machine equipped with a four-station indexing turntable. Before welding, as shown in detail B in Fig. 13, the edge of the hole in the plate rested on the conical land on the shaft.

In the first station, the large-diameter end of the shaft was placed in the lower electrode; in the second station, the plate was dropped onto the shaft; in the third station, the upper electrode was lowered to contact the plate, and the joint was welded; and in the fourth station, the weldment was ejected.

As shown in detail B in Fig. 13, an annular weld nugget was formed by fusion of metal from the lower edge of the hole and from the contacting region of the beveled portion of the shaft. Also, plastic metal was forced into the 0.295-in.-diam recess in the shaft, reinforcing the joint.

As shown in Fig. 13, the upper electrode surrounded the small-diameter end of the shaft and bore against the plate when in welding position, and two lower electrodes



Equipment Details

Welding machine	Automatic, with four-station indexing turntable
Rating at 50% duty cycle	100 kva
Current, max	65,000 amp
Heat control	Eight-tap transformer and phase shift
Electrode material	RWMA class 3
Electrode force, max	2300 lb, approx

Welding Conditions

Welding current, approx	45,000 amp
Welding voltage	7.8 v
Electrode force	1550 lb
Squeeze time (including machine delay time)	99 cycles
Weld time	6 cycles
Hold time	11 cycles
Production per hour	666 assemblies

Fig. 13. Free-machining steel shaft and steel plate that were automatically projection welded together in mass production, producing an annular weld at a pin-and-tenon joint (Example 397)

centered and clamped the shaft. An end stop kept the shaft from moving downward under the force of the upper electrode.

Originally, an angle of 26° was specified for the conical land on the shaft, but with this angle satisfactory welds were not always produced. Use of a 37½° cone angle and the welding conditions given in the table with Fig. 13 produced sound welds. A few faulty welds were caused by a short between the shaft and the upper electrode.

Weldments were tested during setup, to establish the welding conditions, and tests were made after welding each production run of 500 assemblies. The tests consisted of placing the small end of the shaft on an anvil and striking the ends of the plate until they were bent 30°. Welds that did not break were considered satisfactory. This test was preferred to a tensile-load test in which the plate was pushed off the shaft, because the tensile-load test could be passed by weldments that were pressure bonded but that lacked adequate fusion to withstand fatigue loading.

After each 15,000 welds, the electrodes were removed from the machine and dressed by grinding. The two lower electrodes required grinding in sets. Equipment details and welding conditions are given in the table with Fig. 13.

Projection welding of powder metallurgy parts (sintered compacts) is similar to projection welding of free-machining steel in that penetration into the sintered metal must be kept to a minimum. In joining sintered iron to 1010 steel in Example 402, this was accomplished by producing an annular weld nugget at the contact line between the sharp edge of a hole in the steel and the beveled surface of a specially formed truncated conical boss on the sintered iron.

Projection Welding of Tube to Sheet Metal

Standard tube and pipe, and other parts of cylindrical shape, can be projection welded to sheet metal at the sidewall or at the end of the tube. The sidewall of a tube can be welded to sheet metal using elongated projections embossed in the sheet metal component, as shown in Fig. 14. The elongated projection provides localized con-

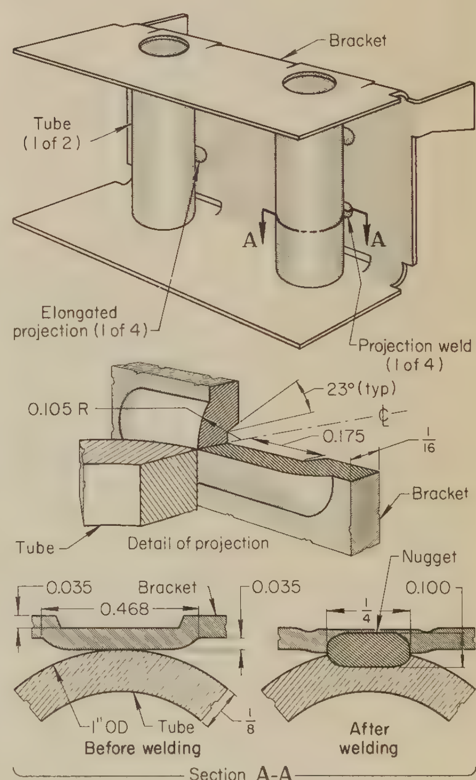


Fig. 14. Projection welding of the sidewalls of tubes to a sheet metal bracket using elongated projections formed in the sheet

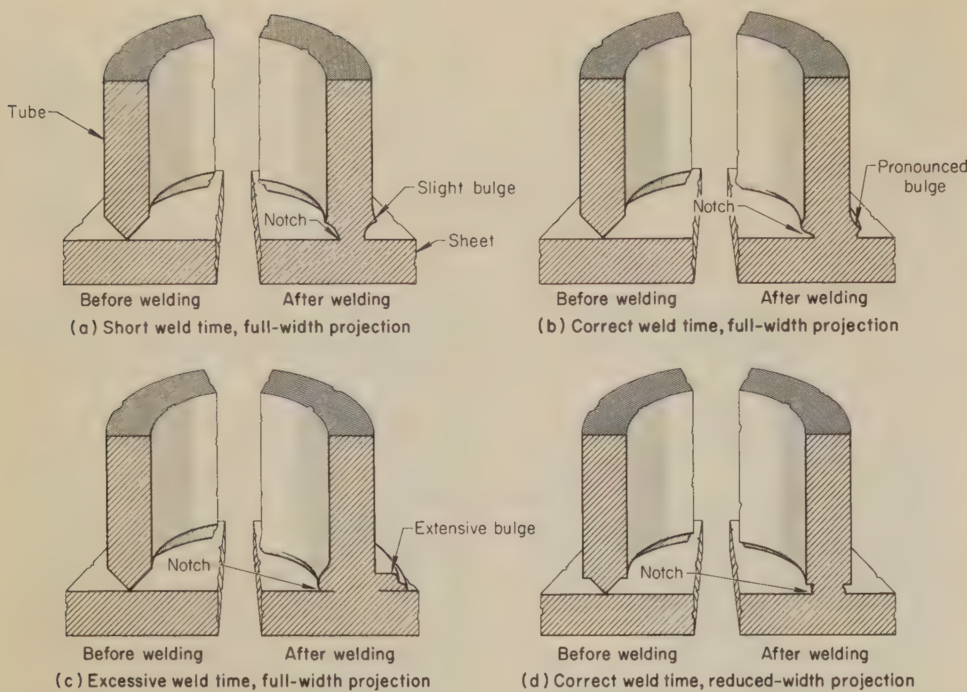

Fig. 15. Effects of weld time and width of annular projection on appearance of tube-to-sheet welds (J. J. Riley and J. F. Harris, "Annular Projection Welding of Tubular Sections to Low-Carbon Steel Sheet", *Welding Journal*, July 1966; reprinted as RWMA Bulletin 35)

tact with the tube and requires less accurate positioning than does a spherical projection.

The end of a tube can be welded to sheet metal by the use of annular projections, which results in uniform, liquid-tight welds. Annular projections are easily machined on tube ends.

Projection Shape. Strength and final appearance of tube-to-sheet welds depend principally on projection shape and welding conditions. The recommended projection, referred to as a full-width projection, has a 90° included angle machined to intersect both the outside and inside surfaces of the tube, and a base width equal to wall thickness (Fig. 15a). A reduced-width projection, which has a base width less than wall thickness (Fig. 15d and Fig. 11g), can be used to minimize deformation of the tube wall.

The appearances of tube-to-sheet welds made with full-width annular projections using short, correct and excessive weld times are shown in Fig. 15(a), (b) and (c). The appearance of a weld made with the correct weld time and a reduced-width projection is shown in Fig. 15(d).

Figure 15(a) illustrates the use of a short weld time to avoid full collapse of the projection. During welding, the outside diameter of the tube is slightly increased at the top of the projection.

With a longer weld time, width of the weld produced is approximately equal to the wall thickness of the tube. As shown in Fig. 15(b), the outside diameter of the tube is increased, and the inside diameter is decreased, at the top of the projection.

The appearance of a weld made with excessive weld time is shown in Fig. 15(c). Flow of the weld metal is restricted in the vertical direction by the clamping electrode, and a well-defined horizontal weld-metal surface is formed around the outside of the tube. Bulging of the weld metal inside the tube is uniform and blends into the tube wall. The weld metal that bulges beyond the original inner and outer tube walls is not subjected to enough electrode force to become properly bonded, and therefore does not add to weld strength.

The reduced-width projection shown in Fig. 15(d) can be used to minimize deformation of the tube wall. The weld width is less than the thickness of the tube wall, and the shape of the weld metal generally is symmetrical about the initial-contact circle.

Regardless of weld time, initial joint preparation or width of the projection, a notch is visible at the intersection of the inner tube wall and the surface of the mating workpiece (see Fig. 15). Unless weld time is excessive, a notch is visible also at the intersection of the outer tube wall and the mating workpiece. There is always some bulging of the weld metal beyond the original inner and outer tube walls when intended weld width approaches wall thickness.

Heat Balance. The two components of a tube-to-sheet joint in which an annular projection is used have different configurations, which can cause unbalanced heating. The welding current flowing through the tube wall near the weld interface heats the tube wall enough to prevent heat loss to this area from the weld interface during welding. However, as the current leaves the projection and enters the sheet, heat starts to flow away from the weld area into the surrounding cold metal. Heat flow in the sheet is limited by its thickness and thermal conductivity. In general, heat loss by thermal conduction is not a major problem in projection welding of low-carbon steel using annular projections.

As sheet thickness increases beyond tube-wall thickness, the assembly becomes increasingly difficult to weld because additional time or welding current is needed to bring the contacting surfaces to welding temperature. The tube wall behind the weld interface collapses more readily because of a large heat-affected zone, and metal expulsion increases during welding.

Electrode Design. The electrodes that clamp the tube should be designed to make contact at two areas — one near the weld for electrical contact and the other near the top of the tube for alignment. This arrangement localizes the welding current near the weld and helps to hold the tube perpendicular to the sheet so that the apex of the projection is in uniform contact with the sheet. Clamping force causes the tube to conform to the electrode shape so that current density is uniform at the electrode contact surface.

If the welding current is unevenly distributed around the tube, unequal heating can occur at the weld interface. If localized melting occurs on the tube near the edge of the electrode, the electrode-contact surface must be enlarged or made uniform by remachining the electrode or the tube. Other alternatives are increasing the clamping pressure, or removing scale, varnish or other foreign material from the surface of the tube, to reduce contact resistance.

The initial extension of the tube from the clamping electrode should be about twice the wall thickness. Longer extensions may cause more heating and upsetting during welding, which can decrease the weld pressure because of a larger weld interface.

Weld Strength. Tube-to-sheet weldments, when tested to destruction, can fail in the tube wall, in the weld, or by tearing a slug of metal from the sheet around the weld circumference. Those assemblies in which the sheet thickness is equal to or greater than tube-wall thickness can be expected to fail at the interface because the sound weld area is smaller than the cross-sectional area of the tube.

The tensile strength of properly welded joints made with reduced-width projections is nearly the same as that of joints made with full-width projections, whether failure in testing is at the interface or in the base metal.

Cross-Wire Welding

Resistance welding of crossed wires, generally in a grid arrangement in which a number of parallel wires are welded at right angles to one or more other wires, is a form of projection welding. Cross-wire products can be welded in a press-type resistance welding machine using a welding die or special individual electrodes.

If the wires are close together, a seam welding machine can be used. The wires are assembled in a fixture and the current-carrying member of the fixture can be placed on a lower platen or can contact the lower electrode wheel. The upper electrode wheel contacts the upper tier of crossed wires. Welding current flows continuously and weld time for each cross-wire weld is determined by the speed of the electrode wheels.

Resistance between electrodes and work metal should be uniformly low to minimize power loss and surface damage, but resistance between faying surfaces should be uniformly high to concentrate heat for welding. Grooved electrodes provide low contact resistance between electrode and work metal. The point contact resulting from the shape of the crossed wires provides high resistance at the work-metal interface. Bars that are square, rectangular or hexagonal in cross section can be cross-wire welded if positioned so that the joint is formed by edges, rather than by flat surfaces.

Wires or bars from 0.020 to ½ in. in diameter have been cross-wire welded. The upper and lower limits of wire diameter are governed mainly by the capability of accurately controlling the welding current and the electrode force for small-diameter wires, or of providing adequate current and force for large-diameter wires.

Metals Welded. Low-carbon steel, stainless steel, copper, and nickel-base alloys such as Monel are among the metals commonly cross-wire welded. Table 6 gives recommended conditions for welding low-carbon steel wire.

Type 304 stainless steel requires the same weld time, 60% of the current and 2½ times as much electrode force as is needed for welding low-carbon steel (see page 464 and Table 7 in the article on Resistance Welding of Stainless Steel), whereas Monel requires the same weld time and current but twice the electrode force.

Cross-wire welding of galvanized and cadmium-plated wire can be done, but destroys the plating surrounding the weld. Also, welding of cadmium-plated metal requires special safety precautions because of the high toxicity of cadmium vapors.

Electrode force needed for a cross-wire weld depends on wire diameter, setdown requirements (the amount the wires are to be embedded into each other), desired appearance and required weld strength.

The values of electrode force, weld time and current given in Table 6 will produce strong welds with good appearance. Lower forces can be used with longer weld times, but weld strength may decrease.

Weld time depends mainly on wire diameter. Consistent results are obtained by using synchronous timing control.

Welding current depends on wire diameter, setdown requirements and weld time. The welding current selected should be slightly less than that resulting in expulsion of hot metal.

Electrode Design. Flat electrodes or dies can be used for cross-wire welding, but electrodes or dies that are grooved to fit the diameter of the wires provide better contact between electrode and workpiece. A suitably grooved electrode reduces contact resistance at the electrode-wire interface and minimizes arcing and excessive marking of the wires. Alignment is critical for producing consistent welds.

Examples of Practice. In the following example, resistance cross-wire welding with grooved electrode faces partly replaced shielded metal-arc welding in producing cage assemblies.

Example 398. Partial Change From Shielded Metal-Arc to Resistance Cross-Wire Welding To Reduce Production Time and Costs (Fig. 16)

The cage assembly shown in Fig. 16 was one of three put together to form a protective guard for a twister winder used in the textile industry for making thread. The components, made from $\frac{5}{16}$-in.-diam 1118 steel bar (except for the base ring, which was made from ¼-by-½-in. 1018 steel bar), were cut to length, shaped and fitted.

Originally, the cut, formed and fitted bars were joined at all contact points by shielded metal-arc welding. The resulting welds were then ground smooth. When arc welding was replaced by resistance cross-wire welding for making all welds not involving the base ring, rejects were eliminated, weld strength was adequate, appearance was improved, and both production time and costs were reduced.

In the improved method, the ends of the two upright members, one end of each of the two diagonal braces, and three brackets (not shown in Fig. 16) were shielded metal-arc welded to the base ring while the components were clamped in a welding fixture. The assembly was then placed in an aluminum alloy fixture, where 15 resistance cross-wire welds were made, joining the three horizontal rings to the diagonal braces and to the upright members.

An aluminum alloy was used for the fixture material because aluminum is light and easily handled, and because it is nonmagnetic and thus has no effect on resistance and reactance, regardless of the amount introduced in the throat of the machine.

The electrodes for resistance welding were notch contoured, as illustrated in Fig. 16. The cage bars were placed in these notches and were forced together to make the weld. The notches were shallow enough to avoid contact and short circuiting between the electrode and the opposing bar.

When all welds were made by shielded metal-arc welding, the cost of producing a three-cage assembly was $169.38. When resistance welding was used for joining the horizontal rings to the diagonal braces and the upright members, cost was reduced to $138.84, for a saving of $30.54. Also, production time for a three-cage assembly was reduced by 2½ hr, because resistance welding was faster than shielded metal-arc welding, and because postweld grinding was not needed to clean the assembly.

All joints were inspected visually for weld soundness. The three cage assemblies, all made in much the same manner, were joined with bolts and hinge pins to form the completed protective guard, which was then painted.

Equipment details and welding conditions for cross-wire resistance welding are given in the table with Fig. 16.

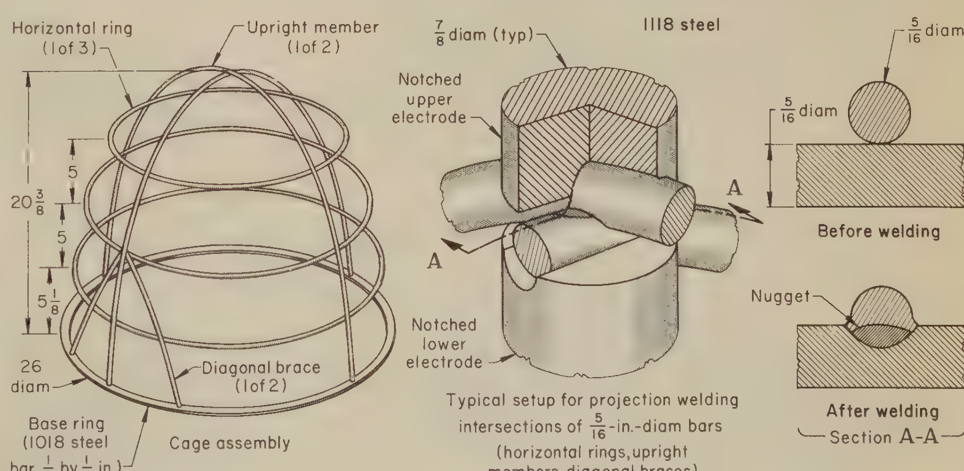
Techniques have been developed for welding crossed wires that have a plastic coating or are separated by a thin layer of plastic. During the squeeze time, sufficient electrode force is applied to cause the wires to penetrate the plastic material and make electrical contact. Sometimes, the penetration can be facilitated by preheating the electrodes by the use of a special heating circuit; in the example that follows, no preheating was needed.

Example 399. Projection Welding of Crossed Wires Through a Sheet of Plastic To Produce a Circuit Board (Fig. 17)

The circuit board shown in Fig. 17 was produced by projection welding crossed 0.020-in.-diam Nickel 200 wires that were separated by a sheet of Teflon or similar plastic 0.010 in. thick. A specially designed 5-kva spot welding machine equipped with a heat-programed timer was used for making the welds through the plastic sheet. Optimum welding current and electrode force were determined experimentally. Both upper and lower electrodes were made of RWMA class 3 material.

The electrode force of 23 lb exerted on each pair of crossed wires corresponded to a local pressure of about 7500 psi, which was sufficient to cause the wires to penetrate the layer of plastic and make electrical contact. Other plastic materials that were found to have sufficiently good cold flow characteristics for use in this application included polyethylene.

The transverse and longitudinal wires were assembled in a grid wireholding fixture. Spacing of parallel wires in both directions was 0.100 ± 0.005 in. Some welds were made to hold parallelism of wires, and others were made to stop off unneeded wires. The portion of a wire not needed in the circuit was removed by piercing a hole through the plastic sheet at the wire-cutoff



Welding machine ....Three-phase manually operated resistance	Electrode force ....700 lb
Rating at 50% duty cycle ....100 or 150 kva	Squeeze time ....25 cycles
Electrodes ....⅞-in.-diam RWMA class 2	Weld time ....4 cycles
Welding current ....1000 amp	Hold time ....18 cycles
	Production rate ....2 cages per hour(a)

(a) Includes 15 cross-wire resistance welds on $\frac{5}{16}$-in.-diam 1118 steel bars and 8 shielded metal-arc welds on ¼-by-½-in. 1018 steel base ring for each cage.

Fig. 16. Textile-machine cage for which partial change from shielded metal-arc welding to cross-wire resistance (projection) welding under conditions given in table reduced production time and costs (Example 398)

point (see detail A at lower left in Fig. 17). The welded circuit board was later encapsulated in plastic to maintain dimensional tolerances and strength.

Parallelism and perpendicularity were measured mechanically; wire positions were held to ±0.005 in. Weld strength was tested by making sample cross-wire welds and pulling the welded crossed wires into a straight line. Production rate was 10,000 cross-wire welds in 8 hr (including testing). Total cost, including testing, was $0.32 per 100 welds plus $0.33 per circuit for setup time.

Methods of controlling the quality of cross-wire welds are described in Examples 403 and 404. In Example 403, wire tensile strength was closely controlled to ensure repeatability of cross-wire welds. In Example 404, wire-inductance tests were used, in place of destructive pull tests, to save time in determining weldability.

Projection Welding of Dissimilar Metals

Metals differing in thermal and electrical conductivity can be projection welded, provided the surfaces being welded are brought to welding temperature simultaneously. This usually can be done by forming the projection in the higher-conductivity metal, by using a low-conductivity copper-tungsten electrode (class 10, 11 or 12) in contact with the higher-conductivity metal, or by combining these two conditions.

If the conductivities of the components are not widely different, a satisfactory heat balance usually can be obtained without using electrodes made of different materials. Differences in thermal and electrical conductivity between two metals ordinarily are closely parallel; the more conductive metal will generate less resistive heat because of its higher electrical conductivity and dissipate heat more rapidly because of its higher thermal conductivity.

In the following example, in which type 430 stainless steel was welded to galvanized steel, the projections were formed on the galvanized steel, which has higher thermal and electrical conductivity than the stainless steel.

Example 400. Change From Spot Welding to Projection Welding of Type 430 Stainless Steel to Galvanized Steel To Reduce Electrode Pickup and Rejection Rate (Fig. 18)

The lower-track assembly for a sliding mirror door in a bathroom cabinet was made by joining two track channels made of type 430 stainless steel to a larger track-support channel made of galvanized steel, using four projection welds (Fig. 18).

Originally, the welds were made one at a time by spot welding. The track channels were positioned manually on the support channel, and two spot welds, one in each track channel, were made in succession at one end of the assembly. The assembly was then turned and the other end was similarly welded. The upper and lower spot welding electrodes had ⅛-in.-diam faces.

Production rate for spot welding was 123 assemblies per hour, and about 10% of the welded assemblies were rejected because of weld breakage. A major factor contributing to weld breakage was pitting of the lower-electrode face, which occurred because the copper electrode became alloyed with zinc from the surface of the support channel. This zinc pickup caused changes in the contact resistance (and therefore, poor welds) and necessitated frequent dressings of the lower electrode. Dressing, which was done manually with a file, produced a nonuniform face contour, which also caused variation in weld quality. Rewelding of faulty assemblies was expensive because of rework itself and need for close inspection imposed by the high rejection rate.

To improve weld quality, the joining method was changed to projection welding. Because galvanized steel has higher thermal and electrical conductivity than type 430 stainless steel, the spherical projections were formed on the support channel, as shown in Fig. 18, permitting a reduction in electrode force and current density on the external zinc-coated surface.

The change to projection welding in the setup shown in Fig. 18 reduced zinc pickup by the electrode while allowing the use of sufficient electrode force to ensure consistently sound welds. Frequent removal of zinc from the lower electrode was not needed, and rejection rate was reduced from 10% to 0.1%, or by a factor of 100.

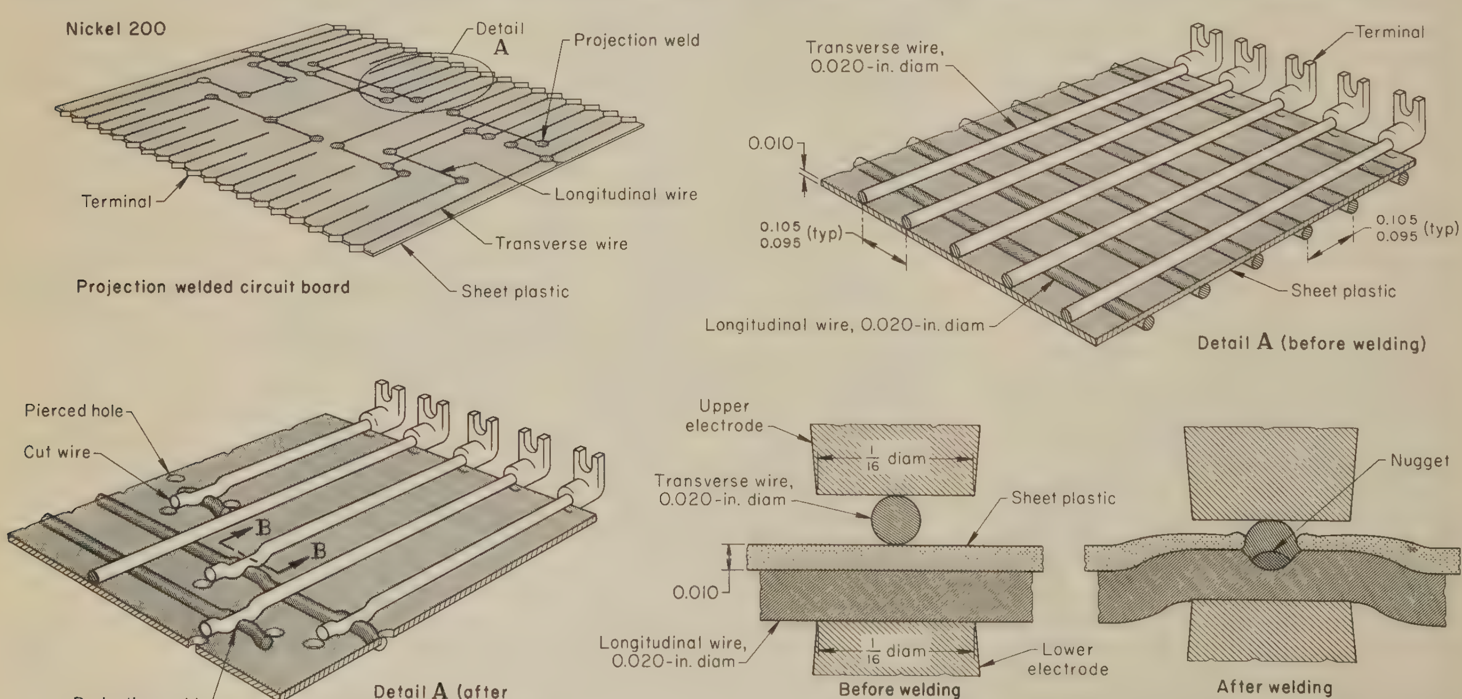
The upper and lower electrodes used for projection welding had large, flat contact faces, and were water cooled to dissipate heat generated at the welds. Gage blocks were attached to the lower electrode for automatic positioning of the three channels for welding. The two projection welds at each end of the track assembly were made simultaneously.

Production rate was increased from 123 to 173 assemblies per operator per hour, and welding cost was reduced from $2.60 to $1.90 per hundred assemblies.

Projection Welding of Coated Steel

Low-carbon steels coated with zinc, lead-tin or aluminum are projection welded in large quantities. Low-carbon steels with thin coatings of copper, tin, nickel, chromium or cadmium are easily projection welded using a welding current generally about 10% greater than that used for welding bare low-carbon steel of equal thickness.

Schedules for projection welding of galvanized low-carbon steel are given in Table 7. These schedules apply for galvanized steel with a commercial coating weight (1.25 oz of zinc per square foot of sheet). Zinc-coated steel having thinner coatings is usually welded using the conditions given for



Welds were made in a specially designed 5-kva resistance spot welding machine equipped with a heat-programed timer, using direct current, square-wave pulse. Electrodes were of RWMA class 3 material, 2 in. long, with type A (pointed) 1/16-in.-diam tips and ⅜-in. diam bodies. Electrode force was 23 lb, equivalent to a pressure of about 7500 psi at cross-wire intersections, sufficient to cause penetration of the plastic sheet by the wires and to establish electrical contact between the wires. Weld time was 5 millisec. Production rate, including testing, 10,000 welds per 8 hr.

Fig. 17. Circuit board that was produced by projection welding of crossed wires separated by a 0.010-in.-thick plastic sheet (Example 399)

bare low-carbon steel in Table 1, or conditions intermediate between those in Tables 1 and 7.

Electrode pickup is common in projection welding of steel coated with aluminum, tin or cadmium because these metals readily alloy with copper-base electrodes. Frequent cleaning and re-dressing of the electrodes are necessary to remove any pickup on the electrode faces. Electrode pickup occurs also in projection welding of zinc-coated steel, but although there is some alloying between zinc coating and copper-base electrodes, most of this pickup results from "soldering" of the zinc to the electrode face, which necessitates frequent cleaning. Copper, nickel and chromium do not diffuse readily into copper-base electrodes, and pickup is less troublesome in projection welding steel coated with these metals.

Generally, less electrode pickup occurs in projection welding than in spot welding of coated steel because the initial heating is concentrated at the tip of the projection, and current density is lower on projection welding electrodes than on spot welding electrodes. For instance, in Example 400, in which galvanized steel was welded to type 430 stainless steel, changing from spot welding to projection welding allowed reduction of electrode force and current density, and thus reduced deterioration of the electrode face.

Electrode pickup in projection welding of coated low-carbon steel can be reduced if careful attention is given to joint design, electrode design and adjustment of hold time.

The joint should be designed so that the metal coating (particularly zinc and tin) can be burned or extruded from between the surfaces to allow formation of a weld nugget in the base metal. Size and shape of the electrode face should be such that heating is adequate but current density at the electrode face is low.

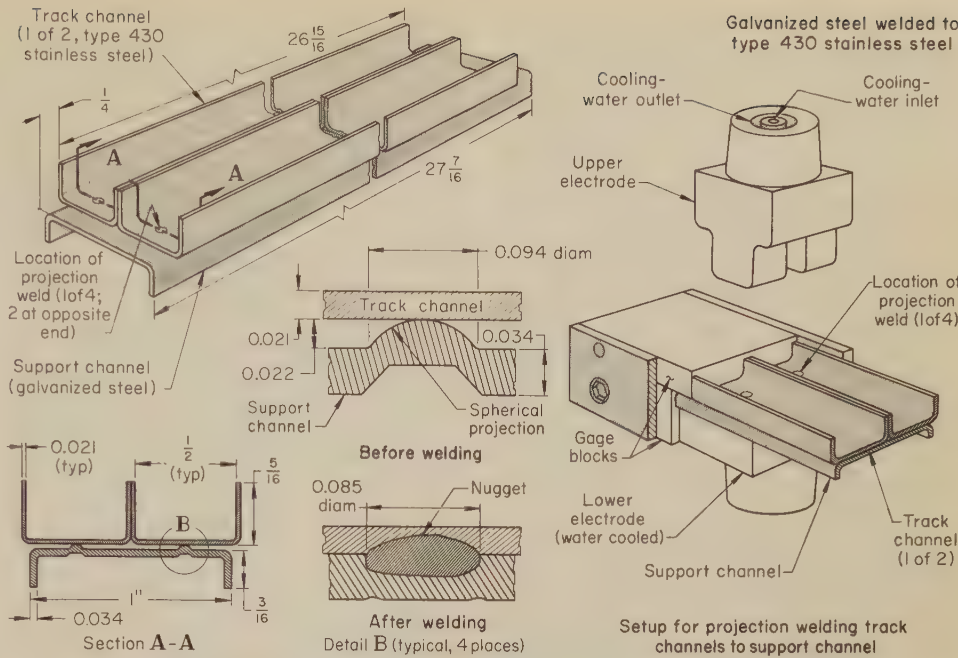
The hold time should be long enough to permit the molten coating metal (particularly zinc and tin) at the contacting surfaces near the weld nugget to solidify, thus reinforcing the weld.

Example of Practice. In the following example, distortion during spot welding of a handle to a trash-can cover, both made of galvanized steel, resulted in an excessive percentage of weak joints between layers of zinc that had melted and resolidified. Changing to projection welding reduced the occurrence of faulty welds.

Example 401. Change From Spot Welding to Multiple-Projection Welding of Galvanized Steel To Avoid a Fit-up Problem That Resulted in Weak Solder-Type Joints (Fig. 19)

The trash-can cover and handle shown in Fig. 19 were joined by four projection welds that were made simultaneously. Both the handle and the cover were made of galvanized steel.

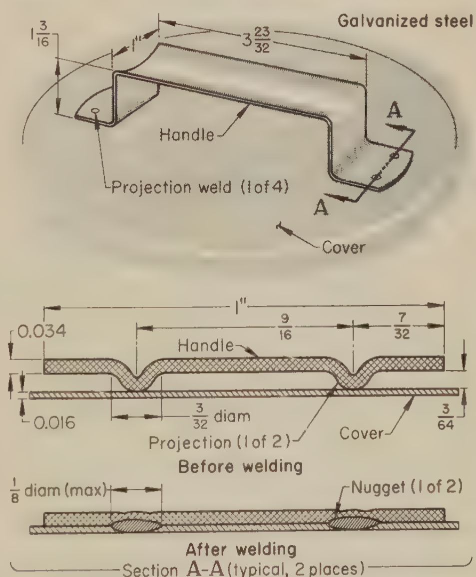
Originally, the handle was joined to the cover with four spot welds that were made one at a time. The cover was placed in a fixture in the welding machine, the handle was manually positioned, and two spot welds were made in one end of the handle. Then the cover was indexed and two spot welds were made in the other end of the handle. About 8% of the assemblies joined by this method had poor welds and required reworking.



Projection welding was done on a press-type machine with electronic controls and a transformer rated (at 50% duty cycle) at 30 kva, using special-shape RWMA class 3 electrodes; production rate was 173 assemblies (692 welds) per hour.

Fig. 18. Lower-track assembly for a sliding door, for which change from spot welding to projection welding increased production and reduced rejections and costs (Example 400)

The high rate of weld failure was caused mainly by poor fit-up of the handle and cover for the second pair of spot welds. When the first end of the handle was



Conditions for Projection Welding

Welding machine	Press type, precision
Electrode material	RWMA class 2
Heat-control setting	91%
Squeeze time	15 cycles
Weld time	7 cycles
Hold time	9 cycles
Production per hour:	
Projection welds	1296 (324 assemblies)
Spot welds(a)	960 (240 assemblies)
Rejection rate:	
Projection welding	0.08%
Spot welding(a)	8%

(a) With a manual, foot-operated welding machine and RWMA class 2 electrodes

Fig. 19. Galvanized handle-and-cover assembly for which change from spot welding to multiple-projection welding increased production by 35% and decreased rejections by 99% (Example 401)

welded, the other end usually gapped away from the cover, producing a spring action that reduced the effective electrode pressure when the second pair of welds was made. With this reduced pressure, contact was insufficient to burn the zinc coating from between the surfaces, and weak solder-type joints were made instead of sound spot welds in the base metal. Also, excessive wear of the upper electrode caused variations in nugget size and weld quality.

When the process was changed to multiple-projection welding using a press-type machine and a welding die, rejection rate was reduced to 0.08%, and production rate was increased from 240 to 324 covers per hour.

In the improved method, the welding die located the two workpieces, and all four projection welds were made simultaneously. The welds were inspected visually for size and could not exceed ⅛ in. in diameter.

In both methods, ten assemblies were randomly selected from each production lot and were tested for weld strength by striking the ends of the handles near the welds with a 4-oz weight swung from a height of approximately 18 in.

The electrodes used in spot welding were dressed manually by the operator as needed. The welding-die inserts used in projection welding required no hand dressing, but were removed for machine dressing at regular intervals. Conditions for projection welding are given in the table that accompanies Fig. 19.

Projection Welding of Powder Metallurgy Parts

In welding powder metallurgy parts (sintered compacts), it is essential to restrict the depth of melting (penetration) of the sintered metal at the joint interface to the shallowest depth that will produce consistent welds and adequate bond strength. In the following example, projection welding was used for attaching powder metallurgy parts to a low-carbon steel rim. The upper electrode was contoured to make contact with the entire upper surface of

the powder metallurgy part. An annular type of projection, provided by the sharp edge of the hole in the rim, was used to minimize nugget penetration in the sintered iron, and thus to produce a strong weld.

Example 402. Use of Conical Bosses To Minimize Penetration in a Powder Metallurgy Part in Welding It to Low-Carbon Steel (Fig. 20)

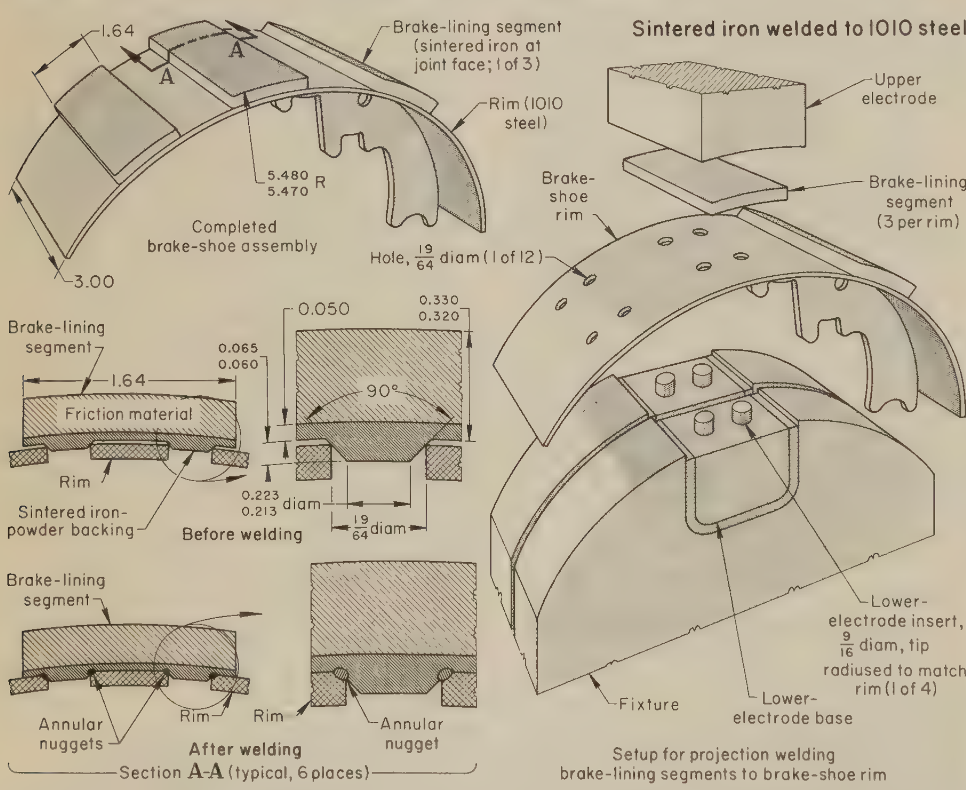
Three sintered powder metallurgy parts, consisting of a friction material and a backing that was made from low-density iron powder, were welded to a 1010 steel brake-shoe rim, as shown in Fig. 20, to serve as brake-lining segments. The friction material was developed for heavy-duty use in automotive drum-type brakes, and because of its composition, could not be expected to form acceptable projection welds with the brake-shoe rim. The sintered iron-powder backing layer of each brake-lining segment was joined to the rim by four projection welds.

Truncated-cone projections on the sintered backing (see section A-A in Fig. 20) were designed so that their conical surfaces would contact the sharp edges of the holes in the rim, to produce an annular nugget with shallow penetration into the sintered metal. This design avoided the formation of porous, weak welds that could have resulted from excessive melting of the sintered metal.

For welding, the rim was clamped in an indexed position on the fixture that held the lower electrodes (see view at right in Fig. 20). The first lining segment was positioned with the projections inserted in the holes in the rim, and the welding cycle was initiated by manually depressing two buttons. An air-operated ram lowered the upper electrode to make contact with the lining segment. This actuated the weld-sequence timer and the four welds were made. Then the ram and upper electrode were retracted, the assembly was indexed, and the operational sequence was repeated to weld the second and third lining segments to the rim. The finished brake shoe was manually removed from the fixture. Equipment details and welding conditions for this application are given in the table that accompanies Fig. 20.

The upper electrode, made of RWMA class 2 material, was radiused to fit the lining segment. The lower electrode consisted of a base made of class 2 material with four 9/16-in.-diam inserts made of class 11 material. The inserts were silver brazed to the base in positions that aligned with the holes in the rim. After about 12,000 assemblies had been welded, the lower electrode was removed from the machine and returned to the toolroom for dressing of the insert tips to the radius matching that of the rim.

Weld quality was spot checked with a destructive push-off test. In this test, the outside diameter of the rim was supported on both sides of a lining segment while force was applied hydraulically to the four projection welds to break them apart. The breaking load for the welds was the essential criterion of acceptance; weld shape and appearance were of minor significance in this application.



Equipment Details	
Welding machine	Manual press type, with 16-tap transformer
Rating at 50% duty cycle	175 kva
Electrodes	RWMA classes 2 and 11(a)
Electrode force, max	4500 lb
Heat control	Electronic tube type

Welding Conditions	
Welding current	35,000 amp
Heat-control setting	90%
Electrode force	1000 lb
Squeeze time	50 cycles
Weld time	22 cycles
Hold time	35 cycles

(a) Upper electrode was made of RWMA class 2 material and was radiused to fit the surface of the brake-lining segment; lower electrode consisted of four 9/16-in.-diam RWMA class 11 inserts radiused to conform to the inside surface of the rim and silver brazed to a class 2 base.

Fig. 20. Setup for joining three brake-lining segments, made of a friction material backed with sintered iron powder, to a steel brake-shoe rim with 12 projection welds, in which the use of truncated conical bosses on the lining segments minimized penetration into the sintered iron (Example 402)

Control of Weld Quality

High-quality joints can be produced consistently by projection welding if proper design of workpieces, correct welding conditions and a program of preventive electrode maintenance are used. Variations in dimensions and physical and mechanical properties of workpieces also affect weld quality.

Structures to be projection welded usually are designed so that the welds are in shear when the welded parts are stressed in tension or compression. Welds usually are inspected visually and by peel or tensile-shear tests.

The quality-control techniques for projection welding generally are the same as for resistance spot welding (page 417). For details of standard methods and quality-control procedures for projection welding, see AWS C1.1-66, Recommended Practices for Resistance Welding, Section V.

Penetration into the base metal can vary from 20 to 80% of the thickness of the thinner sheet. Full-penetration welds cause rapid deterioration of electrodes, are unsightly and may require excessive finishing, and are no stronger than normal-penetration welds. Insufficient penetration results from inadequate or unbalanced heating.

Porous welds usually are caused by overheating, inadequate welding or forging pressures, or too-late application of adequate forging pressure. Premature collapse of the projection and the presence of scale, oxide or other foreign material on the surface to be welded also can cause porous welds.

Effect of Work-Metal Properties. The composition, hardness or temper, dimensions, and mechanical properties of the work metal must be controlled within a suitably narrow range to consistently produce welds having uniform and acceptable size, penetration and strength.

In the example that follows, the tensile-strength specification range for incoming nickel wire had to be narrowed to obtain weld repeatability.

Example 403. Use of a Narrow Tensile-Strength Purchasing Specification To Ensure Repeatability of Cross-Wire Welds (Fig. 21)

Figure 21 shows a portion of a connector grid for an aerospace electronic assembly in which about 1800 cross-wire projection welds were made at right-angle intersections of 0.016-in.-diam nickel connector wires with each other and with component leads made of nickel alloys such as Kovar (53 Fe, 29 Ni, 17 Co) and Dumet (copper-clad 56 Fe, 42 Ni, 1 Mn). Four sizes of component leads, from 0.016 to 0.032 in. in diameter, were used, and both the wires and the leads were gold plated.

The matrix of nickel connector wires was constructed by making cross-wire welds at selected locations on the grid through openings in a polyester panel that separated transverse and longitudinal wires; nickel alloy component leads extending vertically through other openings in the polyester panel were later cross-wire welded to the nickel connector wires.

Original Method of Developing Welding Conditions. Originally, because of variations in the welding behavior of incoming connector-wire stock, each time a new lot of wire was received, welding conditions had to be revised for the 20 material combinations in which the wires were welded. The incoming wire was inspected for com-

pliance with material specifications, and new sets of machine settings were developed, with the aid of iso-strength diagrams, to meet stringent requirements in welding each of the 20 material combinations. This was done using a control machine to develop machine settings that could be applied to each of the 16 production machines used in the operation. Developing the welding conditions for each incoming lot of wire was time-consuming and costly. Also, production time was lost while qualification welds were made on all machines for each new lot of wire.

Qualification tests consisted of making 50 specimen cross-wire welds and testing them to destruction in torsion shear by pulling the legs into a straight line. The weld was required to hold until the legs were in a straight line, and to develop at least half the strength of the weaker of the two members. The strength of one of the 50 specimen welds was allowed to fall as low as 40% that of the weaker member of the joint. However, if more than one weld fell below 50%, or if one fell below 40%, new welding conditions had to be developed for the wire being sampled, and the testing program had to be repeated.

In addition to the strength requirement, the welds had to show setdown not greater than 35% total, and penetration into either wire not greater than 50%.

Process Study. In an attempt to reduce the cost and machine downtime involved in development and qualification of welding conditions, a study was made of the entire operation. It was found that variations in tensile strength of the nickel connector wire affected welding results more than any other single factor. (With electrode force and welding current held constant, the contact resistance of a work metal having lower tensile strength is lower than that of a metal having a higher tensile strength, because the lower-tensile-strength metal deforms more readily, increasing the contact area.) To obtain repeatability of sound welds, adjustments in welding conditions were found to be necessary whenever the tensile strength of the nickel wire varied by more than about ±2000 psi.

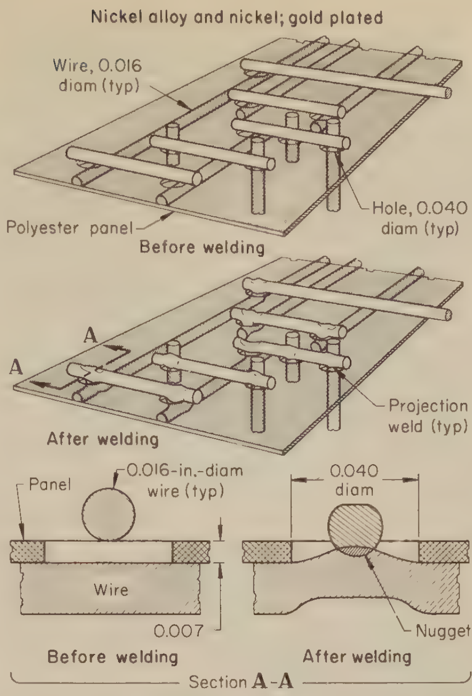
Routine control methods were found to be sufficient for holding all other material and operating factors within suitable limits. Uniformity of the component leads, which had less effect on welding behavior than uniformity of the connector wires, was ensured by narrow limits on chemical composition and diameter.

New Specification and Improved Method. The manufacturer narrowed the connector-wire tensile-strength range on the purchasing specification (formerly 60,000 to 85,000 psi) to 65,000 to 70,000 psi. By adhering to this range and by standardizing electrode force at 6 lb and electrode material as RWMA class 2, standard sets of welding conditions for the 20 material combinations were developed (on the control machine) that were suitable for use on every new lot of connector wire that passed incoming inspection. Thus, the number of welding schedules needed for the entire operation was reduced from 120 to 20.

The standardized welding conditions were programed into each machine, and setup required only that the operator push a button, according to worksheet instructions, to select the correct set of conditions.

Time Saving by Improved Method. Before the acceptable range of connector-wire tensile strength was narrowed, developing and qualifying sets of welding conditions for a shipment of incoming wire required a total of 412 hr — 320 hr for developing a new schedule for each of the 20 material combinations, 36 hr for making 50 sample welds for each material combination on each production machine, and 56 hr for inspecting and analyzing the results.

The improved procedure required a total of 9 hr — 1 hr for making tension tests on the incoming wire and 8 hr for making a total of 50 weld samples on the control machine using several material combinations and the established welding schedules, and testing the welds. Thus, a total of 403 hr was saved for each lot of connector wire by using the narrower acceptance range on tensile strength and the improved qualification method.



Conditions for Cross-Wire Welding

Welding machine	Capacitor-discharge type, bench mounted, equipped with low-inertia, fast-follow-up welding head
Electrode material	RWMA class 2
Electrode force	6 lb
Weld time	12 to 13 milliseconds
Production rates (approx):	
Matrix welds	2 per minute
Welds to component leads	1 per minute

Fig. 21. Portion of a connector grid, showing cross-wire welds for which a standardized welding program was developed on the basis of tensile strength of as-purchased connector wire (Example 403)

Nondestructive techniques for pretesting weldability of workpieces may be of special value in applications requiring extremely high weld reliability, such as those in which the workpieces are costly, in which many critical welds must be made on a complex assembly, or in which weld repair is difficult, costly or impossible. One nondestructive method for the testing of weldability that sometimes, if necessary, can be applied to 100% of the work metal (instead of only to samples, as when destructive tests are used), is measurement of a magnetic or electrical property of the workpiece that is related to weldability. Inductance, for instance, can be measured accurately and rapidly on parts of suitable shape and controlled dimensions, and can be used as an index of weldability in relation to known standards, as in the following example.

Example 404. Use of an Inductance Test in Place of a Destructive Pull Test, To Reduce the Time Needed for Determining Weldability of Wire Leads

Wire leads on components used in a space-module electronic assembly were joined to connector wires by cross-wire projection welding. Conformance to material specifications for all leads and connector wires was checked and wire diameter was measured before welding.

Originally, to test weldability before making a production run, the leads on 5% of the components in a production lot were welded to connector wires, and the welds were pull tested to determine weld quality. The test welds were made at the ends of the leads so that the components could still be used in assemblies, but occasionally components were rendered unusable by the testing procedure. (A description of the materials, welding operation and pull test is given in Example 403.)

In an improved testing method, the inductance of the lead wire, found to be directly correlated to its weldability, was measured on a commercially available instrument. Master lead wires were made of each material that was to be tested and these were used to establish standard meter readings. The inductance of the specimen lead had to match, or approach, that of the master lead within ±1.5 units of scale reading.

At first, the inductance of all component leads was measured before release to production, and those components with leads that failed to pass the inductance test were salvaged by welding under conditions based on tension tests and trial-and-error development. Later, it was found satisfactory to measure the inductance of the leads on a 5% sampling basis. As a continuing check on the validity of the inductance measurement as an index to welding behavior of the leads, sample leads were welded at regular intervals and pull tested to check the strength of the weld.

Metals used for master wires were selected samples of the materials used in cross-wire welding, and included: nickel (99 Ni), Kovar (53 Fe, 29 Ni, 17 Co), and Dumet (copper-clad 56 Fe, 42 Ni, 1 Mn); lead-wire diameters ranged from 0.016 to 0.032 in., and all leads (and connector wires) were gold plated.

In the original method, welding and pull testing required 7 minutes per sample. In the improved method, measuring the inductance of leads on 5% of the components and inspecting 1% of the welds by pull testing took an average of 1.5 minutes per sample, and thus, average testing time was reduced by 5.5 minutes per sample.

Projection Welding vs Other Joining Processes

In some applications, projection welding can be used as an alternative to other welding processes and to some mechanical processes for joining workpieces. In Example 396, unit cost was reduced substantially when projection welding replaced riveting in production of a platen-frame assembly. The next three examples describe applications in which projection welding replaced spot welding, shielded metal-arc welding, and staking.

Projection Welding vs Spot Welding. For some applications, greater productivity can be obtained by using projection welding rather than spot welding, because closely spaced spot welds must be made one at a time whereas two or more closely spaced projection welds can be made simultaneously. Two applications in which projection welding provided increased production rate and lower cost, in comparison with spot welding, are described in Examples 388 and 389 (see page 436).

In the example that follows, when spot welding was replaced by projection welding, production rate was increased, and weld consistency and the appearance of workpiece surfaces (elimination of indentations) were improved.

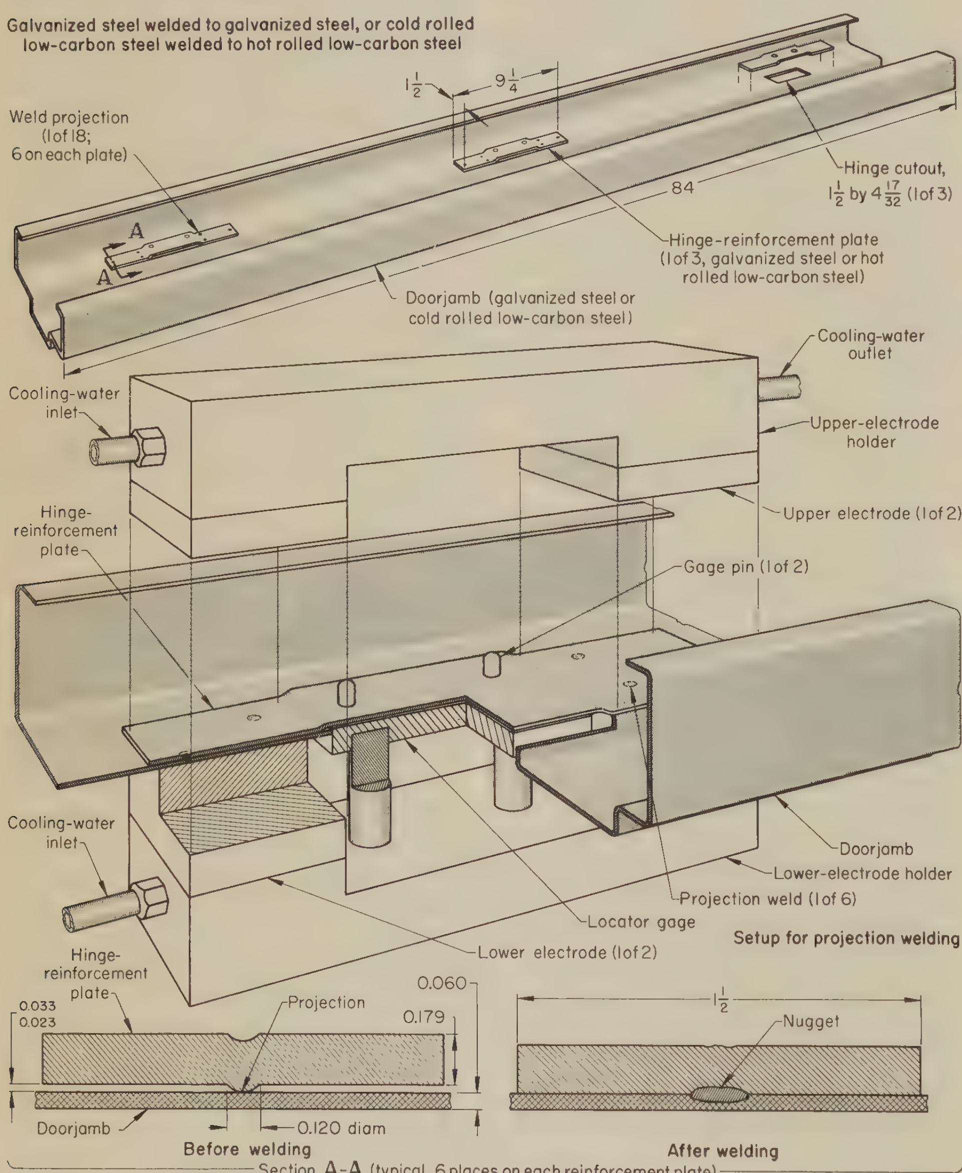
Example 405. Change From Spot Welding to Projection Welding That Improved Weld Quality and Appearance and Increased Production (Fig. 22)

Three hinge-reinforcement plates were joined to a steel doorjamb by means of six projection welds in each plate, as shown in Fig. 22. Originally, the 18 welds were made one at a time by spot welding in a 50-kva rocker-arm machine. To increase production and to improve the appearance of the finished product by eliminating electrode marks, the process was changed to projection welding.

For the improved method, the spot welding machine was replaced with a 150-kva press-type resistance welding machine, and the electrodes shown in Fig. 22 were built. Also, the punch-press tooling was rebuilt to include an operation in which projections were formed in the reinforcement plate. For welding each hinge-reinforcement plate, the doorjamb was positioned with a hinge cutout over the locator gage, and a plate was placed on the two gage pins (see Fig. 22). The upper electrodes were lowered and the six projection welds were made simultaneously, in about the same time that had been required to make one spot weld. In addition, repositioning of the doorjamb for each of the spot welds was eliminated. Thus, with projection welding, output was increased about sixfold.

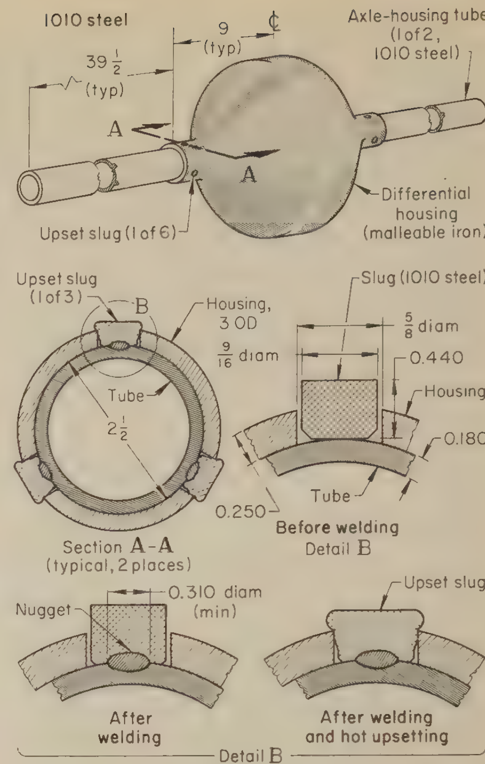
Because of the large area of the upper and lower electrode faces, there was no indentation at the welds, and thus, one of the major drawbacks of the original spot welding procedure was eliminated.

The welded assemblies were examined visually to ensure proper placement of the reinforcement plates and to establish that the projections had been flattened. The plates were struck with a special mallet to test weld soundness. Inspectors subjected one out of every 1200 welded doorjambs to destructive peel and pull tests; the requirement for acceptance was that, for each weld, a nugget be pulled out of the doorjamb, which was the thinner workpiece.



Welding machine	Press-type combination spot and projection
Rating at 50% duty cycle	150 kva
Electrode material	RWMA class 3
Electrode holders	Cold rolled copper
Welding current	70,000 amp
Electrode force	2100 lb
Squeeze time	20 to 40 cycles
Weld time	22 cycles
Hold time	3 cycles
Production rate	250 assemblies per hour

Fig. 22. Assembly of a doorjamb and three hinge-reinforcement plates, for which change from spot welding to projection welding under the conditions listed in the table improved weld quality and appearance and increased production (Example 405)



Equipment Details

Welding machine	Three-station projection welding machine with two eight-tap transformers per station and heat control for welding and upsetting
Rating at 50% duty cycle	100 kva(a)
Electrodes	RWMA class 2, ⅝-in. diam, type C (flat) face(b)
Current, max	35,000-amp ac(a)

Conditions for Welding and Upsetting

Current	Welding, 22,000 amp; upsetting, 15,000 amp
Electrode force	Welding, 2000 lb; upsetting, 3000 lb
Weld time	20 cycles
Cool time	20 cycles
Upset time	30 cycles
Production rate:	
Subassemblies per hour	150
Welds per hour	900

(a) For each transformer. (b) Electrodes hydraulically driven.

Fig. 23. Drive-train housing subassembly joined with three hot upset projection welded slugs, which replaced shielded metal-arc plug welds (Example 406)

Depending on customer requirements, one of two work-metal combinations was used — galvanized steel doorjamb and reinforcement plate, or cold rolled low-carbon steel doorjamb and hot rolled low-carbon steel plate. When uncoated steel was welded, the projection welding electrodes were dressed by milling after four hours. In welding galvanized steel components, zinc rapidly built up on the electrodes, and the electrodes were dressed about every two hours.

The effectiveness of the electrode design and operating procedure adopted for projection welding was demonstrated convincingly by the reduced frequency of electrode dressing, as compared to that necessary when welding by the original spot welding method. The spot welding electrodes had been dressed by hand once an hour in welding bare steel parts, and after every two or three doorjambs in welding galvanized steel parts.

Equipment details and conditions for projection welding are given in the table that accompanies Fig. 22.

Projection Welding vs Arc Welding. Nonweldable components are sometimes joined to weldable components

by means of a mechanical fastener that has been arc welded to the weldable component. Where the assembly sequence or the part design and dimensions prevent access for welding in this manner, arc plug welds can be deposited through holes in the nonweldable member.

Projection welding also can be used for attaching fasteners in joining nonweldable and weldable components; it is fast, and can be done where there is no access for arc welding. Also, projection welding allows the use of a low, controlled heat input to avoid damage to adjacent heat-sensitive components, as shown in the example that follows.

Example 406. Change From Shielded Metal-Arc Plug Welds to Upset Projection Welded Slugs for Joining Steel and Malleable Iron (Fig. 23)

A housing subassembly for a drive train (see Fig. 23) consisted of a malleable iron differential housing and two 1010 steel axle-housing tubes, which were press fitted into the neck of the housing.

Originally, the subassembly was joined by means of shielded metal-arc plug welds, deposited in equally spaced holes drilled through the neck of the cast housing; fusion of the deposits was mainly with the steel tubes. The weld-metal plugs acted as drive pins to transmit torque or thrust from one component to the other. This method of joining, however, was unsatisfactory for several reasons: heat from welding often cracked the malleable iron, fusion to the axle-housing tubes was erratic, welds were porous because of an oil-like sealing compound entrapped between the housing and the tubes, and the confined working area made accessibility for arc welding difficult. Other arc welding methods, including automatic gas metal-arc welding, were considered for the plug welding, but were rejected because all were slow and involved a high heat input.

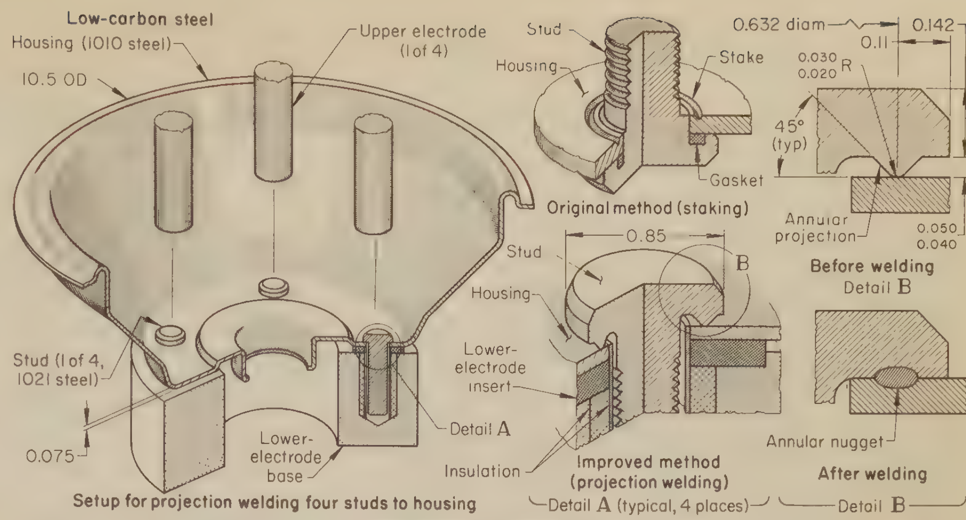
In an improved method of joining the three components (see Fig. 23), in which a three-station projection welding machine was used, three slugs of 1010 steel were inserted in the holes in each end of the cast housing, and were projection welded to the steel axle-housing tubes. The curvature of the tube functioned as a projection for welding.

Two welds were made at once, one on each end of the cast housing. The welds were series welds; a return electrode was clamped to each tube. The subassembly was rotated 120° and transferred to the next station to make the second pair of welds, and these operations were repeated to make the third pair of welds. After each projection weld was completed, the slug was heated by a second impulse and was hot upset by the electrode. The upset slugs partly filled the holes in the housing, and thus served as mechanical retaining pins.

The much lower heat input to the welds, as compared to that for shielded metal-arc plug welding, greatly reduced the volatilization of sealing compound, and resulted in an acceptably low level of weld porosity.

Subassemblies joined by the improved method were able to withstand 38,000 lb-in. of torque. One subassembly per shift was torque tested to destruction. Production rate was 150 subassemblies per hour. Equipment details and conditions for projection welding and upsetting are given in the table with Fig. 23.

Projection Welding vs Staking. Studs in housings are commonly staked and are thus held with adequate rigidity until the assembly is completed and a nut on the end of each stud holds it secure. But in housings for which exceptionally high integrity is needed (as, for instance, in a housing required to be leakproof under air pressure), projection welding can sometimes produce a superior joint, as in the following example.



Equipment Details	
Welding machine	Special four-post, semiautomatic, with two eight-tap transformers
Rating at 50% duty cycle	150 kva each
Upper electrodes	RWMA class 2
Lower electrodes	RWMA class 11 inserts, silver brazed to a class 2 body
Electrode force, max	6650 lb per electrode
Controls	Individual solid-state control devices for each stud

Welding Conditions	
Welding current	50,000 amp
Heat-control setting	80% and No. 7 tap
Electrode force	4700 lb per electrode
Squeeze time	55 cycles
Weld time	6 cycles
Hold time	10 cycles
Production rate:	
Assemblies per hour	180
Welds per hour	720

Fig. 24. Brake-booster housing for which changing from staking to projection welding of studs improved joint tightness (Example 407)

Example 407. Change From Staking to Projection Welding of Studs That Improved Joint Tightness (Fig. 24)

In the brake-booster housing shown in Fig. 24, the joints between the four studs and the housing were required to be leakproof under air pressure of 25 psi. Also, each stud had to be perpendicular to the mounting surface of the housing, within 0.005 in. at the tip of the protruding end of the stud, and to withstand 30 lb-ft torque.

Originally, the four studs were assembled to gaskets and were joined to the housing by staking (see "Original method" view in detail A in Fig. 24). With staking, however, rejection rate was 15%, because of joints that failed to withstand leak tests.

The rejection rate was reduced to 0.6% by changing the method of joining to projection welding, using an annular projection formed on the lower surface of the head of the stud, as shown in details A and B in Fig. 24. The projection welds were made in a four-electrode fixture that was designed to receive the housing in the open-side-up position (see view at left in Fig. 24), and that consisted of four lower-electrode inserts, each with a hole in the center to accept the threaded end of the stud. The inserts were mounted on a common base that made it possible to remove, dress and replace them as a unit.

The welding machine had two transformers for supplying the welding current and four air cylinders for supplying the electrode force. One upper electrode was mounted on each air cylinder, and the welds were made one at a time, using a separate transformer for each weld.

For welding, the housing was placed open side up on the lower electrodes, and studs were inserted into holes in the housing. The welding cycle was started by depressing double palm buttons. The two front upper electrodes were brought in contact with the studs; the left stud was welded using the left transformer, and after a few cycles delay, the right stud was welded with the right transformer. Then the two front electrodes were retracted, the two rear electrodes were brought in contact with the other two studs, and welding was done in the same sequence. After the two rear electrodes were retracted, the assembly was automatically ejected onto a conveyor.

The parts were spot checked for leakage, which was seldom found, and for strength. In the strength test, the stud was pushed from the housing, and the weld was required to be strong enough to tear a slug from the housing metal. In a final series of checks, all completed housings were tested for leaks.

In addition to reducing the rejection rate, the change from staking to projection welding eliminated the cost of the gasket and of assembling the gasket to the stud. Production rates for the two methods were about the same.

The electrodes were removed after each shift, or after welding about 1440 assemblies, and were sent to the toolroom for machine dressing. After being re-dressed five times, the upper electrodes and the lower-electrode inserts were replaced. Equipment details and welding conditions are given in the table with Fig. 24.

Table 8. Examples of Projection Welding Presented Elsewhere in This Volume

Example	Subject of example
408	Type 430 stainless steel welded to type 440A; eight projections were welded at a time
416	Joining type 302 stainless steel cover plate and bracket for close alignment, blemish-free appearance and high production rate
417	Cross-wire welding food-handling trays of type 304 stainless steel; low setdown avoided discoloration
425	Capacitor-discharge welding gold-plated nickel wire to solder-clad beryllium copper strip
426	Beryllium copper sandwiched between low-carbon steel that was welded to low-carbon steel
427	Annular projection coined into a cartridge brass lead wire during flattening, then welded to a red brass terminal
428	Closely spaced projections joined switch elements made of phosphor bronze and cartridge brass

Resistance Welding of Stainless Steel

*By the ASM Committee on Welding and Brazing of Stainless Steel**

STAINLESS STEELS are readily resistance welded by spot, seam and projection methods. Generally the weld time and welding current are less than those used for welding carbon steel, but electrode force is usually greater.

Austenitic stainless steels of the 300 series are resistance welded more often than any other metal except carbon steel of low carbon content. Preferably, stainless steel to be resistance welded should contain a maximum of 0.08% carbon (as in types 304, 316 and 347), although steels with a higher carbon content, such as types 301, 302, 309 and 310, frequently are resistance welded with good results.

The martensitic and ferritic types of stainless steel both can be welded satisfactorily. The martensitic types are less frequently resistance welded, because joints made in them are hard and brittle in the as-welded condition. Exact control of welding conditions is required, and for best results a postweld tempering treatment should be used. Table 1 gives nominal compositions and pertinent physical properties of the types of stainless steel that are commonly resistance welded.

Weld Strength. The minimum breaking load of spot welds in shear is given in Tables 2 and 3. Resistance welds in austenitic and precipitation-hardening stainless steels, if postweld heat treated, provide good service at cryogenic temperatures.

Spot, projection and seam welds in austenitic stainless steel have high corrosion resistance in most atmospheric environments, because appreciable formation of intergranular carbide is not likely to occur in resistance welds during the short weld times used for most resistance welding applications. Resistance of the solution-treated base metal to intergranular corrosion is less likely to be affected adversely than when conventional arc welding, with its longer weld times, is used. (See the sections on Welding Characteristics of Austenitic Stainless Steel, this page, and Welding Characteristics of Martensitic and Ferritic Stainless Steels, next page.)

Equipment. Less transformer capacity is required for resistance welding of stainless steel than for welding equivalent thicknesses of any other metal, with all other welding conditions being the same.

The machines use a single-phase alternating-current power supply, or a three-phase rectifier or frequency-converter power supply. A weld made with a three-phase power supply usually requires slightly higher current and a longer weld time than a weld made with a single-phase supply. The force, material and shape of the electrodes are similar for both single-phase and three-phase power supplies.

Synchronous timing controls are preferred for resistance welding stainless steel, because a variation of one or two cycles in the short weld time can result in a large percentage change in weld time. Current and voltage regulators may be desirable, depending on machine size and power-supply capacity.

Factors Affecting Resistance Welding of Stainless Steel

The characteristics of austenitic stainless steel that necessitate careful attention to the details of operation include sensitivity to heat, low electrical conductivity, low thermal conductivity, high melting temperature, high strength at elevated temperature, high coefficient of thermal expansion, and high contact resistance.

Sensitivity to Heat. The corrosion resistance of stainless steels, which generally is the principal reason for their use, may be adversely affected by heat. In resistance welding, the temperature generated and the time at temperature must be controlled accurately to hold the adverse effects of heat (principally carbide precipitation) to a minimum, while at the same time applying enough heat and pressure to obtain the desired weld properties.

Electrical Conductivity. The low electrical conductivity of stainless steels, compared with that of plain carbon steel, results in faster generation of heat with the same current. Therefore, in welding stainless steel, compared with welding similar thicknesses of carbon steel, a lower welding current or a shorter weld time, or both, should be used. Relative values of electrical conductivity of stainless steels that are commonly resistance welded are given in Table 1. These values are in relation to copper alloy 102 (oxygen-free copper), which is rated at 101% by the International Annealed Copper Standard (IACS) and has an electrical resistivity of 1.72 microhm-cm. Low-carbon steel has a relative electrical conductivity rating of 13.7% IACS, or an electrical resistivity of 12.5 microhm-cm.

Thermal Conductivity. Stainless steel has thermal conductivity lower than that of carbon steel. Therefore, heat is conducted away from the weld zone more slowly than in carbon steel. Relative values of thermal conductivity of stainless steels that are commonly resistance welded are given in Table 1.

Melting temperatures of stainless steels also have an effect on the amount of heat required to produce fusion for welding. The austenitic stainless steels melt in various ranges between 2500 and 2650 F, and the martensitic and ferritic alloys melt in ranges between 2550 and 2790 F. Plain low-carbon steel melts at temperatures between 2700 and 2800 F.

High strength at room and elevated temperatures of the austenitic stainless steels and, to a lesser extent, of the straight-chromium grades, makes it necessary to use greater electrode force to bring the work-metal surfaces together in the required intimate contact at points of welding than is required for carbon steel.

Thermal Expansion. The austenitic stainless steels expand and contract with changing temperature to a greater extent than does plain carbon steel. These dimensional changes and the slower heat diffusion in austenitic stainless steel result in greater thermal stress, which leads to warping. The coefficient of thermal expansion of austenitic stainless steel between 32 F and 1800 F ranges from 10.6 to 11.4 micro-in. per inch per °F, compared with 8.1 micro-in. per inch per °F for plain low-carbon steel.

The straight-chromium grades of stainless steel (martensitic and ferritic) have coefficients of thermal expansion lower than that of plain carbon steel. The corresponding coefficients over the range of 32 to 1800 F are 6.4 to 7.6 micro-in. per inch per °F for these stainless steels.

The effect of thermal expansion on assemblies that are joined by spot and projection welding usually is minimal because of the relatively small area that is heated during welding. In seam welding, however, the effect is greater, because welding is continuous. (See "Effect of Heat Distortion", page 461 in the section on Resistance Spot Welding, and "Heat Distortion", page 461 in the section on Resistance Seam Welding and Roll Resistance Spot Welding.)

Contact resistance of stainless steels is higher than that of carbon steel, and therefore greater electrode pressure is needed to make good resistance welds. Preweld cleaning is necessary for maintaining uniform contact resistance. (See "Surface Preparation for Welding", on the next page.)

Welding Characteristics of Austenitic Stainless Steel

Austenitic stainless steel, in the solution-annealed condition, contains carbon in solid solution. When the steel is heated to the temperature range of 800 to 1500 F, carbon combines with chromium, resulting in chromium carbide precipitation at the grain boundaries. Carbide precipitation makes the material more sensitive to intergranular corrosion. Sensitization to intergranular corrosion is governed in austenitic stainless steel by (*a*) the carbon content; (*b*) the solubility of the carbon; (*c*) the presence of one or more stabilizing elements; (*d*) the proximity of the actual metal temperature to 1200 F

*For committee list, see page 245. Some of the examples in this article were contributed by members of other Metals Handbook welding committees.

within the 800 to 1500 F range; and (*e*) the time period during which the metal is held in that temperature range. The first three factors are controllable only through selection of composition; the latter two are controllable by adjustment of welding conditions such as heat input, size of spot, production rate, and provisions for cooling.

(a) Based on copper alloy 102, which has a thermal conductivity of 226 Btu/hr/sq ft/ft/°F at 68 F, as 100%. Low-carbon steel has a thermal conductivity of about 13% on this relative scale. (b) International Annealed Copper Standard, volume basis at 68 F. For comparison, copper alloy 102 (oxygen-free copper) is 101% and low-carbon steel (1010) is about 14%. (c) Minimum columbium-plus-tantalum content, 10×C. (d) Minimum columbium-plus-tantalum content, 10×C; Co, 0.20 max; Ta, 0.10 max. (e) Carbon range, 0.60 to 0.75. (f) Minimum sulfur, 0.15.

Variations in composition among the standard austenitic stainless steels affect both the behavior of the steels in welding and their performance in service. Types 302, 304 and 304L differ chiefly in carbon content, which determines the amount of chromium carbide precipitation that can occur in the heat-affected zones of the base metal. In extra-low-carbon austenitic steels, the carbon content of which does not exceed 0.03%, carbide precipitation and susceptibility to intergranular corrosion are negligible. Types 316, 316L and 317 contain additions of molybdenum for improved corrosion resistance. In welding, the presence of molybdenum is both beneficial and harmful. Stabilized stainless steels, including types 321, 347 and 348, contain additions of titanium or of columbium-plus-tantalum that form preferential carbides that do not decrease resistance to intergranular corrosion, and thus effectively prevent intergranular chromium carbide precipitation during welding.

The effect of welding heat in producing carbide precipitation is discussed more fully in the article on Arc Welding of Stainless Steel, page 245.

The free-machining grades of austenitic stainless steel contain elements such as sulfur, phosphorus and lead that are intentionally added to improve machinability. These steels are not recommended for resistance welding. However, acceptable welds are frequently made in these grades by using shorter weld times than those normally used for welding stainless steel, and fast follow-up of electrode force.

Welding Characteristics of Martensitic and Ferritic Stainless Steels

The martensitic steels most often welded are types 403, 410, 414 and 431. These steels can be resistance welded in the annealed, hardened or hardened-and-tempered condition. Regardless of prior condition, welding produces a hardened martensitic zone adjacent to the weld. The hardness of this zone, although it can be controlled to a degree by the welding procedure, depends mainly on carbon content. As the hardness of the metal in the heat-affected zone increases, its susceptibility to cracking increases and its toughness decreases. Steels having a maximum carbon content of 0.15%, such as types 403 and 410, often produce satisfactory welds without postweld heat treatment. Steels with higher carbon contents, such as types 420 and 440A, generally require postweld heat treatment.

Chromium content also significantly affects welding behavior.

The ferritic grades of stainless steel most commonly welded are types 405, 430, 442 and 446. Resistance welds in these steels are brittle at room temperature, and if their use in the as-welded condition is unsuitable, annealing must follow welding. Postweld annealing, in addition to reducing brittleness, helps to restore normal resistance to corrosion. In most corrosive environments, ferritic stainless steels are less corrosion resistant than are austenitic stainless steels.

Surface Preparation for Welding

Oil or grease must be removed from the surfaces to be welded. Otherwise, carbon from the oil or grease can be absorbed into the steel, thus increasing the susceptibility of the steel to intergranular corrosion.

Protective adhesive paper used to prevent damage to the surfaces of polished sheets can become oil-soaked during press operations and cause the adhesive to stick to the sheet. This adhesive must be removed before resistance welding.

Burrs should be removed from the overlapping edges of components being resistance welded. Failure to remove burrs can cause the current to shunt through the burr instead of passing through the point of electrode contact.

Stainless steel sheets should not be ground or filed with tools used for ordinary steel, because even very slight iron contamination can reduce the effective chromium content in the ground or filed region and cause rejection of the weldment. Wire brushing must be done only with brushes made of stainless steel.

The chromium oxide that is formed on hot rolled stainless steel must be removed by pickling before the metal is resistance welded. The protective film that forms at ordinary temperatures after pickling is of microscopic thickness and usually does not interfere with resistance welding.

Special etching or chemical cleaning sometimes is needed, as in the following example.

Example 408. Elimination of Oxide Coating To Ensure a Strong Bond in Projection Welding (Fig. 1)

Projection welds joining the shearing head of an electric shaver to its mating channel (Fig. 1a) failed if the surfaces of the components were not adequately cleaned prior to welding. The channel (type 430 stainless steel) was cleaned and deburred by tumbling in a steel barrel containing a special soap solution and was then rinsed in water. The surface of the shearing head (type 440A stainless steel), however, needed special cleaning, because in a previous heat treatment it had developed a light oxide film that increased the contact resistance and acted as a barrier to heat penetration.

To minimize discoloration of the shearing head during heat treating (to Rockwell C 57), the heat treatment was conducted in a vacuum furnace in an atmosphere of prepurified nitrogen with a dew point of −60 F. Nevertheless, a light film of oxide occasionally formed on the surface and had to be removed by pickling the head in 25 to 50% hydrochloric acid at room temperature for a maximum of 30 sec. After pickling, the head was rinsed thoroughly and subjected to a passivating treatment that consisted of immersing the head for 15 min in an aqueous solution of nitric acid maintained at 18° to 21° Be and containing 2½ oz of sodium dichromate per gallon of so-

(a) ⅝ by 2.08 in., with four faces 0.150 by 0.130 in. (b) At 80-psi air pressure. (c) Synchronous, with phase-shift heat control. (d) 6000 welds.

Fig. 1. Stainless steel shearing head and channel for an electric shaver, setup in which the assembly was projection welded, and method of testing for weld strength by insertion of an inspection paddle (Example 408)

lution. The solution temperature was maintained at 120 to 140 F. To avoid stress corrosion, the chloride content of the bath could not exceed 120 parts per million.

The head-and-channel assembly was positioned between upper and lower electrodes to make eight projection welds at one time (four to a side), as shown in Fig. 1(b). An inner supporting mandrel was not needed during welding, because the stiffness of the channel was sufficient to support the 165-lb electrode force. Adequate heat penetration at the joint surface was obtained by using electrodes made of RWMA class 3 material. Additional welding conditions are given in the table with Fig. 1. After being welded, the assembly was rinsed in flowing water, immersed for 10 min in an alkaline cleaner, and then rinsed again in flowing water.

The welded assemblies were tested for weld strength with a 0.364-in.-diam inspection paddle, as shown in Fig. 1(c). This tool was inserted between the walls of the head above the channel and rotated clockwise and counterclockwise until it touched the edge of the channel. The tool was then moved sideways with light pressure. Two out of every 50 assemblies were tested by the operator. If all the welds on both test assemblies held, welding was continued. If one weld failed, another assembly was tested. If this assembly passed, production was continued; if it failed, production was stopped until the difficulty was corrected. If there were two failures in any test interval, production was stopped. Periodic checks were also made by inspectors to ensure an acceptance quality level not exceeding 2.5% in defective assemblies. Dimensions were checked for two out of every 100 assemblies.

During setup, welds were sectioned and etched to determine nugget size, and hardness readings were taken. Microhardness readings across the weld area in the type 440A steel were 370 Knoop at the center of the weld metal, 672 Knoop at the edge of the weld, and 703 Knoop a short distance into the heat-affected zone. At a distance of about 0.0015 in. from the weld interface, the hardness of the 430 stainless steel was 423 Knoop, and at 0.008 in. it was 253 Knoop. The base-metal hardness was 240 Knoop (Rockwell 30-T 74).

Resistance Spot Welding

Resistance spot welding of stainless steel does not differ greatly from resistance spot welding of carbon steel, but the composition and physical properties of stainless steel make it necessary to control weld time and welding current more closely.

Table 2 gives recommended practices for resistance spot welding of series 300 austenitic stainless steels. The values in Table 2 are intended for use as starting points and should be adjusted to suit conditions and job requirements. The procedure for establishing a spot welding schedule on page 417 in the article on Resistance Spot Welding can be followed in making the adjustments.

Welding Current. The electrical conductivity of stainless steel is 15 to 25% that of carbon steel of similar carbon content, and the melting temperature, about 90%. Therefore, the heat for welding, and thus the welding current, should be less than for carbon steel. The values of welding current suggested in Table 2 for welding stainless steel vary from half as much as, to the same as or slightly more than, those suggested for welding carbon steel in Table 4 on page 414 in the article on Resistance Spot Welding in this volume. The welding currents are not in strict proportion to the electrical conductivities and melting temperatures, because other variables require that adjustments be made in weld time and electrode force.

Weld Time. The relative thermal conductivities of austenitic and precipitation-hardening stainless steels are 30 to 35% that of carbon steel. Because the heat is not conducted away from the weld area as rapidly as in carbon steel, less weld time is needed. Also, the weld time usually is so short that it must be precisely controlled because a variation of ±1 cycle may be exces-

sive. In stainless steel 0.062 in. thick, a variation of ±1 cycle would be ±10% of the weld time (Table 2), but for a thickness of 0.006 in., a variation of ±1 cycle would correspond to a variation of ±50% of the weld time.

Electrode Force. The contact resistance and strength of stainless steel remain high at elevated temperatures. Therefore, the electrode force required to make the weld is much higher than that required for welding carbon steel. Large electrode force is needed to forge the weld, and thus to minimize cracks and voids in the weld nugget. The increased electrode force requires that the welding current be decreased, particularly in metal of greater thickness, because of the decrease in contact resistance. With an electrode force that is adequate for a given work-metal thickness, insufficient welding current can result in an undersize nugget, whereas excessive welding current can cause excessive indentation.

Spot Spacing. The shunting effect from one spot to another is somewhat less in welding stainless steel than in welding carbon steel, because of the lower electrical conductivity of stainless steel. Therefore, spots can be more closely spaced and the contacting overlap can be less than that for carbon steel. Recommended practices for minimum spot spacing and contacting overlap are given in Table 2.

Spot welding electrodes for stainless steel are about the same size as those used for welding carbon steel, but because the electrode force is greater for stainless, the unit pressure at the electrode face is greater. Therefore, the electrode can be made of a harder material than that used for spot welding carbon steel.

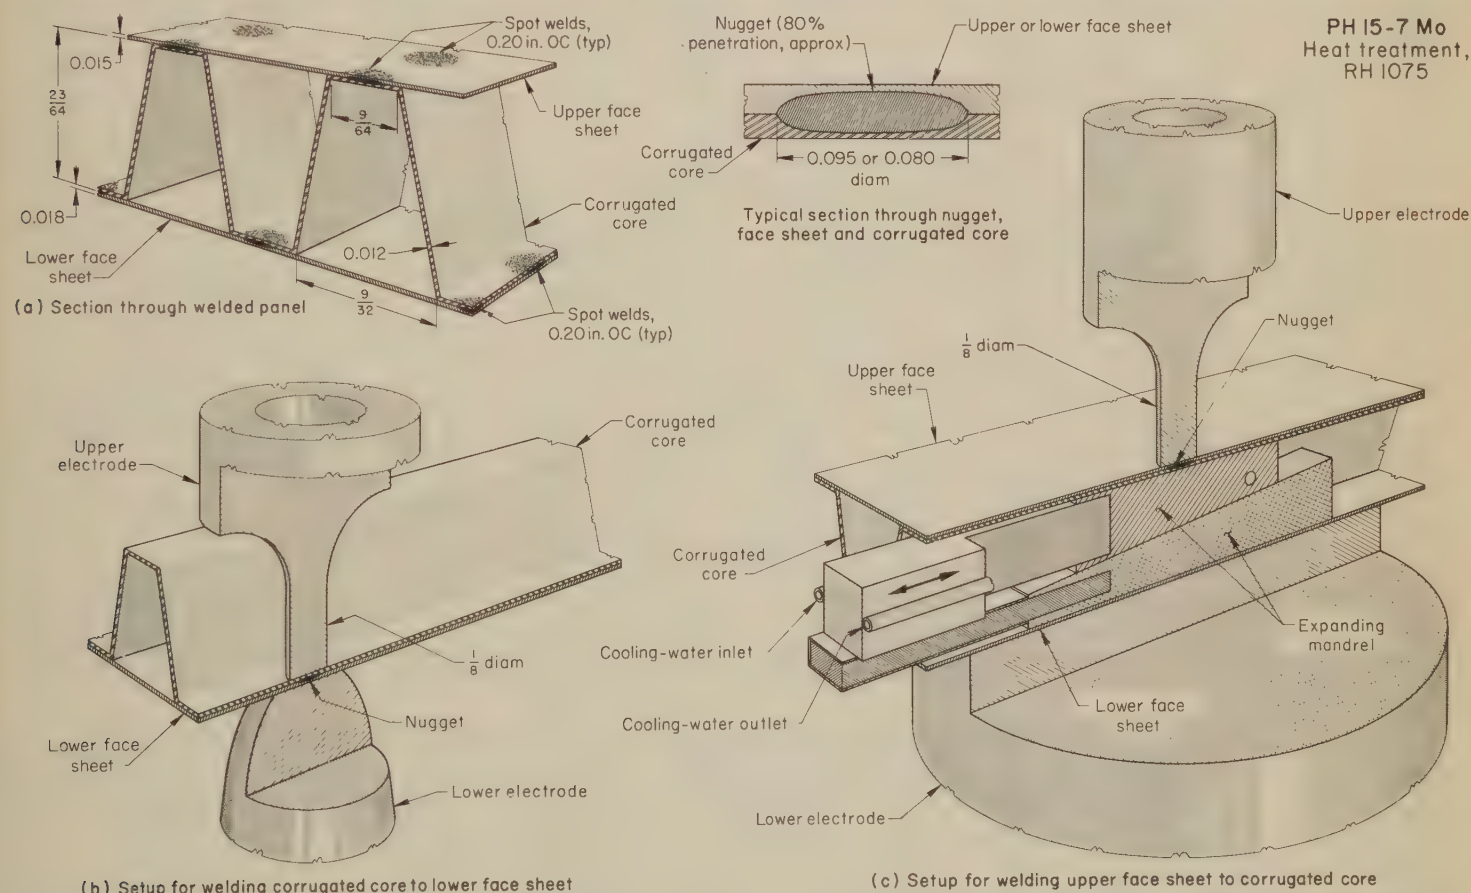
Current requirements generally are low and, consequently, an electrode material with reduced electrical conductivity is permissible. RWMA class 2 and class 3 materials (copper alloys) are generally recommended, but for some applications the refractory metals (classes 10 to 14) can be used. (See Table 2 on page 409 for compositions and properties of electrode materials of classes 2 and 3, and Table 3 on that page for similar information on electrode materials of classes 10 to 14.)

Electrodes of both standard and special designs are used for spot welding stainless steel. In the following example, both the standard and special electrodes were made of a material having high hardness and strength.

Example 409. Resistance Spot Welding of Face Sheets to a Corrugated Core, Using Specially Designed Electrodes (Fig. 2)

A honeycomb panel, 15 in. square, was fabricated by spot welding a 0.012-in.-thick corrugated core to lower and upper face sheets as shown in Fig. 2(a). Before being spot welded, the components of the panel, all of which were made of PH 15-7 Mo stainless steel, were cut to size and the core was corrugated by forming. The components were then heat treated to the RH 1075 condition and chemically cleaned.

The corrugated core was spot welded to the lower face sheet with ⅝-in.-diam electrodes made of RWMA class 3 material. The upper electrode was modified as shown



Conditions for Resistance Spot Welding of Lower Face Sheet to Core

Upper electrode ...Type C, ⅝-in. diam, modified
Lower electrode ....Type A, ⅝-in. diam, ¼-in.-diam tip
Transformer connection ....Series
Weld-heat setting 65%
Postheat setting 20%
Squeeze time ....21 cycles
Weld time ....3 cycles
Hold time ....21 cycles
Postheat time ....3 cycles
Cool time ....2 cycles
Weld impulses ....One
Postheat impulses ....Two
Nugget diameter ....0.080 in.
Production rate ....700 welds per hour

Conditions for Resistance Spot Welding of Upper Face Sheet to Core

Upper electrode ..Type C, ⅝-in. diam, modified
Lower electrode ....(a)
Transformer connection ....Parallel
Weld-heat setting 33%
Postheat setting 10%
Squeeze time ....31 cycles
Weld time ....2 cycles
Hold time ....31 cycles
Postheat time ....3 cycles
Cool time ....1 cycle
Weld impulses ....One
Postheat impulses ....Two
Nugget diameter ....0.095 in.
Production rate ....400 welds per hour

(a) Water-cooled expanding mandrel with 2¼-in.-diam flat-face current-carrying support.

For welding both joints, power supply was 440 v, three phase, 60 cycle; the welding machine was a semiautomatic press type with a series-parallel transformer; welding controls were synchronous, with phase-shift heat control; electrode material was RWMA class 3; electrode force was 350 lb; and weld spacing was five spots per inch.

Fig. 2. Section through a welded honeycomb panel, and setups for resistance spot welding the corrugated core to lower and upper face sheets using specially designed electrodes as shown (Example 409)

in Fig. 2(b) to fit into the corrugation. The lower electrode was of the standard RWMA type A design (pointed face).

The upper face sheet was spot welded to the core using the same modified upper electrode and an expanding mandrel (made of RWMA class 3 material) that was inserted inside the corrugation to serve as an electrode, as shown in Fig. 2(c). The upper portion of the mandrel (1 in. long) was automatically actuated by an air cylinder controlled by the spot welding timer. Up to 100,000 welds were made before the upper portion of the mandrel was replaced. Spot welding progressed along each corrugation from the center of the panel toward each edge; the mandrel was inserted in the corrugation from each edge of the panel.

The lower portion of the mandrel (1½ in. long) was attached to and insulated from the lower platen of the welding machine. A 2¼-in.-diam lower electrode supported the mandrel, and reduced the current density at the contact point between the lower electrode and the lower face sheet so that a weld would be made at the interface between the upper face sheet and the corrugated core. The top half of the mandrel was water cooled, and a filter was needed to prevent dirt particles from clogging the small tube. The two halves of the tapered mandrel were connected to high-strength steel force rods by brazing.

(a) Steel should be free from scale, oxide, paint, grease and oil. (b) Welding conditions are determined by thickness (t) of thinnest outside piece. Data are for total thickness of pile-up not exceeding 4t. Maximum ratio between two thicknesses, 3 to 1. (c) Electrode material, RWMA class 3. Face radius, 3 in. (d) For large assemblies, the values listed should be increased 30%. [SOURCE: Same as Table 2.]

The sequence of operations for welding the upper face sheet to the corrugated core was as follows (steps 3 through 5 were automatically controlled in sequence):

1 Place mandrel in the corrugation (twice for each corrugation) and rest on lower electrode.
2 Depress foot switch.
3 Expand mandrel; lower the upper electrode.
4 Make spot weld and postheat.
5 Raise upper electrode; release mandrel.
6 Relocate panel for next spot weld and repeat steps 2 through 5.

All spot welds were made by single-impulse welding under conditions listed in the table with Fig. 2. After the welds had cooled, they were given a double-impulse postheat cycle that was applied before the electrodes were removed.

Effect of Heat Distortion. Because the coefficient of thermal expansion of austenitic stainless steel is considerably higher than that of carbon steel, expansion and contraction of the heated metal should be considered. When metal is heated and cooled rapidly in resistance welding, there is an upsetting action, followed by shrinkage of the metal in the weld zone. This can cause waviness in sheets and, when long welds are made, an over-all shrinkage of the part.

In spot welding, weld shrinkage can be reduced by decreasing the size of the individual welds in the joint. The safe upper limit for spot-weld diameter is four to five times the thickness of the thinnest sheet being welded. If more spots of smaller diameter are used, in such a way that the total volume of weld metal is the same, distortion will be less.

Adequate water cooling will also help in controlling heat distortion.

Expulsion of molten metal, by arcing or flashing during spot welding, can be caused by using high welding current, low electrode pressure, and small area of contact at the interface of the two workpieces. The small area of contact generally is the result of using sharply domed electrodes or too small a face radius. A copious supply of water around the electrodes, both upper and lower, can minimize flashing and allow wider ranges of usable welding current and electrode pressure.

Multiple-Impulse Resistance Spot Welding

Multiple-impulse resistance spot welding consists of transmitting two or more impulses of welding current without removing the electrode force. One purpose of multiple-impulse spot welding is to add a given amount of heat to the weld with minimum damage to the electrodes. The effects of excessive heat on the heat-sensitive grades of stainless steel are avoided; decreased thermal distortion and a reduced amount of harmful carbide precipitation result. Multiple-impulse spot welding is useful for joining austenitic stainless steels in thicknesses greater than ⅛ in.

Recommended practices for multiple-impulse spot welding of austenitic stainless steels are given in Table 3. Impulses are shorter and fewer, welding current is slightly greater, and electrode force is much greater, than for multiple-impulse spot welding of carbon steels with comparable thicknesses.

Table 5. Continuous Resistance Seam Welding of Three Assemblies Made From Mill-Pickled Stainless Steel Sheets of Dissimilar Thicknesses (Examples 410, 411 and 412)

Item	Example 410	Example 411	Example 412
Details of Sheets Welded			
Upper sheet (alloy and thickness, in.)	Type 310, 0.050	Type 316, 0.062	Type 316, 0.093
Lower sheet (alloy and thickness, in.)	Type 310, 0.043	Type 316, 0.093	Type 321, 0.062
Overlap of sheets at joint, in.	0.400	1.000	0.508

Face width, in.	0.280	0.375	0.312
Face radius, in.	3	12	6
Welding Conditions			
Welding current and voltage	Three-phase half-wave rectified current; 3 to 6 volts across weld		
Heat setting, %	30	30	30
Electrode force, lb	1500	2200	2200
Squeeze time, cycles(b)	72	36	36
Hold time, cycles(c)	36	36	36
Heat time, cycles	10	12	12
Cool time, cycles	6	16	16
Impulses per spot	1	1	1
Nugget width and height, in.	0.21, 0.048	0.22, 0.078	0.25, 0.078
Spots per inch	14	16	16
Welding speed, in. per minute	16	8	8

(a) Electrode material for all three applications was RWMA class 3. (b) Squeeze time at beginning of seam, before welding had started. (c) Hold time at end of seam, after welding had stopped.

The pulsations can also be used for postheat cycles. Two short impulses were used to postheat the weld in the application described in Example 409.

Resistance Seam Welding and Roll Resistance Spot Welding

Resistance seam welding operates on a time cycle of current on (heat) and current off (cool) while the workpieces are traversed and pressure is exerted on them by rotating electrode wheels, which are in continuous contact with the work metal, to produce a line of overlapping spot welds. The overlapping spot welds provide gastight or liquid-tight seams. The spot welds can be spaced apart, which is known as roll resistance spot welding.

Seam welds are usually made in lap joints, and can be made in a straight line on flat metal, can be carried around corners by using a small electrode wheel on the inside, or can be installed as girth joints between cylinder walls and inserted head flanges. Mash-seam welding can be used to produce flush joints on thin metal.

Roll resistance spot welding is done with the same equipment used for resistance seam welding, and is similar to it except that the spots are not overlapping. The spots can be made at any desired spacing, and the seams are not necessarily gastight or liquid-tight.

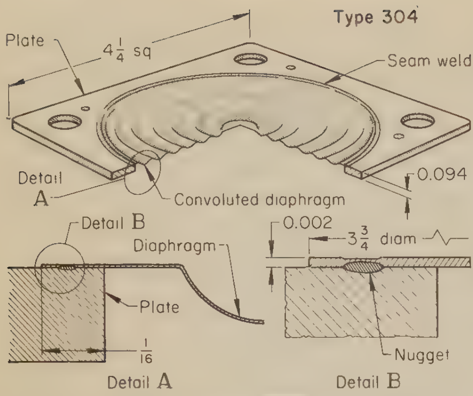
Mash Resistance Seam Welding. Flush joints in stainless steel up to about 0.062 in. thick can be produced by mashing down the double metal thickness of a lap joint to approximately that of one member of the assembly. The operation is made possible by (*a*) reducing the overlap below that ordinarily used for seam welding, (*b*) increasing the electrode pressure, (*c*) decreasing the welding speed, and (*d*) increasing the rate of heat generation in the work metal by eliminating cool time from the weld cycle.

The overlap is a maximum of 1½ times the thickness of one sheet of work metal. The sheets must be assembled carefully before welding and held rigidly during welding. Electrodes are machined to flat faces to straddle the overlap and produce a uniform joint. Electrode pressure has an effect on thickness of the joint and on contact resistance. Square edges are satisfactory on metal thicknesses up to about 0.050 in. On thicker metal, beveling the overlapping edges may be helpful because it reduces the amount of plastic-metal movement needed for thickness control. (See also "Mash Seam Welds" and "Foil Butt Seam Welds", page 433.)

Seam Welding Machines. Seam welding of stainless steel is done with the same machines used for seam welding of carbon steel. Welding pressures are greater and weld time and current are less than in welding carbon steel, but more accurate control over welding conditions is needed.

The annealed austenitic stainless steels are nonmagnetic and do not influence the reactance of the secondary circuit of the welding machine. Therefore, on longitudinal seam welding machines, welding current does not change as the welded assembly is fed into the throat of the machine. However, cold working induces some magnetism in austenitic stainless steels. The martensitic and ferritic grades are ferromagnetic and have a marked effect on the characteristics of the secondary circuit.

Heat Distortion. The installation of a closely spaced succession of spot welds generates considerable heat in the workpieces — a condition that can cause unwanted metallurgical effects or excessive warpage.



Equipment Details

Power supply	220 v, single phase, 60 cycle
Welding machine	Bench mounted, press type
Transformer rating at 50% duty cycle	30 kva
Secondary current, max	15,000 amp
Transformer taps	Four
Electrodes	5½-in. diam, ¾ in. thick at hub, 0.100 in. thick at contact surface
Electrode material	RWMA class 3
Electrode force, max	900 lb
Welding controls	Spike power, synchronous, half-cycle multispot, phase-shift heat control

Conditions for Resistance Seam Welding

Welding current	2000 to 4000 amp
Heat-control setting	No. 3 tap and 50%
Squeeze time(a)	40 cycles
Hold time(a)	40 cycles
Welding speed	20 in. per minute
Spots per inch	8 to 11

(a) Applied at the beginning and end of seam

Fig. 3. Diaphragm-and-plate assembly, and details of joint that was resistance seam welded using close control of welding conditions to minimize distortion (Example 413)

Stainless steels with extra-low carbon content, such as 304L and 316L, or the stabilized compositions (321, 347 and 348) can be used to avoid intergranular carbide precipitation. The best method of controlling thermal distortion on any grade of stainless steel is to prevent excessive heat buildup and absorption during seam welding. Forced cooling of the work metal is commonly done with jets or sprays of water directed on the work at the point of contact with the wheels. The water spray should be directed to the top and bottom of the sheets both before and behind the electrode wheels. A copious flow of water over the electrode wheel is sometimes used. Welding can be done underwater if the size of the workpiece permits.

Welding Schedules. Recommended practices for resistance seam welding of austenitic stainless steels are given in Table 4. Test welds should be made before starting production, to determine optimum conditions, using the conditions listed in Table 4 as starting points. Conditions can be adjusted according to the procedure given on page 428 for setting up a schedule for resistance seam welding.

The wide latitude of conditions under which seam welds can be made between stainless steel sheets of dissimilar thicknesses is illustrated in the group of three examples that follows.

Examples 410 to 412. Conditions for Seam Welding Three Combinations of Stainless Steel Sheets of Dissimilar Thicknesses (Table 5)

Table 5 lists equipment details and welding conditions for continuous seam welding of type 310 sheets 0.050 and 0.043 in. thick (Example 410), type 316 sheets 0.062 and 0.093 in. thick (Example 411), and types 316 and 321 sheets 0.093 and 0.062 in. thick, respectively (Example 412).

For all three applications, the electrode wheels were made of RWMA class 3 material (a low-beryllium copper alloy), to reduce deformation of the contact surface resulting from high heat, long weld time, inadequate cooling and highly concentrated electrode force. The welding machine for the three applications was a circular type. Power was supplied by a three-phase half-wave frequency converter.

The high electrode forces and low welding speeds used for joining these sheets provided consistency in obtaining high-strength, crack-free seam welded joints.

In the following example, the welding procedures and control limits had to be determined experimentally and then followed very carefully, to ensure quality of the seam weld.

Example 413. Control of Current and Electrode Force for Distortion-Free Seam Welding (Fig. 3)

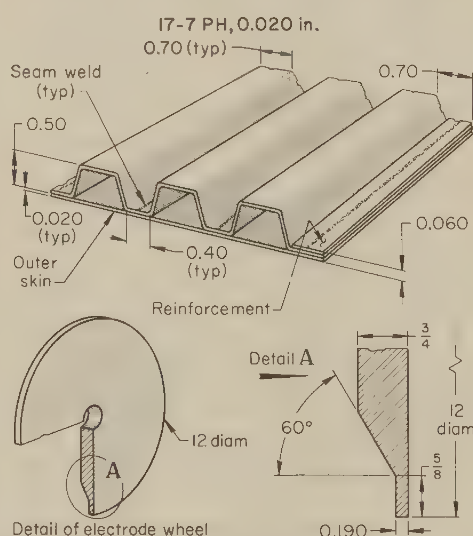
A 0.002-in.-thick diaphragm had to be seam welded to a 0.094-in.-thick plate, as shown in Fig. 3, without causing distortion of the diaphragm or warping of the plate. Overheating could not be tolerated on either component of the assembly (both of which were made of type 304 stainless steel), and the completed joint had to withstand an air pressure of 50 psi under water without leaking.

Welding was done in a manually operated, bench-mounted, press-type welding machine, using a 30-kva single-phase transformer. The machine had spike-power welding controls and could weld a seam up to ⅛ in. wide. Maximum power per spike was achieved in 4.5 millisec. Electrode force was supplied by a 3-in.-diam air cylinder. Originally, the weld width was greater than 1⁄16 in., to permit formation of a nugget at the outside edge of the diaphragm. The electrode wheel could not extend into the hole spanned by the diaphragm, because welds in that area would result in cracks and cutting of the diaphragm.

After preliminary production, the following modifications were incorporated in the welding machine:

1. The machine cycle was changed from continuous to multispot welding.
2. The upper arm of the machine was rebuilt to move the centerline of the electrode wheel outward, and the welding head was counterbalanced by means of springs to provide low inertia.
3. Guide supports were added to the ram to improve alignment of the welding head.
4. Air pressure to the air cylinder that provided the electrode force was adjusted to obtain proper electrode pressure and contact resistance.
5. Weld width was reduced to under 1⁄16 in.

With the above changes, the rejection rate was reduced to 10%, which was a considerable improvement over the 50% rejection rate obtained when welding was done by a subcontractor using three-phase equipment, and the 60% rejection rate obtained in in-plant welding before modification of the machine. Equipment details and welding conditions for the revised procedure are given in the table with Fig. 3.



Equipment Details

Power supply	440 v, three phase, 60 cycle
Welding machine	Circular
Transformer rating at 50% duty cycle	50 kva
Electrodes	12-in. diam, ¾ in. thick, with 0.190-in.-wide flat contact surfaces
Electrode material	RWMA class 3
Electrode force, max	4000 lb
Welding controls	Synchronous, with phase-shift heat control

Resistance Seam Welding Conditions	Two sheet thicknesses	Three sheet thicknesses
Heat-control setting	28%	46%
Electrode force, lb	800	800
Squeeze time, cycles	30	30
Heat time, cycles	2	2
Cool time, cycles	3	4
Hold time, cycles	30	30
Seam width, in.	0.170	0.150
Weld penetration, %	48	42
Welding speed, ipm	44	44
Spots per inch	16 to 17	14 to 15

Fig. 4. Aircraft-fuselage blast panel that was resistance seam welded with electrodes having flat contact surfaces as shown (Example 414)

Electrode wheels for resistance seam welding of stainless steel are often made of RWMA class 3 material in order to withstand high electrode forces. With softer electrode materials, mushrooming of the contact face occurs and weld quality is reduced.

The shape of the contact face on an electrode wheel can have a marked effect on the life of the wheel and on the size of the weld nuggets. In the following example, radius-face wheels were replaced by flat-face wheels because the radius rapidly flattened and thus caused nugget width to increase and penetration to decrease.

Example 414. Effect of Electrode-Wheel Design on Electrode Maintenance and Size of Weld Nugget in Resistance Seam Welding (Fig. 4)

Blast panels (24 by 14 in.) for the tail section of the fuselage of a jet aircraft were fabricated by resistance seam welding a corrugated member to an outer skin as shown in Fig. 4. Both components of the assembly were made of 0.020-in.-thick 17-7 PH stainless steel (annealed). A reinforcing strip of the same material and thickness was added to one edge of the panel, necessitating seam welding three sheet thicknesses along that edge.

Originally, welding was done with 12-in.-diam electrode wheels that had 10-in.-radius contact faces. The contact faces were 0.190 in. in width. However, inaccuracies in dressing the contact faces resulted in surfaces with radii varying from 9 to 11 in. Also, after the wheel had been in use for a short time, wear produced a flat on the radiused contact face, and this resulted in changes in the size of the weld nuggets (increased width and decreased penetration).

By changing from radius-face wheels to flat-face (0.190 in. wide) wheels of the design shown in Fig. 4, wheel life between dressings was increased and weld size was more uniform. The flat-face wheels were dressed after 16 to 24 hours of production. To establish the need for remachining the faces of the wheels and to determine weld quality, test samples were taken hourly and at the beginning and end of each shift. The nuggets were sectioned both longitudinally

and transversely so that weld penetration and nugget size could be measured.

Before being seam welded, the components of the panel were tack spot welded at intervals of 3 to 4 in. The assembly was held at the approximate final contour during tack welding by means of a lightweight laminated fiber-glass fixture. Seam welding was done without the use of fixtures, under the conditions listed in the table with Fig. 4. Initially, speed in seam welding had been 30 ipm; later, speed was increased to 44 ipm, which was established as the practical maximum for this application. Higher speeds made it difficult to guide the panels through the seam welding machine without damaging the components or improperly locating the seam.

Seam Welding vs Induction Brazing. The short weld impulses used in seam welding produce a gastight joint while introducing a minimum of heat into the work metal. Brazing usually requires that the components being joined be heated over a larger area to achieve correct flow of filler metal and proper bonding. The following example describes an application in which induction brazing was replaced by seam welding because brazing did not consistently produce gastight joints.

Example 415. Change From Induction Brazing to Resistance Seam Welding, To Obtain Flux-Free, Gastight Joints (Fig. 5)

The end closure of a solenoid-valve assembly was originally made by induction silver brazing a type 430F stainless steel plug to the end of a type 321 stainless steel tube as shown at upper right in Fig. 5. The tube contained the components of the solenoid valve, including a 17-7 PH stainless steel spring and a brass sleeve-type spacer, about ⅛ in. long, which separated the plug from the spring. Because of the spring, it was important that the assembly be heated rapidly (without overheating) and cooled immediately. The end of the plug was inserted a short distance into the tube to retain the brazing filler metal. The plug had a V-groove that served as a flux trap, and the tube was staked into the groove at four places for longitudinal location.

Brazing did not consistently produce gastight joints, and necessitated cleaning of the outer surfaces of the tubes. Also, there was no assurance that some flux would not be retained inside the tube when the assembly was joined by brazing.

A change was made to resistance seam welding using a special seam welding machine with two flat-face electrode wheels that rotated in the same direction. The tube, which was inserted between the electrode wheels (Fig. 5, upper left), was held in a rotatable fixture. The electrode wheels were driven at their periphery, to maintain a constant peripheral speed regardless of reduction in diameter resulting from wear and re-dressing. The tube was rotated slightly more than 180°, and the assembly was welded in about 1½ seconds. Equipment details and welding conditions are given in the table that accompanies Fig. 5. Welding by this procedure was possible only because the tube wall was very thin in relation to the diameter of the plug.

Production rate in resistance seam welding was 640 assemblies per hour, which was about 2½ times the production rate obtained in brazing. Leakage was reduced by 67%. Because no flux was used, there was no need to clean the finished assembly, and no possibility of flux contamination inside the assembly.

The welded assemblies were leak tested using a mixture of refrigerant gas (dichlorodifluoromethane) and air at 400 psi. The testing unit consisted of a halide detector that was capable of detecting leaks greater than 10^{-6} cu cm per second when measured under standard conditions of one atmosphere at 70 F.

Projection Welding

Projection welding offers advantages in the fabrication of stainless steel similar to those obtainable in welding carbon steel. The current and electrode force are concentrated at well-defined spot areas in projection welding, which minimizes the adverse effects of excessive heat on the more heat-sensitive grades. Such effects are characteristic of spot welding, in which contact areas are larger. Also, in projection welding, shunting effects of surface irregularities are eliminated and areas of contact at individual points are constant.

The same projection designs and methods of forming are used for stainless steel as for carbon steel. When three or more projections are welded simultaneously, variations in diameter, contour, and height of the projections can result in variation in current density, and thus weld quality. When components are of different thicknesses, projections should be in the thicker piece to maintain better heat balance.

Projection welding design data for stainless steel are given in Table 2, page 440, in the article on Projection Welding in this volume.

Example 408 in the present article gives data on projection welding of type 440A to type 430 stainless steel.

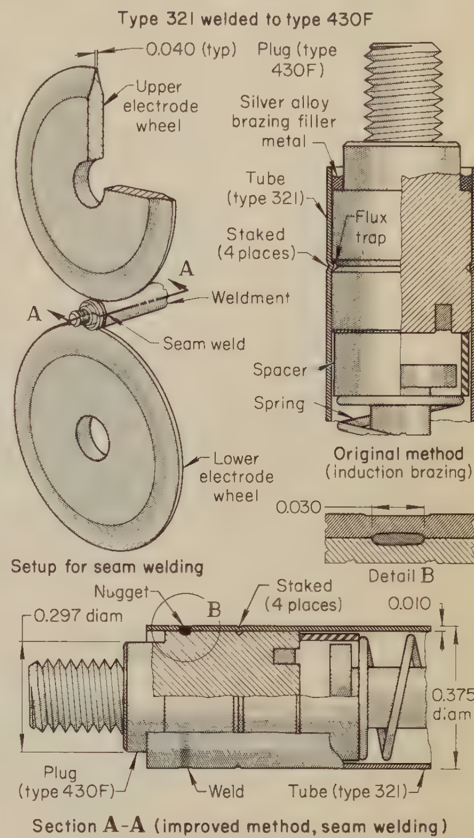
Welding Schedules. Recommended practices for projection welding of austenitic stainless steels are given in Table 6; the values listed there may require adjustment to suit the requirements of individual applications.

Projection Welding vs Torch Brazing. Projection welding can be done without marring one surface of the assembly, and this makes it competitive with brazing for fabrication of assemblies in which appearance is an important factor, as in the following example.

Example 416. Projection Welding vs Torch Brazing for Mark-Free Surfaces (Fig. 6)

A cover plate and a bracket were joined by resistance projection welding using a specially designed fixture, as shown in Fig. 6. Specifications required the bracket to be perpendicular to the surface of the cover plate within a tolerance of ±1°. The components of the assembly, which were made of 0.036-in.-thick type 302 stainless steel, had been designed originally for torch brazing, because the cover plate was a decorative part and was required to be free of weld marks on its outer surface. Resistance spot welding was not considered, because it would have left weld marks.

Brazing was done with AWS No. 3 flux and BAg-1 filler wire, using an oxyacetylene torch having a 0.030-in.-diam hole at the tip. Brazed assemblies, however, were unacceptable because of thermal distortion.



Equipment Details

Power supply ......230 v, single phase, 60 cycle
Welding machine ....Circular
Transformer rating at 50% duty cycle ...30 kva
Transformer taps ....Eight
Electrodes .....5-in. diam; ⅜ in. thick at hub; 0.04 in. thick at contact surface
Electrode material ....RWMA class 2
Electrode force, max ....150 lb
Welding controls ....Synchronous, with phase-shift heat control

Conditions for Resistance Seam Welding

Heat-control setting ....No. 7 tap and 90%
Electrode force ....118 lb
Squeeze time ....20 cycles
Heat time ....3 cycles
Cool time ....1 cycle
Spots per inch ....25 to 27
Production rate ....640 assemblies per hour

Fig. 5. Tube-and-plug assembly for which induction silver brazing was replaced by resistance seam welding, to obtain gastight joints (Example 415)

Table 6. Recommended Practices for Projection Welding of Series 300 Stainless Steels (a)

Thickness (t) of thinner piece (nominal), in.(b)	Electrode face diameter, in.(c)	Net electrode force, lb	Weld time, cycles (60 Hz)	Hold time, cycles (60 Hz)	Welding current at electrodes (approx), amp (60-Hz ac)
0.014	⅛	300	7	15	4,500

Conditions for Projection Welding

Welding current	3750 amp, ac
Welding voltage	5.39 v
Heat-control setting	No. 3 tap and 76%
Electrode force	135 lb
Squeeze time	10 cycles
Weld time	9 cycles
Hold time	20 cycles
Production per hour	300 assemblies (600 welds)

Fig. 6. Cover plate and bracket that were projection welded in the fixture shown, to obtain a combination of close alignment, blemish-free appearance and high production rate (Example 416)

and because flux and brazing alloy flowed to the upper surface of the cover plate regardless of the brazing techniques or fixture design used. Moreover, the pits formed by the flux could not be removed by electropolishing and could be removed only by wheel buffing. Also, the production rate achieved by brazing was only 95 assemblies per hour; rejection rate was about 25%.

By changing from brazing to projection welding, the production rate was increased from 95 to 300 assemblies per hour, and rejection rate was reduced to less than 1%. Projection welding was accomplished by using a fixture (see lower view in Fig. 6) to maintain the desired squareness and alignment between the cover plate and the bracket. The bracket was placed on the stationary lower electrode and held in place with a spring-loaded plunger that passed through the large round hole of the bracket. The cover plate was placed in position on locating pins resting on a spring-actuated phenolic pad that was guided by four leader pins (not shown in Fig. 6).

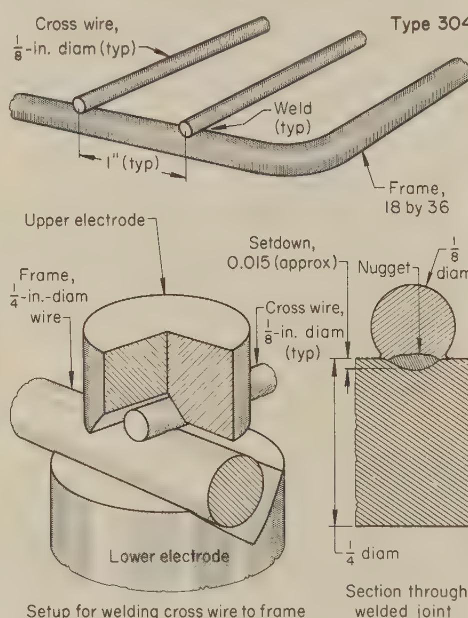
When the upper electrode was lowered, the cover plate was clamped to the phenolic pad and was brought to bear on the weld projections that were formed on the angle-shape bracket. With the components thus aligned and clamped in position, welding current was initiated to make the projection welds. Equipment details and welding conditions are given in the table that accompanies Fig. 6. After being welded, the assembly was removed manually and visually inspected.

To ensure a blemish-free cover plate, the welding electrodes were water cooled. The upper electrode was ground and polished to protect the polished finish on the cover plate. Also, the surfaces of the electrodes were kept parallel within 0.002 in. The upper electrode was dressed after welding an average of 5000 assemblies.

Cross-Wire Welding

Cross-wire welding is a form of projection welding in which the curved surfaces of the wires form the projected or localized areas for the welds.

Conventional press-type resistance welding machines are used for cross-wire welding. Cross-wire resistance welds can be made singly or in multiples, as permitted by part design and the availability of suitable welding machines. Flat-face (RWMA type C) spot welding electrodes or electrodes with a V-groove across the face are used for single welds. Flat bar-type electrodes are used for multiple welds. Cut and formed wire sections are generally held in fixtures during welding.



Equipment Details

Power supply	440 v, single phase, 60 cycle
Welding machine	Press type spot, semiautomatic
Rating at 50% duty cycle	60 kva
Secondary current, max	70,000 amp
Secondary voltage, max	3 v
Transformer taps	Eight
Upper electrode	⅝-in. diam (grooved face)
Lower electrode	¾-in. diam (grooved face)
Electrode material	RWMA class 2
Electrode force, max	3000 lb
Welding controls	Synchronous, with phase-shift heat control

Conditions for Cross-Wire Welding

Welding current	3000 amp, ac
Welding voltage	1 v
Heat-control setting	No. 1 tap and 50%
Electrode force	350 lb
Squeeze time	10 cycles
Weld time	4 cycles
Hold time	10 cycles
Production per hour	20 assemblies

Fig. 7. Cross-wire welding of a food-handling tray, in which low setdown provided adequate strength while minimizing flash and discoloration (Example 417)

The strength of cross-wire welds in types 304 and 430 stainless steels is about the same. However, the austenitic stainless steels provide a sounder and a more dependable welded joint. Weld strength is a function of the setdown of the wires at the joint, and is not affected by any temper in the wire resulting from cold drawing. Maximum strength is achieved in all wire sizes at about 30% setdown. (Percentage of setdown is determined by dividing the setdown, which represents the difference in the combined height of the two wires before and after welding, by the diameter of the smaller wire, and multiplying the result by 100.) Best appearance and avoidance of excess flash from the joint are obtained with about 20% setdown, but lower weld strength is obtained with 20% setdown than with 30% setdown. The optimum electrode force, and tensile breaking-load values for 20% and 30% setdown, for cross-wire welding of three sizes of type 304 wire are given in Table 7.

In cross-wire welding, electrode force is related to wire diameter. Weld time and welding current control the amount of setdown, flash and discoloration. For the application in the following example, strength and appearance were the criteria used for selecting the welding conditions.

Example 417. Cross-Wire Welding of Stainless Steel Trays (Fig. 7)

Food-handling trays measuring 18 by 36 in. were designed for fabrication by cross-wire welding. The trays, consisting of a frame made of ¼-in.-diam type 304 stainless steel wire and ⅛-in.-diam cross wires of the same material, were set up for welding as shown in Fig. 7. Welding was done with the wires held in position by means of a fixture. Equipment details and welding conditions are given in the table that accompanies Fig. 7.

The 350-lb electrode force was selected on the basis of the smaller (⅛-in.-diam) wire. The short weld time (4 cycles) was selected to avoid discoloration. The 3000-amp welding current was selected to produce a setdown of only 0.015 in. (12% setdown) — which provided adequate strength for the application. The small amount of setdown resulted in negligible flash and also helped to avoid discoloration. As a result, bright finishing of the as-welded trays was easily accomplished by electropolishing.

Welding Dissimilar Metals

In resistance welding of stainless steel to another metal, the maximum electrical resistance may not be at the interface of the two workpieces, but within the stainless steel workpiece, because of its high electrical resistivity. The low thermal conductivity of the stainless steel can result in a greater heat loss in the weld zone of the other work metal because heat is conducted away more rapidly than in the weld zone of the stainless steel workpiece.

The low electrical conductivity of stainless steel reduces the shunting effect from one spot to another. However, in resistance welding stainless steel to another metal, the heat and follow-up of the electrode must be carefully controlled. Too little heat does not give enough penetration in

the stainless steel to produce adequate weld strength, and too much heat can cause identation and expulsion of the other metal at spots close to the edge of the joint.

In the following example, an austenitic stainless steel was spot welded to a copper alloy. The welding conditions were carefully controlled; adequate electrode force and a low-inertia welding head with fast follow-up were needed to prevent cracking in the stainless steel.

Example 418. Control of Heat and Electrode Follow-up in Spot Welding a Flat Phosphor Bronze Spring to a Stainless Steel Strip in a Hem-Type Joint (Fig. 8)

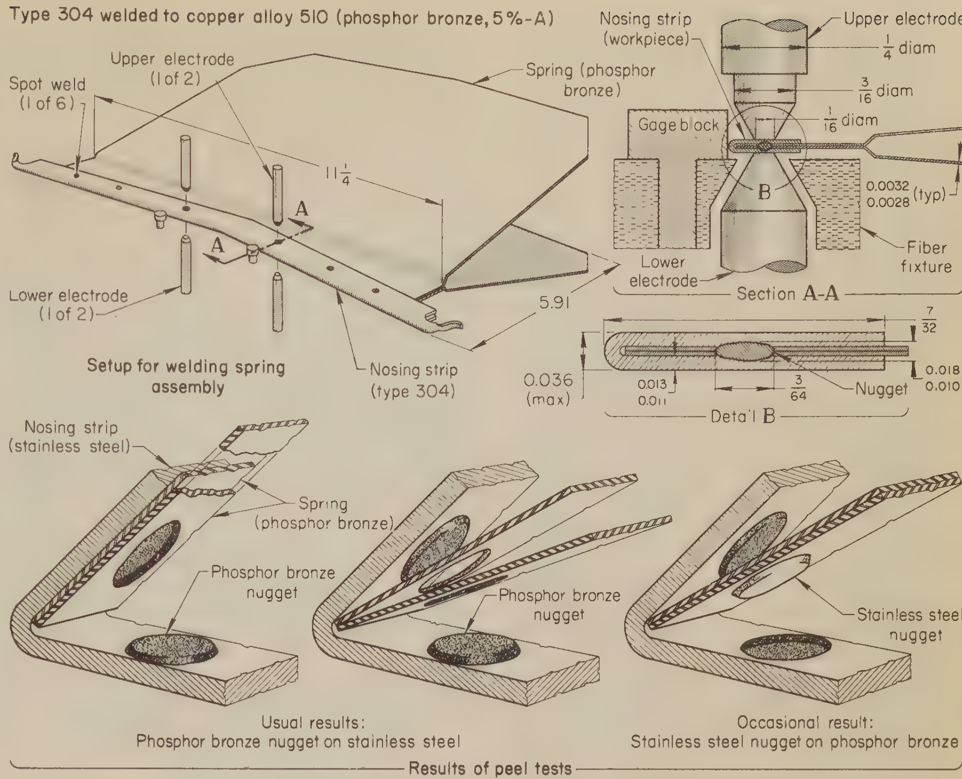
The spring assembly shown in Fig. 8 (upper left) was used in an electronic memory unit, to provide uniform pressure for holding a magnet card against its magnetizing plane. The flat ends of the two halves of the spring, which was made of 0.003-in.-thick phosphor bronze (copper alloy 510) foil, were sandwiched between a U-shape nosing strip of 0.012-in.-thick type 304 stainless steel, and the assembly was joined by means of six spot welds. The design of the joint avoided burn-through, which is often encountered in welding such thin metal in the usual sheet-to-sheet arrangement. The stainless steel strip, which was primarily intended to provide structural strength, also served as a connection for electrical grounding.

The welded assembly was required to be of uniform thickness (0.036 in. max), except for a slight depression in the nosing strip at each bearing point of an electrode. The presence of waviness and weld spatter were unacceptable.

A press-type semiautomatic spot welding machine was used that had a head with a low-inertia inner-shaft assembly capable of providing fast follow-up. Holders for the two upper electrodes were mounted to the inner shaft, and holders for the two opposing lower electrodes were mounted on the platen. The six spot welds were made, two at a time, by direct welding. Conditions for welding were closely adjusted to the settings given in the table with Fig. 8, to avoid expulsion of the copper alloy and to obtain adequate weld penetration in the stainless steel. Expulsion of the copper alloy was avoided as long as the spots were made with the specified welding current and the correct edge distance. Because stainless steel has higher electrical resistivity at room temperature than does phosphor bronze, only a small percentage of the current was shunted around the nosing strip.

During welding, the assembly was positioned and supported by a fixture made of a nonconducting material and was held against gage blocks in three locations (one for the position of each pair of spot welds). The upper electrode had a portion of its shank reduced to 3/16 in. in diameter to clear the gage blocks (see Fig. 8, upper right). As the welding-machine head was lowered by an air cylinder, deflection of a leaf spring, incorporated in the head and bearing on an inner shaft that carried the electrode holder, provided the actual electrode force. The leaf spring also served as a decoupling device and allowed the low-inertia inner shaft, electrode holder and electrode assembly to follow quickly as the metal in the weld zone softened on reaching welding temperature. The resulting electrode indentation was shallow, and the fast follow-up made sound welds and prevented cracks in the stainless steel at the weld. Deflection of the leaf spring also closed a limit switch to start the welding current. When follow-up was slow and force was insufficient, cracks were visible on the outer surface of the stainless steel and extended through to the phosphor bronze.

In peel tests, which were conducted at regular intervals, the nugget usually was pulled from the phosphor bronze, but occasionally, if the welds were made with higher heat, the nugget was pulled from the stainless steel (Fig. 8, bottom view).



Equipment Details	
Power supply	460 v, single phase, 60 cycle
Welding machine	Press type, semiautomatic
Transformer rating at 50% duty cycle(a)	3 kva
Secondary current & voltage(b)	5400 amp, 6 v
Transformer taps	Ten
Electrodes	RWMA class 2(c)
Electrode force, max	60 lb per electrode
Welding controls	Synchronous, with phase-shift heat control

Conditions for Resistance Spot Welding	
Welding current	2000 amp, ac
Welding voltage	3.25 v
Heat-control setting	No. 4 tap and 70%
Electrode force	50 lb per electrode
Squeeze time	(d)
Weld time	2 cycles
Machine cycle time	1 sec
Hold time	Provided in machine cycle time
Production per hour	200 assemblies(e)

(a) Two transformers, one for each set of electrodes used in making the spot welds two at a time. (b) Maximum. (c) Type E (truncated), 1/4-in. diam, 1 3/4 in. long, 60° chamfer, 1/16-in.-diam face. (d) Not required, because of delay in initiating the welding current. (e) 1200 welds.

Close control of heat was needed to obtain sufficient weld strength and to avoid expulsion of phosphor bronze; a low-inertia, fast-follow-up head was used to prevent weld cracking.

Fig. 8. Assembly consisting of a foil-thin phosphor bronze spring and a stainless steel nosing strip, which was resistance spot welded in the setup shown, and results of peel tests after welding (Example 418)

Nickel-base heat-resisting alloys of both solid-solution and precipitation-hardenable types can be resistance spot welded to austenitic stainless steels by making moderate adjustments in the welding schedules for joining the nickel-base alloys to themselves.

In a study of the resistance welding behavior of the solid-solution alloy Hastelloy X and the precipitation-hardening alloy GMR-235, sound spot welds were produced between 0.090-in.-thick type 321 austenitic stainless steel and 0.063-in.-thick Hastelloy X, and between 0.090-in.-thick type 316 austenitic stainless steel and 0.063-in.-thick GMR-235. Best results were obtained by multiple-impulse spot welding, using high welding current, high electrode force, and long welding time.

Grain-boundary fusion in the nickel-base alloys at the periphery of the weld nugget was minimized by directing a stream of cooling water at the electrodes all during welding.

The spot welding was done on pickled and degreased sheets. The Hastelloy X was in the solution heat treated condition, and the GMR-235 was in the precipitation-hardened condition. Spot welding conditions and test results are given in Table 8. Evaluation of welds consisted of (*a*) macroscopic examination for soundness, penetration, and nugget diameter; (*b*) measurement of shear strength and cross tensile strength; and (*c*) x-ray examination to detect porosity and cracking. Maximum indentation was 10%, and penetration was 50 to 60% — both based on the total thickness of the sheets.

Table 7. Optimum Electrode Force and Tensile Breaking Load for Cross-Wire Welding of Three Sizes of Type 304 Stainless Steel Wire

Wire diameter, in.	Optimum electrode force, lb	Tensile breaking load, lb, for setdown(a) of: 20%	30%
0.125	350	1350	1800
0.156	600	...	3350
0.250	1700	5800	8100

(a) Percentage of setdown is determined by dividing the setdown (difference between the combined height of the two wires before and after welding) by the diameter of the smaller wire, and multiplying the result by 100.

Table 8. Multiple-Impulse Resistance Spot Welding of 0.090-In.-Thick Austenitic Stainless Steels to 0.063-In.-Thick Hastelloy X and GMR-235

Equipment Details and Welding Conditions

Power supply . . 440-v, three-phase, 60-cycle ac
Welding machine . . . . 100-kva air-operated press type, with electronic timing and phase-shift heat control
Electrodes . . Flat, 5⁄16-in. diam; RWMA class 3; internal and external water cooling
Welding current . . . . 26,600 amp
Welding pulsations . . . . 8 impulses, each of 10 cycles heat time plus 2 cycles cool time
Electrode force, lb . . . . Weld, 2000; forge, 4000

Flash Welding

Flash welding is used for butt joining of stainless steel bars, tubing and pipe. Also, it is used for making joints in rings that have been rolled from strip stock, bars and extrusions. The making of type 410 and 17-7 PH stainless steel rings is described in Examples 433, 440 and 450 in the article on Flash Welding, which begins on page 485 in this volume.

Stainless steels can be joined to themselves and to other metals by flash welding. Table 2 in the article on Flash Welding lists metals to which stainless steel has been successfully flash welded.

The flashing-current requirements for welding stainless steel are slightly less than those for welding carbon steel. The upsetting pressures range from 13,000 to 25,000 psi, which are somewhat greater than those needed for carbon steel. Best results are obtained when relatively long flash-off periods and a large amount of upset are used. The clamping pressures used on stainless steel are about 50% greater than those used on carbon steel, because of the high contact resistance of stainless steel and the high upsetting forces needed. A protective atmosphere may be desirable during flashing, to improve the mechanical properties.

Causes and Prevention of Weld Defects

Indentations and discoloration of resistance welds are common weld defects that detract from the appearance of finished welds. Cracks and voids in the weld nugget and cracks in the base metal are also common defects.

Indentations are the result of plastic yielding of base metal under the force of the electrodes at the welding temperature. Improper maintenance of the electrode face, excessive electrode force and welding current, and shrinkage in the weld nugget are common causes.

Heat Tinting. All stainless steels are susceptible to discoloration at temperatures above about 400 F. The oxygen in the atmosphere will cause tinting if the electrode is withdrawn before the metal has cooled sufficiently. To safeguard corrosion resistance in atmospheres that are more than mildly corrosive, and to improve appearance, the work-metal surfaces should be cleaned after welding. Cleaning can be done by light pickling, by electropolishing, by light buffing, or by scouring with mild abrasives.

Cracks and voids in the weld nugget generally are a result of insufficient forging force or a hold time too brief to permit the weld metal to solidify under a given force. The high strength of stainless steel at elevated temperatures necessitates the use of high electrode force to make a sound weld. Flat-face, large-diameter electrodes provide a low unit pressure on the work-metal surface. An electrode having a small tip radius may produce a good weld, but can cause expulsion at the surface or at the interface of the two sheets, or excessive indentation. When the welding current is too high in relation to the electrode force, weld time and hold time, cracks can occur in the heat-affected zone as well as in the weld nugget.

Resistance Welding of Aluminum Alloys

*By the ASM Committee on Welding of Aluminum Alloys**

ALUMINUM ALLOYS, both the non-heat-treatable and heat treatable types, either wrought or cast, can be resistance welded, some more readily than others. Aluminum alloys have comparatively high thermal and electrical conductivity, a relatively narrow plastic range (about 200 to 400 F temperature differential between softening and melting), considerable shrinkage during cooling, a troublesome surface oxide, and an affinity for copper electrode materials.

Resistance spot and seam welding of aluminum alloys are used in the manufacture of cooking utensils, tanks (both for seams and for securing baffles), bridge flooring, and many aircraft components. Resistance welding of aluminum aircraft components such as wing-skin sections, deck sections, brackets and cowling usually involves making many high-quality welds in one structure, and may require elaborate and expensive equipment for cleaning, welding and control of weld quality. In many commercial applications, resistance welding of aluminum is done with less cleaning and a lower level of acceptable weld quality.

*For committee list, see page 296.

Weld Strength. The strength of resistance welds in aluminum alloys varies with the alloy and its thickness. Resistance welds should be located so that the weld is under shear loading. For tensile or combined loading, the tensile strength of the welded joint is only about 25% of the shear strength. Nuggets with diameters equal to two thicknesses of base metal plus 0.06 in. should have shear strengths greater than the values given in Table 1.

The heat of resistance welding decreases the strength and hardness of strain hardened and of solution treated and precipitation hardened aluminum alloys, depending on the temperature attained and the length of time that a temperature of 400 F or more is maintained during welding.

Base Metals

Although all aluminum alloys can be resistance spot and seam welded, some alloys or combinations of alloys have higher as-welded properties than others. Melting ranges, electrical and thermal conductivities, and resistance weldability of some wrought alloys and casting alloys are given in Table 2.

Resistance welding is also done on alclad products made by roll cladding some of the alloys listed in Table 2 with a thin layer of aluminum, or an aluminum alloy, that is anodic to the core alloy and thus provides electrochemical protection for exposed areas of the core. Alclad alloys 2219, 3003, 3004, 6061 and 7075 have a cladding of alloy 7072, which contains 1% zinc; alclad alloy 2014 has a cladding of alloy 6006, or sometimes of alloy 6053, both of which contain about 1.2% magnesium; and alclad alloy 2024 has a cladding of alloy 1230, which contains a minimum of 99.3% aluminum.

The hardness of an alloy affects its weldability. Any alloy in the annealed condition (O temper) is more difficult to weld than the same alloy in a harder temper. In general, alloys in the softer tempers are much more susceptible to excessive indentation and sheet separation, and to low or inconsistent weld strength. Greater deformation under the welding force causes an increase in the contact area and variations in the distribution of current and pressure. Therefore, welding of aluminum alloys in the annealed condition or in the softer tempers either requires

special electromechanical or electronic controls or else is not recommended.

High-strength alloys such as 2024 and 7075 are easy to resistance weld, but they may require special welding techniques because they are more susceptible to cracking and porosity than the lower-strength alloys. Sheet separation in welding high-strength alloys is low, and weld strength is consistent. Alloys clad with alloy 1230 or 7072 are less easily resistance welded than bare alloys of the same composition, because of the low electrical resistance and high melting point of the cladding at the contacting interfaces.

Although the strength of welds made in low-strength alloys such as 1100 and 3003 may vary, these alloys can be resistance welded readily in most applications. High welding current or low electrode force may be needed to compensate for the low electrical resistance of these alloys.

Shrinkage cracks in the weld metal are confined almost exclusively to welds made in the copper-bearing and zinc-bearing alloys such as 2024 and 7075. Such high-strength alloys, as well as the chromium-bearing alloys such as 5052 and 6053, may develop some porosity in the weld metal, particularly when they are welded in the hardened condition.

In joining dissimilar aluminum alloys, those with similar electrical conductivities and melting temperatures are easiest to weld together; those pairs with the greatest difference in electrical conductivity and melting temperature are the most difficult to weld together.

Wrought aluminum alloys are frequently spot welded to permanent mold, sand and die castings made from aluminum alloys. Of these types, permanent mold castings are easiest to weld, because the thickness is more nearly uniform. Such castings are sound, and have smooth surfaces and a low as-cast surface resistance, if welded within a reasonable time after casting. Die castings also are dimensionally accurate, but may require special cleaning to prepare the surface for welding, and sometimes special dies and foundry practice are needed to ensure the soundness of the metal in the region to be welded.

Spot and seam welds in non-heat-treatable alloys such as 1100, 3003 and 5052 are not selectively attacked by corrosion, but have the same corrosion resistance as the unwelded metal. Welds in heat treatable magnesium-silicon alloys such as 6061 and 6063 also have good corrosion resistance.

Welds in unclad *2xxx* and *7xxx* series alloys may be attacked preferentially under severely corrosive conditions and, therefore, weldments made from these alloys should not be used in a corrosive environment unless properly protected. However, when these same alloys are resistance welded to aluminum-clad parts of corresponding composition, the cladding electrochemically protects the unclad base metal at the interface and thus improves the over-all resistance to corrosion at the joint. Maximum resistance to corrosion at the welded joint is achieved when each of the parts being welded is an alclad alloy.

Factors Affecting Resistance Welding of Aluminum Alloys

Because of the inherent characteristics of aluminum alloys, resistance welding of these alloys requires procedures different from those used for resistance welding of steel. Included among these characteristics are high electrical and thermal conductivities, low melting-temperature ranges and low strengths at elevated temperatures, narrow plastic ranges, high shrinkage during solidification and the presence of natural oxide coatings.

Table 1. Minimum Shear Strength of Resistance Spot Welds in Aluminum Alloys

Thickness of thinnest sheet, in.	Minimum shear strength, lb per spot, for alloy: 1100-H14, 1100-H18	3003-H12, 3003-H18, 5052-O	5052-H32, 5052-H38, 6061-T4, 6061-T6, 5050-H34	2024-T3, alclad 2024-T3, 7075-T6, alclad 7075-T6

(a) In this table, wrought alloys are identified by Aluminum Association designations, and casting alloys by industry designations. For Aluminum Association designations of casting alloys, see Table 2 on page 297 in the article on Arc Welding of Aluminum Alloys.

(b) International Annealed Copper Standard, volume basis at 68 F. For comparison, copper alloy 102 (oxygen-free copper) is 101% and low-carbon (1010) steel about 14%.

(c) Based on copper alloy 102 as 100%, which has a thermal conductivity of 226 Btu/sq ft/ft/hr/°F at 68 F. Low-carbon steel has a thermal conductivity of about 13% on this relative scale. (d) RW, readily weldable; ST, weldable in most applications but may require special techniques for specific applications; LW, limited weldability and usually requires special techniques; NR, welding not recommended.

Electrical and Thermal Conductivities. Aluminum alloys are much higher in electrical conductivity than most metals that are commonly resistance welded. For example, the electrical conductivity of alloy 2024 (one of the low-conductivity aluminum alloys) is more than twice that of low-carbon steel. This high electrical conductivity necessitates the use of high-capacity welding machines capable of supplying high welding currents, because high current density is needed to generate enough heat to melt the aluminum alloy and produce the weld. The high thermal conductivity of aluminum alloys necessitates rapid welding to avoid dissipation of heat into the workpieces.

Effect of Melting Temperature. As the temperature is increased during resistance welding, aluminum alloys soften more rapidly and at lower temperatures than does steel. Low-inertia welding-machine heads are needed so that electrodes can make the rapid movements necessary for maintenance of weld force and workpiece contact. Although these movements are small, they must take place during an interval of about 2 to 5 milliseconds.

The plastic range in which a weld can be made is very narrow for aluminum alloys. Therefore, the energy input to the weld must be precisely controlled to bring the metal up to, but not above, its plastic range.

Effect of Shrinkage During Cooling. Aluminum alloys exhibit considerable shrinkage during cooling from the liquidus temperature to room temperature. This property is most pronounced in the high-strength heat treatable alloys such as 2024 and 7075, and can result in cracking. The non-heat-treatable alloys and the *6xxx* series alloys are less likely to crack as a result of shrinkage of the nugget.

Porosity and cracking can result from shrinkage unless the electrodes can maintain proper pressure on the nugget until solidification is completed. Machines for welding aluminum alloys generally have, in addition to low-inertia heads, a means of increasing the electrode force as the nugget solidifies. This permits forging of the nugget, and thus improves weld soundness.

Effect of Surface Oxide. Aluminum combines almost instantaneously with oxygen in the atmosphere to produce an aluminum oxide coating that has a high and somewhat erratic electrical resistance, which in turn affects the amount of heat produced in the metal beneath during resistance welding. Therefore, for aircraft-quality welds, this oxide film should be removed or changed to a film of uniform electrical resistance before welding.

Commercial spot or seam welding often can be done on aluminum without cleaning or oxide removal, but electrode pickup increases, electrode life decreases, and welds will be lower in shear strength, variable in quality and erratic in shape. The amount of sur-

face preparation needed depends on the strength and quality requirements of the welded product and on the alloy being welded.

Resistance Welding Machines

Aluminum alloys can be resistance welded with single-phase direct-energy, three-phase direct-energy, and stored-energy machines. Best results are obtained by using a machine that has the following features:

1 Ability to handle high welding currents for short weld times
2 Synchronous electronic controls for weld time and welding current
3 A low-inertia welding head for rapid follow-up of electrode force
4 Slope control (for single-phase welding machines)
5 A multiple-electrode-force system to permit proper forging of the weld nugget, and re-dressing of electrodes.

The three types of machines are discussed briefly in the following paragraphs. For additional information, see the article on Resistance Spot Welding, beginning on page 401 in this volume.

Single-Phase Machines. Single-phase direct-energy machines have high intermittent kva demand and low power factor, and may disturb other electrical equipment. A wide variation in line voltage can cause nonuniformity in welding. However, adequate transformers or substations reduce the variation.

The addition of upslope and downslope control to a single-phase machine is recommended for spot welding of aluminum (see discussion headed "Slope control", below).

Three-Phase Machines. Three-phase direct-energy machines, of either the frequency-converter or the dry-disk-rectifier types, produce excellent resistance welds in aluminum because of their partial control of the shape of the welding-current wave. The gradual increase in current at the beginning of the weld cycle and the decay at the end of the cycle are similar to the upslope and downslope used with single-phase machines.

Stored-Energy Machines. Electrostatic stored-energy machines use a three-phase full-wave rectifier to charge a capacitor bank to a predetermined voltage. The weld is made by discharging the bank of capacitors through a suitable welding transformer. The use of these machines has been largely superseded by three-phase direct-energy machines.

Synchronous controls for weld time and welding current are recommended for resistance welding of aluminum alloys because they provide precise control of short weld times and high welding currents. Magnetic and mechanical controls generally are not suitable.

Slope control permits adjustment of the rate of rise and fall of the welding current. Upslope control causes the welding current to increase gradually during the first few cycles of the weld time. The maximum current level is not reached until the electrode face has seated itself into the softened aluminum; therefore, excessively high currents do not normally occur at localized points. Overheating of metal at the interface of the electrode and the workpiece is reduced, which results in

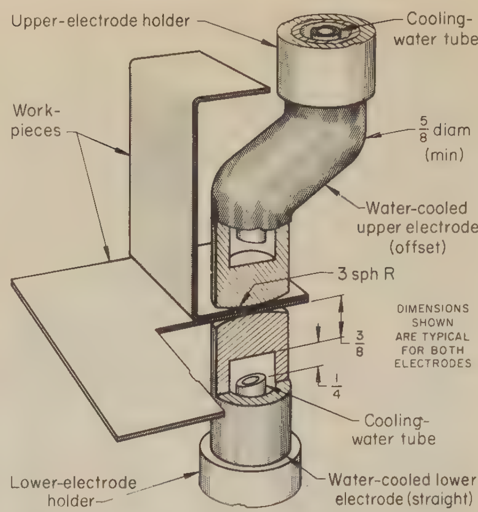

Fig. 1. Details of construction of straight and offset radius-face electrodes used in resistance spot welding of aluminum alloys

increased weld quality and electrode life and in better surface appearance.

Downslope control tapers the current off gradually, which prevents rapid chilling of the nugget. Downslope also permits better forging, which results in finer grain structure, eliminates cracks and voids in the nugget, and permits wider variations in amount and time of application of forging force.

Figure 16(b) on page 414 in the article on Resistance Spot Welding shows upslope and downslope in a weld cycle.

Multiple-electrode-force cycles usually consist of three stages. In the first stage, a high precompression force is exerted to seat the electrodes firmly on the work metal and to establish good electrical contact. The electrode force is then reduced to increase contact resistance while the weld is being made. After the nugget has formed, the force is again increased to forge the nugget. Figure 16(d) on page 414 in the article on Resistance Spot Welding shows a multiple-electrode-force cycle incorporated in the welding cycle.

A low electrode force for welding permits the use of a lower welding current and minimizes sheet separation. Use of high forging force reduces cracking. Multiple-electrode-force cycles make the accuracy of the machine settings less critical and increase the range in which high-quality welds can be produced.

Some welding machines can also produce an electrode force of 100 to 200 lb for use in re-dressing the electrodes with a paddle-type dresser.

Electrodes and Electrode Holders

Selection of electrode material and face shape, maintenance of the face and cooling of the electrode are important in producing consistent spot and seam welds in aluminum alloys.

Copper alloy electrodes, RWMA classes 1 and 2 (Table 2, page 409 in the article on Resistance Spot Welding), are used when welding aluminum alloys. These electrode materials have high electrical and thermal conductivities — which, together with adequate cooling, help to keep the temperature of the electrode below the relatively low point at which aluminum will alloy with copper, causing electrode pickup.

Design of Spot Welding Electrodes. Both straight and offset electrodes are suitable for spot welding of aluminum. However, straight electrodes should be used whenever possible, because deflection and skidding may occur with offset electrodes under similar welding conditions. If offset electrodes are used, the amount of offset should be the minimum permitted by the shape of the assembly being welded. Only electrodes that have the cooling-water hole within ⅜ in. of the face surface should be used. Fluted cooling-water holes provide more cooling surface than round holes. Construction details for both straight and offset electrodes suitable for spot welding of aluminum are shown in Fig. 1.

Face Contour. The face of at least one electrode must be shaped so that the current is highly concentrated at the weld. For most spot welding applications, an RWMA type F electrode, with a face having a spherical radius greater than the diameter of the electrode, is used on one or both sides of the workpieces. A radius face provides easy alignment and minimum sheet separation, concentrates the welding current, and is easier to clean and to maintain than is a flat face. One flat-face (RWMA type C) electrode can be used to minimize indentation on one workpiece, although higher joint strength usually is obtained by using equally radiused electrodes in joining workpieces of approximately equal thickness. (Types of electrode faces are described and shown in the section on Electrode Design, page 409, in the article on Resistance Spot Welding.)

Electrode-face radii for a variety of metal thicknesses and tempers are given in Table 3. When workpieces of dissimilar thickness are being welded, a radius-face electrode of correct dimensions should be used in contact with the thinner member; good-quality welds are more difficult to make if an electrode with too large a face radius or a flat-face electrode is used against the thinner workpiece.

Electrode Maintenance. Correct maintenance of electrode faces is essential if spot welds of uniform size and shape are to be made. The quality of resistance welds in aluminum alloys is more dependent on the contour, surface finish and cleanness of the electrode face than is the quality of welds made in other metals and alloys. The faces should be regularly re-dressed and periodically replaced or re-machined to their original shapes with properly designed tools when they show signs of wear or an appreciable change in contour. (Shaping of electrode faces by hand with a file is inaccurate and should be avoided.)

In the spot welding of aluminum alloys, electrode life is determined by metal pickup on the electrode face, and not deformation, as in the welding of steel. The copper-aluminum alloy formed on the electrode face by pickup is of low electrical conductivity and, if welding is continued, the electrodes will stick to the work metal and the surface of the work metal will melt. Aluminum must be removed from the

electrode face by periodic hand dressing to avoid marking the surfaces of succeeding welds and to maintain the original condition of the face.

Recommended practice is to clean the electrode when the center portion of the spot weld appears either dirty or crusty, or when work metal begins to adhere to the electrode. Less frequent cleaning will cause rapid electrode deterioration and poor weld quality. Electrode pickup can be minimized by proper preparation of the work-metal surface prior to welding, use of adequate electrode force, and avoidance of excessive welding current.

The cleaning operation must remove all the aluminum pickup, but must not change the face contour by removing an appreciable amount of electrode material. To maintain the original shape of radius-face electrodes, a dressing tool in the shape of a paddle with two depressions contoured to match the desired face radius should be used. The two depressions are faced with No. 240, or finer, abrasive cloth.

The dressing tool is clamped between the electrodes with a force of 100 to 200 lb and is rotated a few times to remove the copper-aluminum alloy. The faces are then cleaned, using a cloth dampened with a solvent, to remove any clinging abrasive dust, and then wiped dry. Abrasive grit or deep scratches in the electrode face caused by coarse grit can be transferred to the workpiece during welding, and thus should be avoided. A rubber block and two pieces of abrasive cloth can be used instead of a metal dressing tool.

Electrode Cooling. An adequate means of cooling the electrode face must be provided. This is usually done by a flow of water or refrigerated coolant through the inside of the electrode. Electrodes with either round or fluted water holes are available. Fluted holes provide more cooling surface than round holes. For continuous welding, each water-cooled electrode should be operated at a cooling-water flow rate of at least 1 gallon per minute, and preferably 1½ to 2 gallons per minute. The cooling water should be brought to within ¼ to ⅜ in. of the electrode face, and the inner cooling-water tube should extend to within ¼ in. of the bottom of the cooling-water hole to provide good circulation (see Fig. 1). The end of the cooling-water tube should be cut at an angle, so that if it bottoms in the cooling-water hole in the electrode, the water flow will not be stopped.

Cooling-water temperature should be 60 F or less, and should not vary more than 10 F. If the water temperature is above 60 F, or if it varies widely, the use of a refrigerated coolant may be helpful in improving electrode life and weld consistency. By cooling the electrodes with refrigerated coolant at temperatures of 38 to 40 F, the number of spot welds made between face cleanings can be increased appreciably. When a refrigerated coolant is used, however, condensation of water on the electrodes and electrode holders may present a problem.

Electrode Holders. The commercially available electrode holders are suitable for use in welding aluminum alloys.

Table 3. Face Radii for Resistance Spot Welding Electrodes or Seam Welding Electrode Wheels for Use on Aluminum Alloys of Various Thicknesses (a)

Condition of work metal	Radius, in., for work-metal thickness of: Up to 0.020 in.	0.021 to 0.032 in.	0.033 to 0.064 in.	0.065 to 0.094 in.	0.095 to 0.125 in.
Annealed or as-extruded	2	3	4	4	...
Intermediate tempers of non-heat-treatable alloys	2	3	3	4	6
Heat treated	1	2	3	4	6

(a) Spherical radii for faces of spot welding electrodes and transverse radii for edges of seam welding electrode wheels. When a flat surface is needed on one side of the workpiece, one electrode is made to the above radius, and the electrode that contacts the surface to be flat is either flat or has a 10-in.-radius face or edge. [Source of table: Same as Table 1]

Offset electrode holders sometimes are required for spot welding assemblies not accessible to straight holders and are preferred to offset electrodes because they are more rigid and less likely to cause skidding of electrodes.

Seam welding electrode wheels are from ⅜ to 1 in. thick and from 6 to 12 in. or more in diameter. An electrode wheel less than 6 in. in diameter sometimes is required, depending on the configuration or accessibility of the parts being welded. Electrode wheels usually have two curvatures — the radius of the wheel, which changes only slightly when the wheel is dressed, and the transverse radius of the crown on the edge of the wheel. Transverse radii of electrode wheels used for welding aluminum alloys of various thicknesses and tempers are given in Table 3. Electrode wheels with flat faces or with crowns 10 in. or more in radius can be used against work-metal surfaces to avoid marking or indentation.

Maintenance practices for seam welding electrodes are essentially the same as for spot welding electrodes. Electrode pickup can be removed from the face of an electrode wheel by dressing with a suitable grade of abrasive cloth. A moderately coarse grade of cloth produces a rough surface that prevents slippage between the wheel and the work metal. Some form of a medium-fine grade of abrasive held against the wheel under a load of 5 to 10 lb can be used for continuous dressing of electrode wheels. Knurl-driven electrode wheels should not be used because they roughen the surface of the wheel excessively, mark the aluminum work metal and cause electrode pickup.

Electrode wheels usually are cooled by a flow of water directed against the periphery of the wheel at the weld and sometimes are cooled internally.

Preweld Surface Preparation

Although welds satisfactory for some purposes can be made without any preweld surface preparation, welds free from cracks, porosity, and sheet separation and having maximum strength, symmetry, and consistency and that are economical are obtained only with correct procedures for cleaning and for reduction or removal of oxide film. Adequate surface preparation also reduces electrode contamination.

Commercial spot and seam welding of aluminum alloys such as 1100, 3003 and 5052 can be accomplished with only a degreasing and cleaning operation for surface preparation. However, consistency in commercial welding of the more highly alloyed compositions generally requires additional mechanical or chemical cleaning. Aircraft construction, regardless of the alloy used, demands the utmost in cleaning and oxide removal and requires continual checking of surface resistance.

Oxide can be removed by either mechanical or chemical methods. Usually, the length of time tolerable between oxide removal and welding varies from 48 hours to several days, depending on methods of oxide removal and handling and on storage environment.

Cleaning begins with the removal of any stencil identification marks with alcohol, paint thinner or other suitable solvent. Then parts heavily soiled with dirt, oil, grease, or lubricants from forming operations are cleaned with commercial solvents by wiping, dipping, washing, spraying, or vapor degreasing, depending on the size and quantity. Vapor degreasing with an acceptable chlorinated solvent generally is used whenever a large number of parts is involved. If only a few parts are to be cleaned, they can be immersed in or wiped with acceptable chlorinated solvents or acetone. Cleaning of metal with these chemicals should be done in a well ventilated area.

Degreasing is often followed by treatment with a nonetching alkaline cleaner specially formulated to produce low, consistent surface resistance on aluminum (see Alkaline Cleaning, page 615 in Volume 2 of this Handbook). After the cleaning operations, the work-metal surface should be able to support a water film without a break. Lightly soiled workpieces can be alkaline cleaned without degreasing.

Mechanical removal of oxides is primarily a hand operation and its effectiveness depends on the skill of the operator. The contact resistance of surfaces cleaned by this method sometimes is lower than that of surfaces cleaned by a chemical method. The cleaning action must be severe enough to cut through the hard oxide film, yet gentle enough not to form an excessively rough surface in the comparatively soft metal underneath.

When welding is confined to a small area and the oxide film is thin, mechanical methods provide quick and complete removal of the oxide film over that portion of the surface where the welds are to be made, with little investment for equipment, and without danger of subsequent formation of a high-resistance film. Mechanical cleaning can be done immediately preceding welding. Also, mechanical methods are useful for removing oxide from workpieces that are too large to be dipped and rinsed. After the workpieces have been degreased, the oxide film can be removed with a fine grade of abrasive cloth, a fine stainless steel wool or a motor-driven brush made of fine stain-

less steel wire. Glass brushes and aluminum wool have also been used. Carbon or low-alloy steel brushes or steel wool should not be used.

Chemical Removal of Oxides. An acid dip is used after heavy oxide removal or directly after cleaning, to obtain uniform surface resistance. A typical solution contains 12% (by volume) concentrated nitric acid, 0.4% (by volume) hydrofluoric acid and 0.2% (by weight) wetting agent, and is used at a temperature of 70 to 80 F. Immersion time in this solution is 2 to 6 min. This is followed by rinsing in clear water and drying.

Forgings, castings, extrusions or similar parts having thick oxide accumulation may need an alkaline etch before the acid dip. A commonly used alkaline-etch treatment is immersion in an aqueous solution of 5% sodium hydroxide at 150 to 160 F for 20 to 50 sec, followed by rinsing in cold water. The alkaline-etch solution may contain additives to prevent the formation of scale in the tank.

Aluminum alloys 1060, 1100 and 3003 and aluminum-clad alloys frequently are immersed for 1½ to 3 min in a warm (190 F) solution containing 10% (by volume) concentrated nitric acid, 6 oz sodium sulfate per gallon and 0.1% (by weight) wetting agent. The parts are then rinsed in cold running water for 5 min and dried rapidly. Heat treatable alloys such as 6061 are immersed for 1½ to 3 min in a warm (185 F) solution containing 15% (by volume) concentrated nitric acid, 13 oz sodium sulfate per gallon and 0.1% (by weight) wetting agent. The parts are then rinsed in cold running water for 5 min and dried rapidly. For more detailed information on cleaning and etching of aluminum alloys, see the article on Cleaning and Finishing of Aluminum and Aluminum Alloys, page 611 in Volume 2 of this Handbook.

To ensure satisfactory preparation of the surfaces for spot and seam welding, it must be determined that the cleaning and deoxidizing procedures are adequate and that the strength of the solutions is correct. This determination should be made by measuring the surface contact resistance after surface treatment of small coupons of the material to be welded; visual inspection is not a satisfactory control method. Measurement of contact resistance should be made also on each batch of workpieces being welded. Corrections in the procedures or additions to the solutions should be made as required to maintain the contact resistance of the control samples and of the workpieces at the desired value.

Occasionally, special surface-preparation methods are used to solve particular problems. For instance, in Example 293 in the article on Arc Welding of Aluminum Alloys, a method is described that met the exacting requirements of gas metal-arc and gas tungsten-arc welding on that job, and that could be adapted easily to preparation for resistance welding.

Contact-Resistance Test. A standard test can be used to determine the electrical resistance of an interface between aluminum alloy samples or workpieces. The two samples or workpieces are placed between two spot welding electrodes ⅝ in. in diameter with faces 3 in. in spherical radius, and are clamped under a static force of 600 lb. A 50-milliamp (ma) direct current is transmitted through the electrodes, and the resistance between the workpieces is determined with a suitable instrument.

The tests must be performed under identical conditions of force, applied current, and electrode size and contour. The measurement is sensitive to small changes in test procedure, and values are usually obtained by averaging at least 2 or 3 readings on each of the four possible interface combinations of a pair of specimens. Movement of either specimen after the electrode pressure is applied breaks the oxide coating and causes false low readings. The presence of burrs on the specimens also causes low readings.

The contact resistance of well cleaned aluminum alloys is from 10 to about 200 microhms, while that of unclean stock can be 1000 microhms or more. For noncritical welding, contact resistance of 200 to 500 microhms is satisfactory. For best results (as required for military applications), contact resistance should be about 50 microhms. A narrow spread in readings generally is preferable to low average values with an occasional high reading.

Seam Sealants. Elastic materials have been used between members of resistance welded joints to make containers fluid-tight and to limit interface corrosion, especially in high-hu-

midity environments. For instance, welds of military quality can be made through gun-grade caulking compounds, which consist of finely divided aluminum powder in a special elastic binder, with no significant change in machine settings. Some tapes and paints provide equally good results.

Resistance Spot Welding

All of the commercial aluminum alloys that are produced as sheet, extrusions or castings can be spot welded; the combined maximum thickness with ordinary equipment is between ½ and ¾ in. Process control is much more critical than for spot welding of low-carbon steel, and the range of permissible welding-machine settings is narrower for a given work-metal thickness. Also, the condition of the work-metal surface is extremely important for production of satisfactory welds.

Figure 2 shows a typical spot weld between two 0.102-in.-thick sheets of alclad alloy 2024-T4 (alloy 1230 cladding; 99.3% min Al). In the center of this spot weld is an oval zone with an equiaxed grain structure. Surrounding this zone is a zone made up of a dendritic (or columnar) type of grain structure. The area of these two zones constitutes the spot weld nugget. Each is essentially a cast structure. The large size of the dendritic zone is the result of a welding technique that employed a postweld heat treatment permitting grain growth.

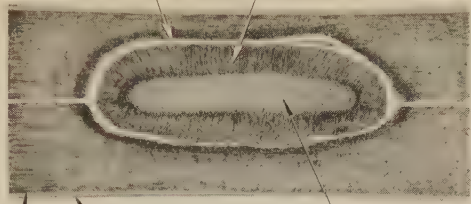
Surrounding the dendritic zone is a band of light color that consists of a layer of metal that has been heated close to the melting point, and in which segregation of eutectic material has occurred in the base metal. Forcing of this eutectic material into adjacent base metal results in a dark-color ring immediately surrounding the lighter ring. The cladding at the interface was completely absorbed with the base metal into the nugget. Indentation was not severe and the outer surfaces of the work metal in contact with the electrodes show no effect of heating.

Welding Current. As the thermal and electrical conductivities of aluminum alloys are about two to four times those of low-carbon steel, the heat for welding, and thus the welding current, must be greater than that used for welding steel of equivalent thickness. Tables 4, 5 and 6 list typical conditions for spot welding aluminum alloys in single-phase direct-energy, three-phase direct-energy, and capacitor-type stored-energy welding machines. These values are starting points and should be adjusted to suit the particular alloy and job requirements.

The higher the current, the more rapidly the nugget is formed. Also, the longer the duration of current flow, the greater the penetration of the nugget into the base metal. If the current is too low, the nugget forms too slowly, and excess heating and warping occur in the surrounding area. If the current is too high, formation of gas pockets and expulsion of metal result, causing sheet separation and weak welds.

Weld time is the actual time that the welding current flows through the workpieces, and must be sufficient to

Alclad alloy 2024-T4, 0.102 in. thick



Spot weld was made with a three-phase direct-energy resistance welding machine, using forging pressure and postheating. See text for discussion. (SOURCE: RWMA Bulletin 18)

Fig. 2. Typical spot weld nugget made in a heat treated alclad aluminum alloy

form the weld without excessively heating the remainder of the weld area. As work-metal thickness increases, longer weld times are required, as shown in Tables 4 and 5.

Within a narrow range of weld time, weld strength is approximately proportional to weld time. Using weld time beyond this range produces no appreciable further increase in weld strength.

Electrode force used for spot welding of aluminum alloys generally is greater than that needed for spot welding of steel of equivalent thickness. Low-strength aluminum alloys usually need lower electrode force than high-strength alloys.

Use of insufficient electrode force can result in expulsion of weld metal, internal defects, surface burning and excessive electrode pickup. Use of excessive electrode force can result in extreme indentation, sheet separation, work distortion, and asymmetrical welds. When a low electrode force is used, high contact resistance is developed at the interface, requiring a low welding current; when a high electrode force is used, contact resistance is reduced, and a higher current is needed.

A multiple-electrode-force cycle, in which the weld is made at a low electrode force followed by application of a higher force during hold time, is used to provide forging action during solidification of the nugget. In minimizing internal defects, timing of the application of forging force is important. If the forging force is applied before completion of weld time, the contact resistance is decreased excessively, and welds may be unsound. If forging force is applied too late, after the weld has solidified, forging will be ineffective.

Table 7. Suggested Minimum Joint Overlap, Weld Spacing and Distance Between Rows for Resistance Spot Welds in Aluminum Alloys

Thickness of thinnest sheet, in.	Minimum joint overlap, in.(a)	Minimum weld spacing, in.(b)	Minimum distance between rows, in.(c)

0.072	13/16	3/4	7/16
0.081	7/8	3/4	1/2
0.091	15/16	7/8	1/2
0.102	1	1	1/2
0.125	1 1/8	1 1/4	5/8

(a) Minimum edge distance is equal to one half of minimum overlap. (b) Measured from center to center. (c) For rows of staggered welds at minimum weld spacing. [Source of table: Same as Table 1]

Spacing of Spot Welds. When rows of spot welds are made, each successive weld can be affected by shunting of part of the welding current through the preceding welds. The shunting effect increases as spot spacing, work-metal thickness and electrical resistance of the alloy being welded decrease. Also, the shunting effect increases as the contact resistance between the workpieces increases.

In order to eliminate most of the shunting effect, the minimum spacing of spot welds made in aluminum alloy sheets normally should be no less than eight times the sheet thickness ($8t$), and preferably not less than the values given in Table 7. Where it is necessary to space welds at less than $8t$, the current can be increased after making the first spot weld to offset the loss from shunting. An alternative is to use two or more rows of spot welds with the welds in each row spaced apart by at least $8t$. Table 7 gives the suggested minimum distance between rows of staggered spot welds.

If a spot weld is made too close to the edge of a workpiece, the metal between the weld and the edge may bulge out or split, and molten metal may be expelled from the joint. The minimum distance a spot weld should be from the edge of a workpiece is one half the minimum joint overlap given in Table 7. If more than a single row of spot welds is made, the minimum overlap must be increased by the distance between rows.

Welding Practice. Use of the welding conditions given in Tables 4, 5 and 6 should produce welds having shear strengths exceeding those given in Table 1. Larger welds with proportionately higher shear strengths sometimes can be obtained with stored-energy equipment. Smaller welds with strengths lower than those given in Table 1 should be avoided. Settings that result in small-diameter welds in aluminum are likely to cause a substantial percentage of unacceptable welds under production conditions.

Although the welding conditions given in Tables 4, 5 and 6 are good starting points, optimum conditions must be determined by making and testing welds in sample setups of the job, and adjusting the given conditions accordingly. During production, it is necessary to test welds frequently to ensure that optimum conditions are maintained.

Welding conditions optimum for a specific application may vary substantially from those given in Tables 4, 5 and 6. For instance, in welding a 0.102-in.-thick handle flange to a 0.125-in.-thick frying pan (Fig. 3), both made of alloy 3003, using a three-phase frequency-converter welding machine, an electrode force of 1440 lb was used and a welding current of 70,000 amp was applied in two 5-cycle weld pulses separated by a 2-cycle off time for cooling the electrodes. With these conditions, output was 600 assemblies in 8 hours.

In welding workpieces of unequal thickness, the thinner workpiece governs

the welding conditions that should be used and the diameter of the resulting nugget.

Three or more thicknesses of aluminum alloy can be spot welded simultaneously. Conductivity of the alloy welded and thickness of the outside sheets govern the choice of machine settings. Because of the added resistance of the additional interfaces, electrode pressures are higher than those used for welding two sheets.

When spot welded aluminum assemblies must have smooth outer surfaces for purposes of aerodynamics or appearance, a flat-face electrode can be used on one side of the joint and a radius-face electrode on the other. Indentation will occur primarily on the side that contacts the contoured electrode, but some indentation results from shrinkage of the nugget. However, higher joint strength usually is achieved when electrodes of the same contour are applied to both sides of the joint, provided that the sheet thicknesses are about equal.

Preweld positioning of components by means of fixtures, clamps, spring fasteners or tack welds is recommended. Otherwise, some of the electrode force may be expended in bringing the components into contact, thus affecting the quality of the weld, especially if the effective electrode force varies. Mating parts should fit together so that the surfaces to be joined are in contact with each other, or can be readily pressed into contact with each other, at the weld area. All tooling that is in the throat of the machine during the welding operation should be nonmagnetic; aluminum, fiberglass and various types of plastics are often used.

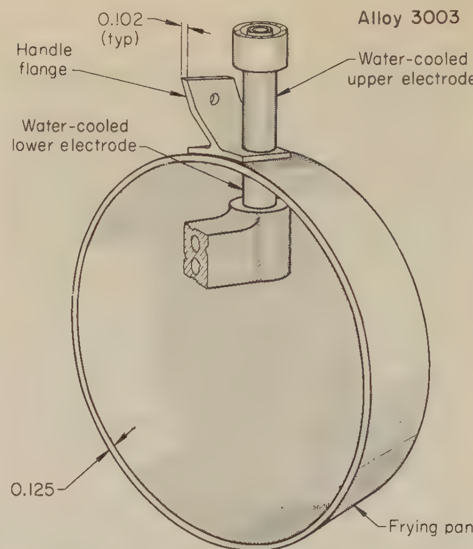

Fig. 3. Spot welding of a handle flange to an aluminum alloy frying pan

In the following example of spot welding for a military application, both fixturing and welding procedures were critical. In this example, as in spot welding of the frying pan shown in Fig. 3, the welding conditions finally selected differed substantially from those given in Tables 4 and 5.

Example 419. Resistance Spot Welding of Truck-Door Frames Using Both Press-Type and Portable Equipment (Fig. 4)

Structural frames for doors of military truck-tractors were made of alloy 6061-T6 extrusions and alloy 6061-T4 sheet, all 0.090 in. thick (see Fig. 4). The truck-tractors were designed to float in water through buoyancy of the all-aluminum cab, and the die-formed and unmachined mating surfaces between door and cab had to be accurately aligned to make watertight joints. Welding the heat treated and cold worked aluminum alloy gave rise to distortion difficulties, because the welding heat relieved high residual stresses. Welded construction was necessary, however, to meet the production demand of 400 frames per week.

A typical frame was held together by mechanical fasteners, as well as by welds at seven major joints. Five of the joints were resistance spot welded, by two different methods. The two other joints were gas metal-arc welded, as described in Example 303, in the article on Arc Welding of Aluminum Alloys.

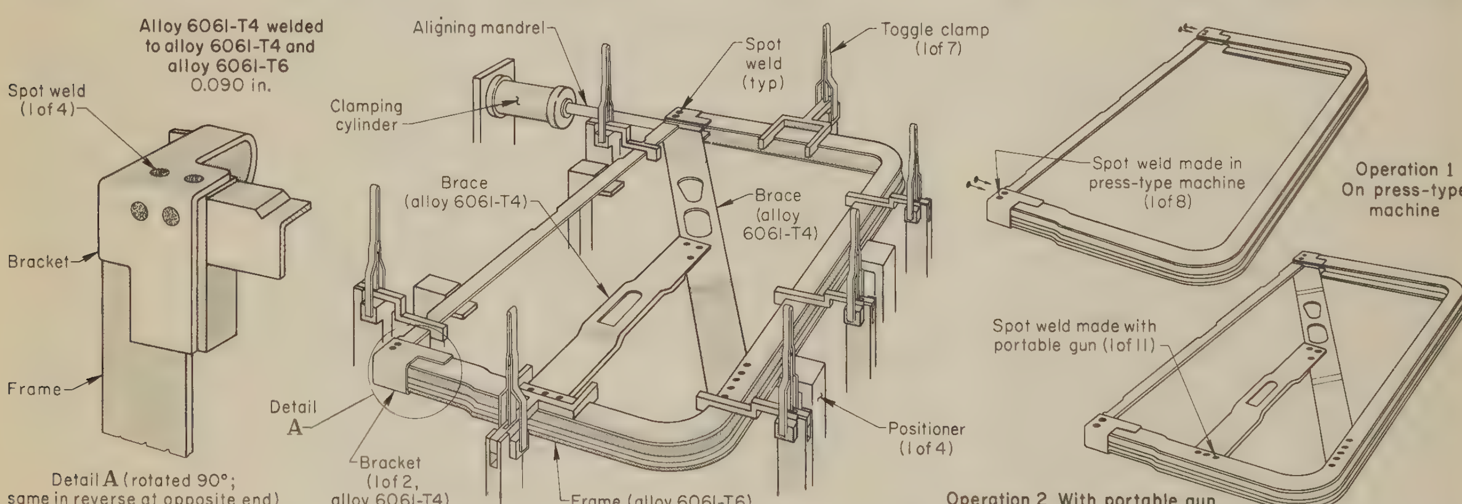
Cleaning for both methods of spot welding was the same; proprietary cleaners and oxide-removal solutions were applied to reduce the electrical resistance of joint surfaces to a range of 150 to 250 microhms. Prior to welding, the surfaces were wiped with oxide-removal solution.

Each of two corner brackets was attached to the extruded frame with four spot welds, as shown in detail A in Fig. 4. The brackets, aligned in a hand-held fixture, were welded in a press-type spot welding machine under the conditions given in the table with Fig. 4.

Then the subassembly was removed from the hand-held fixture and was placed in a floor fixture for the addition of two braces. A portable spot welding gun was used to weld a joint between the two braces and to weld two of four joints between the braces and the frame. The locations of the 11 spot welds at these joints are shown in the views at right in Fig. 4. Welding conditions for this operation are given in the table with Fig. 4.

Toggle clamps were used to hold the braces in alignment in the floor fixture, as shown in Fig. 4, and to prevent distortion of the formed outer-frame extrusion. A mandrel was inserted in one leg of the outer frame to serve as an alignment reference for the assembly.

Both the press-type welding machine and the portable gun had controls that enabled



Item	Welding of brackets	Welding of braces
Equipment Details

the electrodes to be re-dressed in the machine, using a low-pressure contact on a paddle-type electrode dresser. The electrodes used in the press-type welding machine were dressed after making 80 to 100 welds, and those in the portable gun were dressed after 40 to 70 welds.

The order in which spot welds are made in a multiple-weld assembly is important in controlling warpage of the assembly and maintaining the strength of the spots. Making a spot weld produces slight lateral expansion of the work metal, and therefore spot welding preferably should be started from the center of the sheet and made in succession at the desired spacing toward the ends. Additional spot welds should not be made between two existing welds because shunting through adjacent spot welds could result in poor welds; also, expansion or warpage could prevent good contact of the sheets during welding. If three or more rows of welds are being made, the center row or rows should be made first.

Roll Resistance Spot Welding

Roll resistance spot welds can be made in conventional seam welding machines either with continuously rotating electrode wheels or with intermittent-motion electrode wheels. With intermittent motion, better surface appearance and better weld quality are obtained in welding aluminum alloys. Weld spacing is obtained by proper adjustment of electrode speed, or indexing time, and of the hold time. The individual roll resistance spot welds are essentially the same as resistance spot welds made in the conventional manner, except that shorter hold times are employed. With continuously rotating electrode wheels, heat times are usually shorter than those normally used for spot welding. The high current employed sometimes requires the use of high electrode force. Also, nuggets made by continuously rotating electrode wheels are usually elongated because of electrode travel.

Extruded or roll-formed sections frequently are roll spot welded to sheets. For instance, 0.060-in.-thick alloy 2024-T3 roll-formed Z-sections were attached to 0.060-in.-thick alloy 2024-T3 sheets to serve as stiffeners (see Fig. 5). The electrode wheels were stationary during welding (intermittent motion), and the electrode force was increased from 1500 lb for welding to 3600 lb for forging the nugget as it contracted during cooling, thereby producing high-quality, crack-free welds. The weld current of 55,000 amp was supplied from a 60-cycle three-phase frequency-converter welding machine in a single impulse of 2 cycles of heat time and 6 cycles of current decay. The 6-cycle current-decay time was an advantage because it served to decrease the cooling rate of the weld.

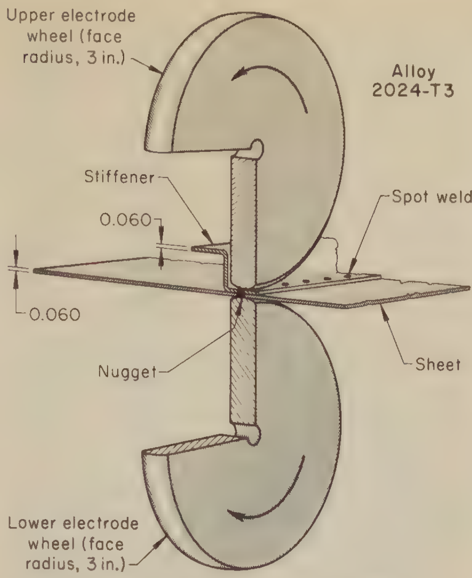

Fig. 5. Roll resistance spot welding of a Z-section longitudinal stiffener to a sheet, using intermittent electrode motion, a welding force and a forging force

Resistance Seam Welding

The overlapping spot welds produced in resistance seam welding result in a continuous gastight and liquid-tight seam. The welding current can be applied either when the wheels are moving or while they stop momentarily. Intermittent motion results in better surface appearance and better weld quality in aluminum alloys, and is ordinarily used for work of military quality when the work metal being seam welded is 0.080 in. or more in thickness.

Seam welding of aluminum alloys with continuously rotating electrodes was used in the assembly of the integral leading-edge wing fuel tank shown in Fig. 6. In this application, 0.040-in.-thick alloy 6061-T6 sheet was joined to 0.081-in.-thick alloy 2014-T6 clad sheet. Nylon rollers were used for guiding and supporting the workpieces and for easily moving the assembly between the electrode wheels without marring the work-metal surface. The welding force was 2800 lb. The weld current of 58,000 amp was supplied from a three-phase frequency-converter welding machine in a single impulse of 2 cycles preheat time and 4 cycles heat time, with 6 cycles cool time. The overlapping spot welds were made 12 to the inch at a rate of 25 in. per minute.

Typical conditions for seam welding alloy 5052-H34 using a conventional single-phase direct-energy seam welding machine are given in Table 8. Data in this table also can be used as a basis for developing conditions for welding other alloys or tempers. The maximum heat time should be between one fifth and one third the total time. Use of a heat time shorter than one fifth the total time helps to reduce electrode pickup, but also reduces nugget size. Electrode force, welding current, heat time, cool time and welding speed are adjusted to produce the desired spacing and weld width. Width of a seam weld should be twice the thickness of the sheet being welded plus 0.06 in. ($2t + 0.06$ in.).

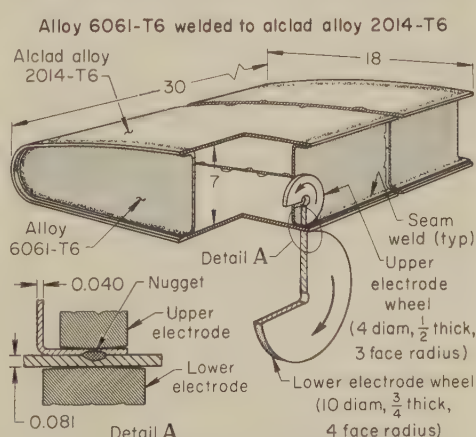

Fig. 6. Resistance seam welding of an aircraft integral wing fuel tank, using continuous electrode motion

Quality control for seam welding is the same as for spot welding except that an additional test, such as the pillow test, may be required for determining gastightness or liquid-tightness.

Projection Welding

Aluminum alloys are seldom projection welded, because extremely close control is needed in order to produce acceptable welds. Embossed projections like those used in low-carbon steel sheet, if made in aluminum alloy sheet, would collapse prematurely, and therefore are not used. Projections that have been coined in aluminum alloy workpieces are stronger and better able to resist collapse than are embossed projections, and are preferred.

Because of the narrow plastic range of aluminum alloys, the quality of projection welds is less uniform than that of spot welds of equivalent size.

Cross-Wire Welding

Aluminum alloy wires, round and in other shapes, can be cross-wire welded to make racks, grills or screens. Press-type resistance spot welding machines with low-inertia heads and fast follow-up are needed to maintain proper welding force on the joint as the wires deform and melt. Each cross-wire weld must be made individually; multiple-wire welding with bar electrodes has been unsatisfactory on aluminum alloys.

Selection of alloy and temper is the same as for spot welding. All aluminum alloy wires from about 1/16 to 3/8 in. in diameter can be cross-wire welded. Wires of equal diameters, or of unequal diameters in ratios up to 2 to 1, are readily weldable. Low-strength ring-type welds can result if the ratio of wire diameters is greater than 2 to 1.

Wire can be welded to a tube if the thickness of the tube wall is equal to or greater than the diameter of the wire. Wire can be welded to extruded aluminum alloy angles, or to other structural shapes, that have elongated projections extending at right angles to the wire direction. For optimum results, the cross-sectional radius of the projection should be approximately equal to the radius of the wire.

Optimum welding conditions are established by twist tests and by measuring setdown. Twist tests are made by twisting the wires so as to tear the area between wires. Tests of properly made cross-wire welds usually result in base-metal fracture outside the weld.

Setdown is the difference in the combined height of both wires before

Table 8. Typical Conditions for Making Gastight Resistance Seam Welds in Alloy 5052-H34 Sheets With 60-Cycle Single-Phase Direct-Energy Welding Machines(a)

Sheet thickness, in.	Spots per inch	Total weld time, cycles(b)	Wheel speed, fpm(c)	Heat time, cycles(d) Min	Max	Electrode force, lb(e)	Welding current, amp(e)	Width of weld, in.

0.125	7	28½	1.5	5½	9½	1350	45,000	0.32

(a) Electrode wheels and work metal must be cooled with 2 to 3 gallons of water per minute. (b) Heat time plus cool time. (c) Wheel speed is adjusted to give desired number of spots per inch. (d) Heat time must be set at full-cycle setting if total time is set at full-cycle setting. (e) Electrode force and welding current are adjusted to give desired width of weld. Values are for 5052-H34 aluminum alloy. Lower forces should be used for 5052-O and 3003-H14 aluminum alloys. [Source of table: Same as Table 1]

and after welding. For joints between wires of equal diameter, setdown should be 25 to 35% of the combined height before welding. For joints between wires of unequal diameter, setdown should be 25 to 35% of twice the diameter of the smaller wire. The quality of cross-wire welds is usually consistent when, during a production run, the variation in setdown does not exceed ±5% of the nominal value.

Flash Welding

All wrought aluminum alloys can be joined by flash welding. The process is particularly suitable for making butt and miter joints between two workpieces of similar cross-sectional shape. Aluminum alloy bars and tubes can be flash welded to copper bars and tubes.

Machines for flash welding of aluminum alloys require much larger transformer capacity than is needed for flash welding of steel. For best results, the welding machine must be capable of supplying a current density of 100,000 amp per sq in. while the workpieces are held in firm contact, without arcing. A secondary voltage of 2 to 20 v is required. Upsetting pressures are 8,000 to 40,000 psi.

Copper alloy clamping dies, RWMA classes 1 and 2, are used when flash welding aluminum alloys if a long die life is required. Hard-drawn copper may be used instead if a limited number of pieces are to be welded.

Initial die spacing varies according to work-metal thickness. About ½ in. of initial die spacing is suitable for thin-wall tubing and for thin sheets or extrusions, and about 1 in. is needed for flash welding a ¾-in.-diam bar.

Pinch-off dies provide the best weld quality in flash welding of aluminum alloys. These dies are made of hardened steel and are sharpened to a cutting edge. They are used to trim the upset metal or flash from the joint at the end of the upsetting stroke.

For additional information, see the article on Flash Welding, page 485 in this volume. Examples 432 and 434 in that article present applications of flash welding of aluminum alloys.

Inspection and Testing

Peel, twist or tear tests are common methods of determining the quality of resistance welds made in aluminum alloys. To meet commercial requirements, a button of metal having a diameter at least twice the thickness of the thinnest workpiece plus 0.06 in. ($2t + 0.06$ in.) should be pulled from one of the workpieces at each weld. To meet military standards, the button diameter should be equal to or exceed the nugget diameter given in Tables 4, 5 and 6. Spot welds in aluminum alloys 2014, 2024, 6061 and 7075, either bare or clad, will not always pull buttons completely through the sheet when the work-metal thickness is greater than about 0.080 in. In these alloys and metal thicknesses, the weld is peel tested and the diameter of the fractured area is determined.

When peel testing indicates that welds of the proper size are being produced, test welds can be made for use in determining shear strength. Welds also can be sectioned for metallographic examination to determine nugget diameter, penetration and microstructure. Radiographic examination can be used to determine the soundness of test welds.

During production, visual examination can be used to detect electrode pickup, surface burning, cracks, skidding, expulsion of molten metal, and excessive indentation. Radiographic inspection can, in some alloys, be used to detect internal defects such as cracks, porosity, and segregation, and to evaluate the size and shape of the nugget and the structure of the weld metal. In general, radiographic examination is used principally in the establishment of optimum welding conditions, and not as a production-control method. Other inspection methods sometimes used are eddy current, ultrasonic and sonic.

Indentation of the base metal can be determined by measuring the thickness of the weld with ball-tip micrometers, or by determining the difference in height between the weld and the surrounding area using a dial-indicator depth gage. Sheet separation can be measured with feeler gages.

Causes and Prevention of Weld Defects

Resistance weld defects most common in aluminum alloys include electrode pickup, cracks and porosity, expulsion of molten metal, indentation and sheet separation, and irregular-shape and unfused welds.

Electrode pickup, or alloying of the work metal with the electrode material, is usually the result of excessive heating at the interface between the electrode and the work metal. In severe cases, there is actual melting or burning of the work-metal surface.

Electrode pickup can be minimized by using adequate electrode force during welding, or by not using excessive welding current or weld time. Pickup may be caused by improper cleaning of work metal or electrodes, by use of improper electrode material, size, or contour, by inadequate cooling of the electrodes, or by skidding. Electrode pickup can occur with all types of welding equipment, but it usually occurs sooner when welding is done with the use of single-phase alternating-current equipment.

Cracks and porosity in the weld metal may result from too-rapid heating of the weld metal, an excessively high cooling rate, or inadequate or incorrect application of electrode force during or after welding. Spot welds in some high-strength alloys such as 2024 and 7075 are subject to cracking if welding current is too high or electrode force during welding is too low. Cracking may also result from too-rapid quenching of the weld metal after the welding current has been turned off. Changes in the downslope of the current or the use of postheating may eliminate cracking. On machines with dual electrode force, readjustment of the forge-starting time may also eliminate cracking.

Expulsion of molten metal from the weld area by flashing or arcing can usually be eliminated by use of better cleaning methods or by a slight reduction in welding current. Another cause of expulsion is an initial electrode force that is too low, followed by excessive forging pressure.

Indentation and sheet separation generally occur together. One of the major causes of these defects is the use of work metal of too soft a temper. These defects sometimes can be minimized by decreasing the electrode force, increasing the face radius of the electrode, or reducing the welding current or time. Sheet separation also can be caused by lack of flatness of the sheets being welded.

Welds with irregular shape and incomplete fusion are caused by incorrect fit-up of workpieces, incorrect electrode alignment, skidding of the electrodes, inadequate surface preparation, or an irregular electrode contour.

Inadequately fused welds in clad sheet may have some unfused cladding metal in the nugget. This defect can usually be avoided by a moderate increase in welding current.

Burning of holes through the workpieces can result from: (*a*) insufficient electrode force to squeeze the metal effectively; (*b*) the presence of foreign material such as paper or steel wool between the workpieces; (*c*) emery dust or emery cloth adhering to one or both electrodes; and (*d*) attempts to spot weld at points where there are screws, projections, or drilled holes. If none of these appear to be the cause of the difficulty, the welding machine and its controls should be inspected.

Resistance Welding of Copper and Copper Alloys

*By the ASM Committee on Welding and Brazing of Copper and Copper Alloys**

THE COPPERS AND COPPER ALLOYS that are most often resistance welded are listed in Table 1, which gives nominal compositions, melting points (liquidus temperatures), relative thermal and electrical conductivities, and welding indexes for resistance spot welding. Leaded and other free-machining copper alloys, which are seldom resistance welded, are not listed.

Spot welding is the resistance welding process most widely used for joining coppers and copper alloys. The principal applications are in welding sections up to about 0.060 in. thick, particularly on alloys that have low electrical conductivity. Many copper alloys with low conductivities can be seam welded easily. The coppers are difficult to seam weld. Projection welding is not recommended for copper or for most brasses. The bronzes can be projection welded with satisfactory results in many applications. Flash welding can be used for joining round stock, tubing, sheets and mill shapes made of copper and copper alloys. The abutting ends, as they become plastic, must be pushed together with a minimum of upsetting force to produce a satisfactory weld.

The articles on Resistance Spot Welding, Resistance Seam Welding, Projection Welding, and Flash Welding in this volume describe these processes.

Welding Characteristics

The resistance weldability of any copper or copper alloy is inversely proportional to its electrical and thermal conductivities. In general, the alloys with lower conductivities are easier to weld (see Table 1) and require lower welding currents (see Tables 1 and 2). Compared with steel, most copper alloys require shorter weld time, lower electrode force, higher current, and different electrode materials that are compatible with the alloy being welded. The conditions for spot welding various copper alloys are given in Table 2.

The minimum spot spacing and contacting overlap for spot welding high-zinc brasses are given in Table 3. When workpieces of unequal thickness are welded, spot spacing should be equal to the minimum spacing recommended for the average thickness. The values listed for contacting overlap are designed to prevent bulging of the edge and expulsion of weld metal in welding workpieces that are manually positioned between the electrodes. The contacting overlap can sometimes be less than shown when the workpieces are held in fixtures. Breaking loads in shear of spot welded joints are also listed in Table 3.

*For committee list, see page 337.

Welding Equipment

The moving-force member of a spot, seam or projection welding machine should be as light as possible to reduce inertia, and relatively free of friction to ensure rapid follow-up during welding. For a discussion of low-inertia heads and electrode holders, see page 437. Because copper alloys have a narrow plastic range, the force member must follow rapidly to maintain pressure on the joint and to prevent expulsion of weld metal.

Single-phase and three-phase direct-energy and electrostatic stored-energy (capacitor-discharge) welding machines are used for resistance welding of copper and copper alloys. The addition of slope control to single-phase direct-energy welding machines is not necessary for spot welding most copper alloys, although in welding high-zinc brasses, the use of upslope can result in an increase of as much as 20% in weld strength. Downslope is not recommended for welding any of the copper alloys. For a discussion of slope control, see the subsection beginning on page 468 in the article on Resistance Welding of Aluminum Alloys in this volume.

Electrostatic stored-energy machines use for the welding current an energy charge that is stored in a bank of capacitors. A three-phase, full-wave, grid-controlled thyratron rectifier is used for furnishing a direct-current power supply to the bank of capacitors. A vacuum-tube leveling circuit is used to predetermine and maintain the capacitor-voltage level.

During the instant of recharging the capacitors, the value of the rectifier current is determined by the impedance of the rectifier transformer and the resistance of a resistor in the circuit. The leveling circuit generally consists of an ordinary radio-tube-type circuit and the necessary direct-current positive-bias and negative-bias voltages for the proper on and off conduction time of the rectifier tube.

When the welding contactor is closed, the capacitor energy is discharged into a center-tapped welding transformer, and current flows into one half of the transformer. At the instant of closure, the rectifier tubes are automatically cut off by reversing the bias on the grid of the thyratron tubes to a high negative value. After discharge, the welding current ceases to flow, the rectifier tubes are made conductive by the reversal of the negative bias to a positive value, and the capacitors are automatically recharged. When successive welds are made, two welding contactors alternate the welding current between the two halves of the welding transformer to prevent saturation.

Generally, an electrostatic machine can be recharged rapidly enough to be used for roll-spot and seam welding as well as for spot and projection welding.

Welding-Machine Controls. Copper alloys are particularly sensitive to variations in welding conditions, and therefore all direct-energy machines used for welding these alloys should be equipped with synchronous electronic controls, especially in applications requiring short weld times. These devices are capable of controlling weld time and welding current for repeated operations with extreme accuracy, and of eliminating transient currents that sometimes result from random switching of power to the welding machine.

Electrodes

The current used for resistance welding of copper alloys is much higher than that used for welding low-carbon steel, and therefore the electrode must have high electrical conductivity to minimize heat buildup. Also, the thermal conductivity of the electrode must be high so that heat generated at the workpiece-electrode interface can be dissipated, preventing these surfaces from fusing. Proper cooling of the electrode is especially important for these alloys. Because of the low electrode force that is used in resistance welding of copper and copper alloys, deformation and wear of the electrode face have less effect on electrode life than does alloying of the face with the work metal.

Electrode Materials. The RWMA class 1 electrode materials, containing copper and cadmium, are sometimes used for welding copper and high-conductivity brass and bronze. Class 2 materials, containing copper and chromium, are used on low-conductivity brass and bronze and the copper-nickel alloys. Class 3 materials are used in electrodes for seam welding.

The RWMA group B materials (refractory metal compositions) are used as facings on electrodes for spot welding copper alloys because these materials do not readily alloy with copper alloys. Class 11 (a mixture of copper and tungsten), class 13 (commercially pure tungsten), and class 14 (commercially pure molybdenum) electrodes give good performance and long life when used in the resistance welding of copper and copper alloys that have high electrical conductivity.

Properties of electrode materials are listed in Tables 2 and 3, on page 409 in the article on Resistance Spot Welding in this volume.

Electrodes must be efficiently water cooled to minimize sticking to the work metal and to prolong their life. Face contours must be carefully prepared

(a) Based on alloy 102, which has a thermal conductivity of 226 Btu/sq ft/ft/hr/°F at 68 F, as 100%. For comparison, 1010 steel has a thermal conductivity of 30 Btu/sq ft/ft/hr/°F, or about 13% on this relative scale. (b) The ratio of the resistivity of the International Annealed Copper Standard at 20 C to the resistivity of the material at 20 C, expressed in percent and calculated on a volume basis. (c) Welding index from the Third Edition of Volume I of the "Resistance Welding Manual", published by the Resistance Welder Manufacturers' Association. A is the basis of comparison, and is the equivalent of conditions for clean, cold rolled steel. B indicates that the alloy is readily weldable, but not as easily as steel. C, D, E, F and G represent progressive stages of increasing difficulty. G indicates that the alloy can be successfully welded, but 100% uniform results cannot be expected. H includes those metals which are considered commercially impractical to spot weld. The numbers following the letters indicate the approximate percentage of secondary current required, based on mild steel = 100. (d) In precipitation hardened condition. (e) Alloys 443, 444 and 445 contain a nominal 0.06% As, Sb or P, respectively. (f) Alloys 465, 466 and 467 contain a nominal 0.06% As, Sb or P, respectively. (g) Alloys not having a spot welding index by RWMA, but which are listed as not recommended for spot welding by the Copper Development Association. (h) Alloys not having a spot welding index by RWMA, but which are listed as good under suitability for being joined by spot welding by the Copper Development Association.

and the electrodes must be properly aligned for welding. Type F (radius-face) electrodes having a face radius of 3 to 6 in. are often used for spot welding copper alloys. The smaller face radii are used for welding thinner workpieces. A type C (flat-face) electrode is used where good appearance and minimum indentation are required on the surface of one workpiece. Rigid holders are needed to avoid deflection or skidding of the electrodes on the work when force is applied.

Selection of Process

Weldability of the work metal often determines which process should be used for a given application. Some of the coppers and copper alloys can be spot welded, but not seam welded because of high conductivity, and not projection welded because of low compressive strength of the projections at elevated temperature. (For further discussion, see the subsequent sections of specific alloys.) In welding dissimilar metals, heat balance can also be important in the choice of process.

Spot and seam welds can be made in work metal as thin as 0.001 in. Spot welding of metal as thick as 0.125 in. has been reported for copper alloys. Projection welding is best suited for work thicker than 0.020 in.

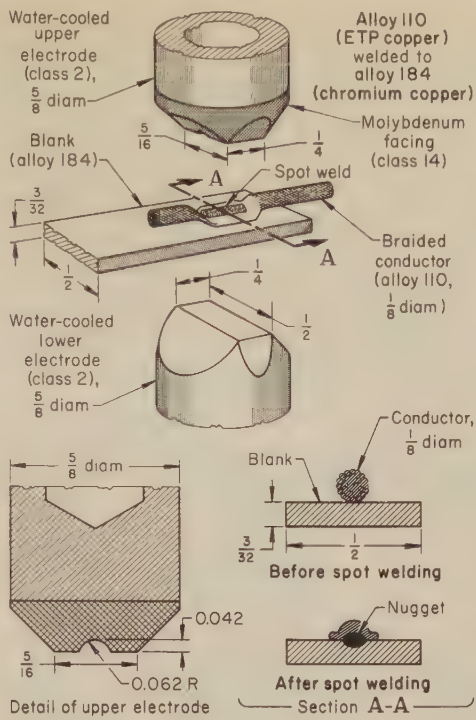
The use of projection welding frequently can increase the quality of joints in high-conductivity alloys, because welding current can be concentrated where needed. Distortion and electrode pickup are minimized because the electrode contacts a large area of the work metal. Projection welding may be preferred when the components are self-locating, or to simplify fixturing or improve dimensional accuracy.

Lap joints that must be liquid-tight usually are made most efficiently by seam welding. However, if a seam does not require the leaktightness provided by overlapping spots, spot welding is frequently preferred.

Electrode forces lower than those needed for welding low-carbon steel are used, but extremely low forces, which can cause electrode pickup, and weak welds, should be avoided. Low electrode force can also cause high-zinc alloys to flash or burn through.

Seam welding is nearly impossible on copper and many of the high-copper alloys, but most low-conductivity copper alloys can be seam welded readily using higher welding current and lower electrode force than those used for welding low-carbon steel. The usual spot spacing is 12 to 18 spots per inch. If fewer than 12 spots per inch are used, the spots sometimes do not overlap. Spots that are too closely spaced can cause excessive hot working of the base metal. Cooling by flooding, immersion or mist protects the work metal and electrodes from overheating and electrode pickup.

Projection welding is best suited for copper alloys of less than 30% electrical conductivity. The design of the projections in relation to the thickness and type of work metal is important. In general, to prevent collapse of the metal in the projection before welding temperature is reached, coined projections are preferred to formed projections. In Example 427, the projection was designed to minimize weld spatter and to contain the weld metal.



Conditions for Resistance Spot Welding

Lower electrode	⅝-in. diam, RWMA class 2, with ¼-by-½-in. face
Upper electrode	⅝-in. diam, RWMA class 2, ¼-by-5/16-in. class 14 face
Welding current	8500 amp, ac
Electrode force	350 lb
Squeeze time	10 cycles
Weld time	12 cycles
Hold time	16 cycles
Production rate	420 welds per hour

Fig. 1. Braided copper conductor and chromium copper blank that were joined by resistance spot welding, instead of by resistance brazing, to avoid use of a filler metal, minimize distortion of the blank and increase production (Example 420)

Preweld Cleaning

Dirt, scale, oil, drawing compound or other foreign matter on the surface of the workpiece should be removed before resistance welding. An indication of surface cleanness is the surface contact resistance, which should be uniform for best welding results. High or erratic contact resistance usually causes poor welds rather than reduced electrode life, although increased electrode pickup is an indication of high surface resistance. Surface cleaning can be done by various mechanical or chemical methods. See the article on Cleaning and Finishing of Copper and Copper Alloys, which starts on page 635 in Volume 2 of this Handbook.

Table 2. Conditions for Resistance Spot Welding Various Copper Alloys(a)

Alloy No.	Alloy name	Weld time, cycles	Electrode force, lb	Welding current, amp

(a) For spot welding 0.036-in.-thick sheet using RWMA type E electrodes with 3/16-in.-diam face and 30° chamfer, and made of RWMA class 1 material.

Coppers

Coppers and copper alloys having electrical conductivity higher than about 30% IACS (see Table 1) are the least suitable for resistance spot, projection or seam welding, mainly because of severe electrode pickup. Thin copper stock can be welded using electrodes faced with RWMA class 13 (tungsten) or class 14 (molybdenum), but surface appearance is poor and frequent electrode maintenance is required. A tinned coating on wire or sheet is helpful in welding copper.

When welding braided copper wires, best results are obtained if the wires are first bright dipped, then electrotin plated to a maximum thickness of 0.0002 in. Copper wires treated in this manner can be stored for 2 to 3 months, then welded with good results. The groove in the face of the electrode contacting the wire should have a depth not greater than one half the wire diameter. Tapering the electrode tip so that the length of the groove is equal to or slightly greater than the wire diameter will help prevent brittle welds. The sides of the electrode should be tapered in a like manner so that the face of the electrode is almost square in shape. The use of electrodes made of class 10 to 14 materials (refractory metals) helps heat the workpieces.

An internally water-cooled electrode with a molybdenum face shaped to conform to the top surface of the workpiece, and water cooling of the joint, were used in the example that follows. Clean joints were made at a higher production rate by spot welding than by resistance brazing.

Example 420. Joining a Braided Copper Conductor to a Chromium Copper Blank by Resistance Spot Welding vs Resistance Brazing (Fig. 1)

For joining a braided copper (alloy 110) conductor to an alloy 184 (chromium copper) blank, resistance spot welding was used instead of resistance brazing, to avoid

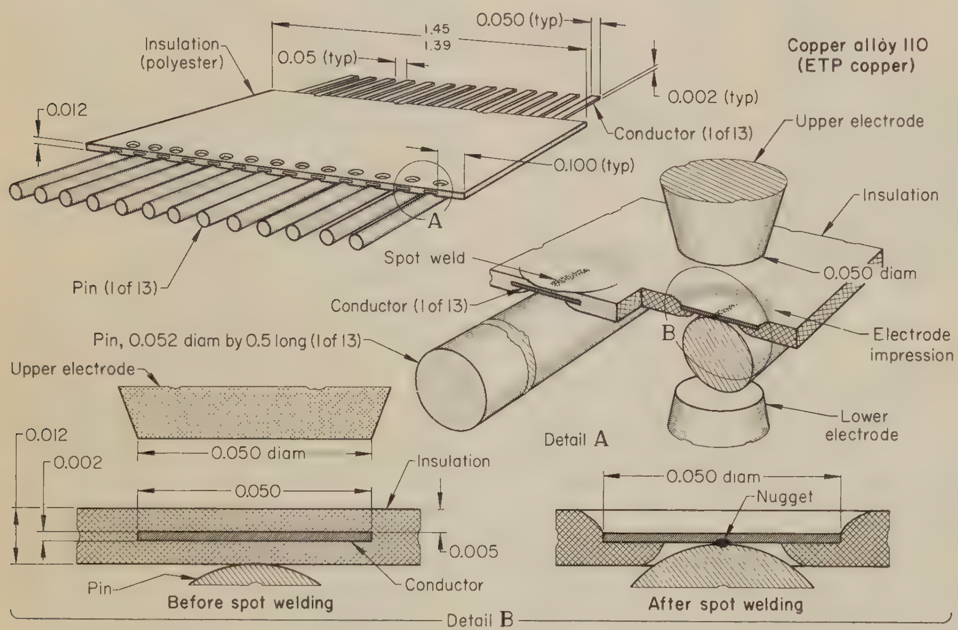
(a) Minimum edge distance is equal to one half the contacting overlap.

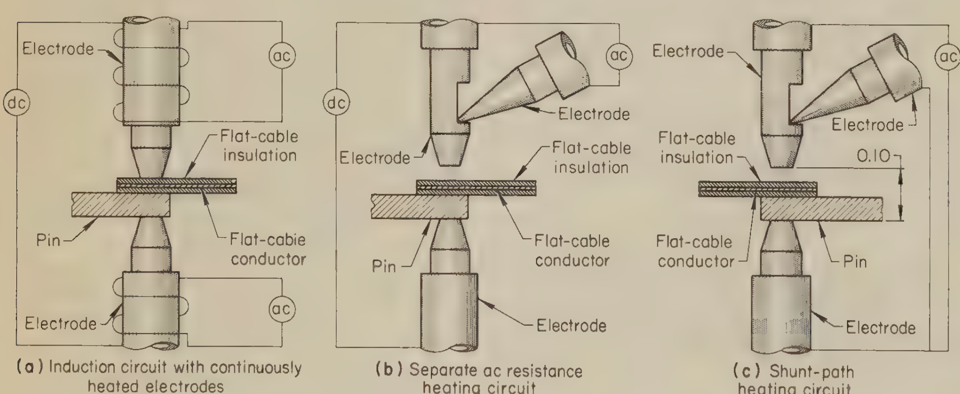
using a filler metal and to minimize annealing and distortion of the blank. Spot welding produced a joint of excellent conductivity and an assembly that was inherently clean because no flux or filler metal was used. The production rate for spot welding was more than twice that for resistance brazing, and thus a less costly part was produced by spot welding.

The ⅝-in.-diam water-cooled electrodes were made of RWMA class 2 material. The high conductivity of the copper conductor required that the upper electrode be faced with molybdenum (class 14 material) and be grooved, as shown in Fig. 1, to localize the contact area. The groove in the electrode face also helped to gather and hold together the strands of the conductor end as it was mashed to make a compact and dense weld. The lower electrode had a flat rectangular face ¼ by ½ in. As the weld was made, cooling water was directed on the joint to minimize annealing and to avoid burning of the copper conductor.

The production rate for spot welding was 420 welds per hour. Previously, when resistance brazing was used, production rate was 180 joints per hour. Resistance brazing required preplacement of a filler-metal disk, application of flux, use of a brazing time longer than the weld time used in spot welding, and excessive cleaning of the brazing electrodes.

Additional conditions for resistance spot welding are presented in the table that accompanies Fig. 1.





Equipment Details

Power supply	110-v single-phase ac(a), 220-v single-phase ac(b)
Welding machine	Press type, stored energy
Rating of capacitor bank	755 mfd
Storage voltage	13 to 408 v, dc
Energy storage	Low, 0.06 to 9 watt-sec; high, 0.1 to 45 watt-sec
Electrodes	1⁄16 in. in diam by 1¼ in. long, tapered to 0.05 in. in diam at tip, class 13
Electrode force	0.5 to 15 lb

Conditions for Resistance Spot Welding

Welding current	200 amp, dc
Welding voltage	0.6 v, dc
Electrode force	3 lb
Melting time	0.3 sec
Squeeze time	0.0025 sec
Weld time	0.0045 sec
Hold time	0.5 to 1 sec
Area of weld	40 sq mils (0.00004 sq in.)
Current density	5 amp per sq mil
Electrode gap	0.10 in.

(a) For heating the electrode to melt plastic insulation from the conductor. (b) For welding.

Electrode-heating circuits: (a) Induction circuit using alternating current for heating both upper and lower electrodes, and direct current for welding. When a high-temperature-resistant plastic insulation was used, electrode temperature offered considerable resistance to the flow of welding current. (b) Separate alternating-current circuit for heating the upper electrode only, and direct current for welding. (c) Alternating current for both heating and welding; shunt-path heating of upper electrode only.

Fig. 2. Three types of patented electrode-heating circuits, and setup for melting plastic insulation from copper conductors and resistance spot welding the conductors to copper pins, using a capacitor-discharge welding machine and the heating circuit shown at lower left (Example 421)

Often one or both members of a copper joint are coated with a protective or insulating material that interferes with direct welding of the joint. However, other considerations, such as expediency, loss of protection, or cost, may dictate that the coating not be stripped or cleaned away in a separate operation. Some coatings, like paint or insulation, can be penetrated by melting, burning or volatilizing them away during resistance welding. In Example 399, in the article on Projection Welding, a plastic sheet between two nickel wires was penetrated by pressure and heat that were applied to the rounded surfaces of the wires.

In the example that follows, a patented electrode-heating circuit was incorporated into the welding machine to burn or melt plastic coatings from copper conductors in welding the conductors to copper pins.

Example 421. Use of a Special Auxiliary Electrode-Heating Circuit To Melt Plastic Insulation From a Copper Conductor in Resistance Spot Welding (Fig. 2)

Plastic-coated conductors 0.050 in. wide by 0.002 in. thick were spot welded to 0.052-in.-diam pins using electrodes that were heated by an auxiliary alternating-current circuit to melt the 0.005-in.-thick insulation at the weld zone. Both components were made of copper alloy 110 (ETP copper). Thirteen conductors were contained in a flat connector board that was about 1⁷⁄₁₆ in. wide, as shown in Fig. 2. The insulation used on the parts described in this example was a polyester, but a higher-temperature-resistant plastic was sometimes used. Spot welding produced good joints at a high production rate without the need for stripping the insulation from the conductors.

Any of the patented heating circuits shown in Fig. 2(a, b or c) could be incorporated into a welding machine to melt through the plastic coating on the conductors. The system shown in Fig. 2(a) was selected for this application because it was superior to the other two with respect to all-around capabilities and performance. The direct-current welding circuit, because of its speed and dependability, was preferred for welding the copper workpieces. The electrodes were heated by heating elements powered by an alternating current. A disadvantage of this system is that when the electrodes were heated sufficiently to remove a high-temperature-resistant insulation, their resistance was increased and they would not easily pass direct current, and more electrical energy was required for welding. The welding cycle included a pulse of alternating current to melt the insulation, a squeeze time to bring the workpieces together and to allow the electrodes to cool, and a pulse of direct current to weld the workpieces together. Cooling the electrodes increased the efficiency of the direct-current welding pulse. Energy stored in a bank of capacitors was used for the welding current.

The circuit shown in Fig. 2(b) worked as well as the circuit shown in Fig. 2(a) and could be turned off between welds to cool the upper electrode, which was the only welding electrode in the heating circuit. The circuit shown in Fig. 2(c) used alternating current for both heating and welding. The alternating current could be used for welding the conductor to the pin if one of the components were made of a metal that was less conductive than copper.

Equipment details and welding conditions are given in the table with Fig. 2.

Resistance welding of small-diameter stranded copper wire to terminals made of either similar or dissimilar metal is difficult because the wires pro-

vide such a small heat sink that they melt before the mating workpiece reaches welding temperature. The copper-to-copper joint described in Example 655, in the article on Brazing of Copper Alloys, was made successfully by adding BCuP-5 filler metal and resistance brazing at a temperature below the melting point of the 0.014-in.-diam wires. Making the joint without a filler metal was unsuccessful because the small-diameter copper wires melted before a weld was made. In Example 420 in the present article, a braided copper conductor was successfully spot welded to a small chromium copper blank. In the example that follows, a stranded conductor containing 0.016-in.-diam wires was spot welded to a ring made of coin silver. The welding conditions were selected so that the maximum temperature reached in the two workpieces was above the melting point of the silver-copper eutectic (1436 F), but below the solidus temperature of ETP copper (1949 F).

Example 422. Careful Selection of Welding Conditions To Control Heating of Workpieces in Spot Welding (Fig. 3)

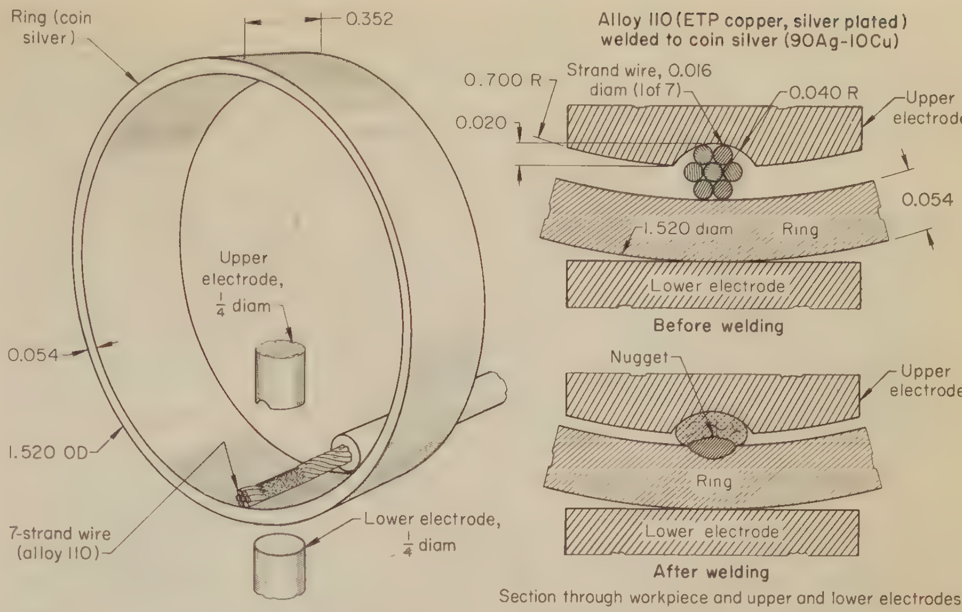
A silver-coated seven-strand lead wire of alloy 110 (ETP copper) was spot welded to a coin silver (90Ag-10Cu) ring at a production rate of 190 welds per hour. Originally, the assembly was made by lead-tin soldering, but the production rate was only 60 assemblies per hour and the solder spread over a large area of the ring. Also, brazing with silver alloy filler metal was not acceptable because of the increased cost and the need for removal of flux residue after brazing.

With the proper selection of electrode materials for resistance spot welding, shape of the electrode faces, and spot welding conditions, liquid started to form at the workpiece interface when the silver-copper eutectic temperature (1436 F) was reached, and the joint was fused without completely melting the small-diameter copper wires.

Use of a class 14 (molybdenum) electrode in contact with the copper wire and a class 2 (chromium copper) electrode in contact with the coin silver ring helped to maintain heat balance. The molybdenum electrode material promoted heating at the workpiece interface and prevented electrode pickup. A semicircular groove was machined into the upper (molybdenum) electrode to contain the stranded wire. The lower electrode had a flat face that made line contact with the ring and concentrated the welding heat. Both upper and lower electrodes were cooled by water flowing through passages in the electrode holders, and were cleaned by wire brushing after making 200 to 250 welds. Electrode life was about 5000 welds between redressings.

The coin silver ring was degreased with trichlorethylene before welding. Removing the insulation was the only preweld preparation needed for the wire. The ring was held in a vertical position against a stop; the wire was manually located beneath the upper electrode. The welding cycle was initiated with a pedal. Equipment details and welding conditions are given in the table with Fig. 3.

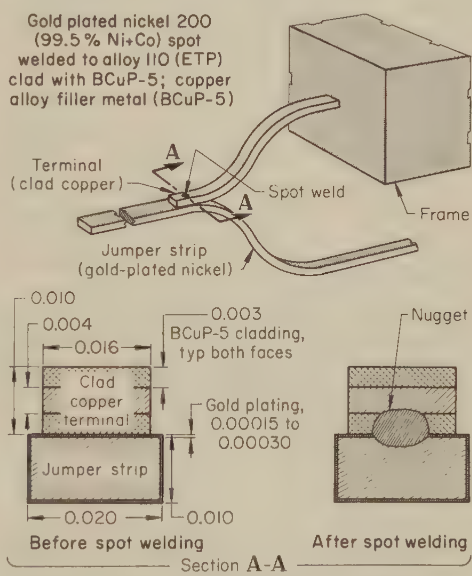
Spot welds can be made between metal-plated or metal-coated base metals, provided the thickness, composition and density of the coating are consistent. The ambient atmosphere and time between coating and welding can have an effect on the weldability of coated base metals. The contact resistance and the electrical resistivity of the coating can have a critical effect on spot welding of coated metals, as in the next example.



Equipment Details	
Power supply	440 v, three phase
Welding machine	Press-type
Rating at 50% duty cycle	100 kva
Lower electrode	Type C, ¼-in. diam, RWMA class 2
Upper electrode	¼-in. diam, RWMA class 14, with grooved face

Conditions for Resistance Spot Welding	
Welding current	70 amp, ac
Welding voltage	3.7 v
Heat-control setting	62%
Electrode force	120 lb
Squeeze and weld times	5 cycles each
Hold time	30 cycles
Production rate	190 welds per hour

Fig. 3. Stranded copper wire and coin silver ring that were resistance spot welded using electrode design and welding conditions given in the table to control heating of the workpieces (Example 422)



Equipment Details	
Welding machine	Press type, stored energy
Power supply	110 v, single-phase, 500 watts
Rating of capacitor bank	1500 mfd
Electrodes	RWMA class 2, 0.071-in. diam(a)

Conditions for Resistance Spot Welding	
Welding current	2500 amp
Electrode force	2.5 lb
Welding heat	20 watt-sec
Weld time	0.0012 sec
Hold time	1.0 sec

(a) Ends of electrodes were cut at 30° angle to provide elliptical faces; positive electrode was used in contact with the clad copper terminal.

Fig. 4. Gold-plated nickel jumper strip and clad copper terminal that were joined by resistance spot welding. Presence of more than 2% cobalt in the gold plating affected weld strength adversely. (Example 423)

Example 423. Effect of Composition of Plating on Quality of Spot Welds (Fig. 4)

A gold-plated nickel jumper strip was joined, as shown in Fig. 4, to a copper terminal clad with BCuP-5 (copper alloy brazing filler metal), by capacitor-discharge resistance spot welding. (The filler-metal coating was used for making other joints.) The spot welded joints were welded successfully for several years but, suddenly, joints made under the established welding conditions failed the specified 6.5-lb tensile-shear test. Adjustment of welding conditions did not produce acceptable welds.

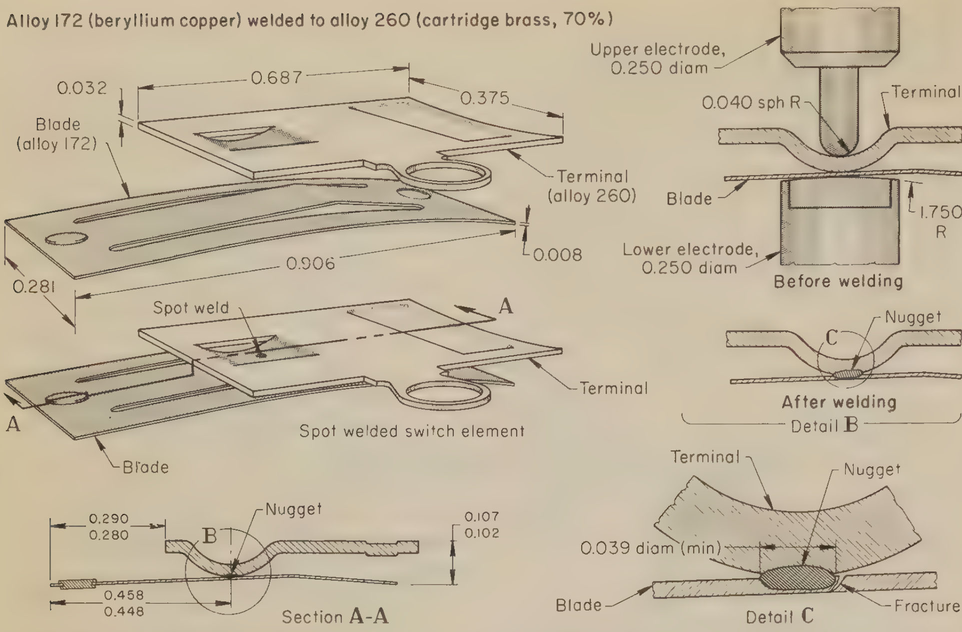
The 99.99% gold plating on the Nickel 200 (99.5% Ni+Co) jumper strip was 0.00015 to 0.00030 in. thick. The terminal was made of 0.004-in.-thick alloy 110 with an 0.003-in.-thick coating of BCuP-5 filler metal.

When tensile-shear breaking loads from 0.9 to 4.5 lb were obtained, instead of the specified 6.5-lb minimum value, it was found that the 99.99% gold plate had been changed to a hard gold plate containing a nominal 2% cobalt. Tests showed that 2% cobalt could be tolerated, but that the plating actually contained considerably more than 2% cobalt. When the plating was changed back to 99.99% gold, no further difficulty was encountered in maintaining the minimum 6.5-lb tensile-shear value.

Although the mechanism by which the cobalt weakened the joint was not known, variation in the thickness of the Au-2%Co plating caused a variation in contact resistance and a nonuniform electrical response to capacitor discharge. The IACS electrical conductivities of the metals in the joint were: copper, 101%; gold, 73.4%; nickel, 18%; and BCuP-5, 9.9%. Gold containing 1% cobalt has an electrical conductivity of 9.6%; a larger cobalt content decreases the conductivity of the plating more.

The weld nugget penetrated deeper into the nickel jumper strip than into the copper of the terminal, and there was no electrode identation on either side of the joint.

The electrodes were made of class 2 material and were 0.071 in. in diameter. The end of each electrode was cut at an angle



Equipment Details	
Power supply	110 v, single phase, 60 cycle, 20 amp
Welding machine	Press type, stored energy
Rating of capacitor bank	400 mfd
Storage voltage	100 to 1500 v, dc
Energy storage:	
Low	2 to 50 watt-sec
High	20 to 500 watt-sec
Output voltage	1.5 to 25 v

Upper-electrode face	0.040-in. spherical radius
Lower-electrode face	1.750-in.-radius crown, 0.125 in. wide

Conditions for Resistance Spot Welding	
Welding current	8000 amp
Welding voltage	12.5 v, dc
Welding energy	250 watt-sec
Electrode force	22 lb
Pulse time	2.5 millisec
Production rate	300 welds per hour

Fig. 5. Switch element that was made by capacitor-discharge resistance spot welding a beryllium copper blade to a cartridge brass terminal. Rejection rate was reduced by careful control of welding-machine setup and electrode maintenance. (Example 424)

of 30° to the centerline of the electrode, resulting in a face of elliptical shape with a major diameter of about ⁹⁄₆₄ in. The positive terminal of the welding machine was connected to the electrode that was in contact with the copper terminal. Additional equipment details and welding conditions are given in the table with Fig. 4.

The high-conductivity coppers have been projection welded to silver alloy contacts successfully. The copper workpieces were cleaned and plated with tin to a maximum thickness of 0.0002 in. The projections were coined on the silver contacts. Low electrode forces were used to prevent premature collapse of the projections during heating. An increased welding force and a fast electrode follow-up were used to ensure a good weld.

Tin plating kept the workpieces clean and the workpieces could be stored for 2 to 3 months without affecting weldability. There was a minimum amount of tin vaporization, and the tin melted and alloyed with the base metal with only a trace of flow during welding.

Nickel plating on copper can serve a similar function, and plating thickness and composition must be carefully controlled.

Beryllium Copper

Beryllium copper alloys can be resistance welded, most successfully in thin gages. Spot welding produces satisfactory welds; seam welding is less successful. Projection welding is satisfactory, provided that the projections can be formed with the work metal in the annealed condition and without cracking the work metal around the projection. Close control of welding conditions is required for consistent weld size and joint strength. Oxide films produced by heat treating must be removed to ensure low and consistent contact resistance. Work metals that have not been heated after rolling frequently need only degreasing before welding.

Low electrical conductivity (22% IACS for alloys 170 and 172) contributes to the weldability of beryllium copper alloys. However, they are more difficult to resistance weld than low-carbon steel. Alloy 175 has an electrical conductivity of 45% IACS, and is more difficult to resistance weld than higher-strength, lower-conductivity beryllium copper.

Resistance welding of beryllium copper requires the rapid heat input that can be provided by the short impulse length of a capacitor-discharge power supply. A low-inertia welding head is needed for fast follow-up to prevent expulsion of molten metal by arcing and to forge the weld nugget. Because capacitor discharge equipment supplies direct current, polarity can be a factor in weld strength when beryllium copper is welded to another copper alloy or to another metal.

In the two examples described next, beryllium copper was resistance welded either to itself or to a dissimilar metal. Capacitor-discharge welding was employed in two of the examples to produce high heat for a short time, which is needed to minimize diffusion of heat.

The size and location of the spot weld and the strength of the welded joint were important in obtaining maximum service life for the switch component described in the following example. Weld quality was maintained by setting up the welding machine carefully and by frequent electrode maintenance.

Example 424. Use of Careful Control of Welding-Machine Setup and Electrode Maintenance To Reduce Rejection Rate in Spot Welding (Fig. 5)

The snap-action switch element shown in Fig. 5 was produced by capacitor-discharge spot welding a blade made of alloy 172 (beryllium copper) to a terminal made of alloy 260 (cartridge brass, 70%). The location and size of the spot weld and the strength of the welded joint were critical in the performance and life of the switch.

If the weld joining the blade and terminal was too large, the blade failed prematurely by fatigue because of hardening in the heat-affected zone. As shown in Fig. 5 (detail C), the fracture developed in the heat-affected zone.

Mislocation of the weld either caused the blade not to have the snapping action, or changed other operating characteristics of the switch unacceptably. A riveted joint could not be used because the rivet hole in the blade so weakened it that the blade failed to have the snap action.

The rejection rate for the welded assemblies in snap-action testing sometimes was 25%, which could not be tolerated. Variations in the work-metal properties and in the welding equipment were at first suspected of causing poor switch life. Finally, the test failures were reduced to 5% by careful attention to the setup of the welding machine and to the shape and surface condition of the electrodes.

The electrodes were ¼ in. in diameter, and were made of class 2 material. The end of the upper electrode was reduced in diameter and had a 0.040-in. spherical radius; the lower electrode had a 1.750-in.-radius crown 0.125 in. wide.

During machine setup, the upper electrode was carefully clamped in its holder, and the upper electrode holder was lowered and temporarily locked so that a plate cam on the holder contacted the cam follower of a limit switch with the switch in the closed position. (This switch actuated the capacitor-discharge welding current.) The lower electrode was aligned, was raised until it touched the upper electrode, and then was clamped in its holder. The spring that provided the electrode force was then compressed so that it would exert a force of 22 lb on the workpieces during welding.

The components were held in a fixture during welding. The blade nest was adjusted to give the blade firm contact with the lower electrode, and the terminal nest was similarly adjusted for proper contact of terminal and blade so that the blade could not flex when force was exerted on the terminal by the upper electrode.

The electrodes were cleaned with crocus cloth after welding every 25 assemblies. When pitting developed on the lower electrode surface, the electrode was removed for refinishing. Refinishing of electrodes usually was a successful remedy when poor welds were produced.

The welded assemblies were subject to 100% inspection for snap action. The weld nugget was to be a minimum of 0.025 in. from the edge of the center leg, and molten metal formed during welding was to be confined between the blade and the protrusion on the terminal. If molten metal was ejected from this area, malfunction of the switch was possible. After welding, the blade surface had to be smooth and free of pitting; pitting would reduce service life. Also, the weld nugget was required to be strong enough to withstand 0.23 lb-in. of torque without permanent set in a torsion-shear test.

Destructive tests, in which a blade was peeled from the terminal, were made on

0.5% of the welded switch assemblies. To pass inspection, the blade had to pull a button 0.0012 sq in. in area (0.039 in. in diameter), or greater, yet small enough to fit completely under the end of a 0.062-in.-diam rod.

In the example of projection welding that follows, one of the workpieces was a nickel wire, and thus, as in cross-wire welding, a manufactured embossment was not needed for the projection. A capacitor-discharge power supply was used and, until the system was changed, the rate of recharging the capacitor bank affected the production rate, or the weld quality, if welding current was initiated before the capacitors were recharged. Polarity also had an effect on weld quality.

Example 425. Change in Power-Supply-and-Control System That Reduced the Number of Faulty Welds in Projection Welding (Fig. 6)

The gate module shown in Fig. 6 was used in a telephone thin-film circuit pack, and consisted, in part, of an electronic circuit deposited on a small glass substrate with 11 beryllium copper (alloy 172) clips 0.005 in. thick that served as electrical leads. The beryllium copper clips were joined to 0.023-in.-diam flash gold-plated nickel wires that were in a phenolic molded body. The completed module was subsequently installed on a printed circuit board. A stored-energy (capacitor-discharge) welding machine was used for the operation.

The beryllium copper clips were formed and mechanically attached to the glass substrate and soldered to the thin-film circuit, so that each clip was aligned and held in position during the clip-to-wire welding operation. The substrate and phenolic subassemblies were positioned by hand with the nickel wires and the beryllium copper clips overlapping for welding as shown in Fig. 6. The wire and clip were then manually positioned between the welding electrodes to make each of the 11 welds needed to complete the assembly.

The beryllium copper used for the clips was coated with 60-40 Pb-Sn solder to a thickness of 0.0002 in. The weld nugget undoubtedly contained some solder from the coating on the beryllium copper clip and some gold from the plating on the nickel wire. However, it would have been difficult to isolate the actual nugget metal because of the solder fillet that surrounded the nugget and joint. If the solder coating was too thick, welding heat was inadequate, but with the coating thicknesses used, the solder and gold did not affect the strength or ductility of the joint. Welding response was determined largely by the thermal conductivity of the beryllium copper, which required that the welding-current pulse be delivered quickly to minimize diffusion of heat.

The short pulse length of the capacitor-discharge welding current necessitated the use of a welding head with a low-inertia, fast-follow-up force system. The system used consisted of a decoupling spring between the ram and the electrode. Deflection of the spring actuated the welding switch on the downstroke when the correct welding force was reached. Because a capacitor-discharge pulse is direct current, weld properties are affected by the polarity of the electrodes during welding. The breaking load of the clip-to-wire welded joint was 13 lb or greater when the negative electrode was used against the nickel wire and the positive electrode against the beryllium copper clip, and only 4 lb when the electrodes were reversed.

Originally, the capacitor bank was discharged through a relay, and thus the welding current could be initiated before the capacitors were completely recharged. The pedal-release and relay-reset time was only 0.15 to 0.20 sec, while the capacitor-recharge time was 1.0 sec, so even an experienced operator, when making closely spaced welds or welds in closely spaced components, could initiate the welding current before the capacitor bank was sufficiently recharged. This led to faulty welds and it was necessary to change the system of supplying and controlling the power.

The system that was finally used was fully electronic with a capacitor-recharge time of 0.30 sec. Recharge was started automatically after a 0.15-sec shutoff pulse, even with the pedal depressed. In addition, a lockout circuit prevented the welding current from being initiated before the capacitors were 90% recharged. This feature reduced the number of faulty welds.

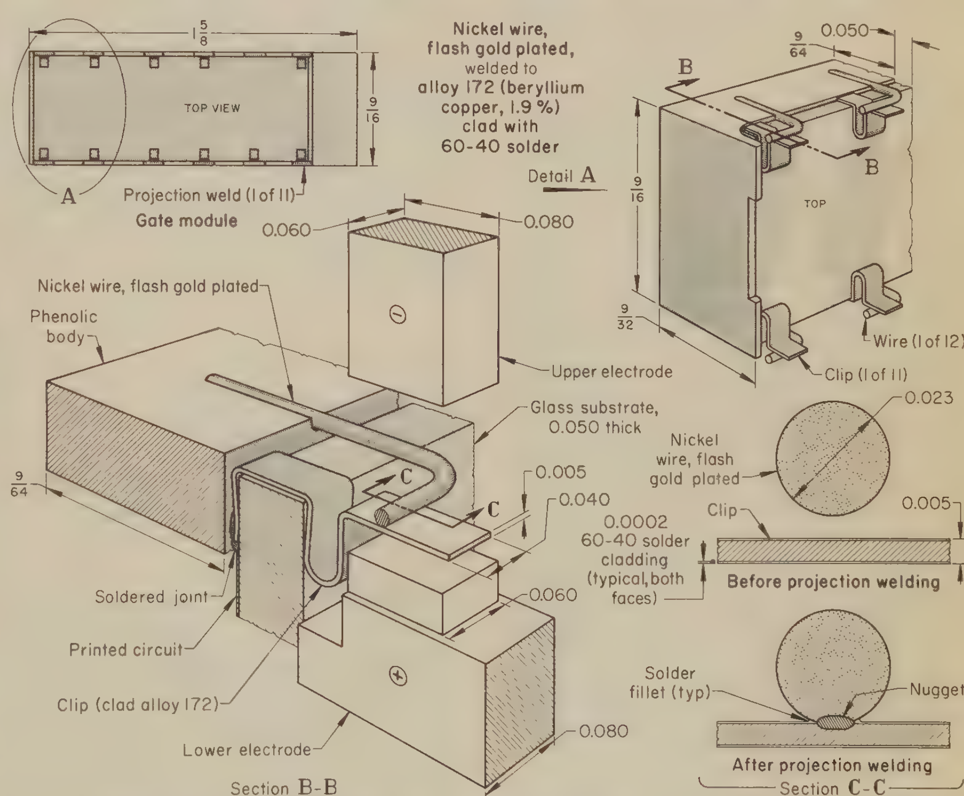
Electrodes of special shape helped to position the workpieces during welding and to control weld quality. The lower electrode positioned the glass substrate horizontally and supported the beryllium copper clip. Solder pickup was removed from the electrode faces by placing a fine emery cloth between the electrodes and reciprocating and oscillating the cloth while the electrodes were lightly closed.

The welding-machine settings were established experimentally by making and testing samples, then adjusting the machine settings until the samples met the minimum strength requirements. The test consisted of holding the wire of a simulated clip-to-wire weldment and pulling the tab at right angles to the wire. A minimum breaking load of 5 lb was required in this test. An average value of about 13 lb was observed on welds made with the correct polarity. Pull tests were made approximately every 4 hr. In addition, 10 welds per hour were tested by probing with a force gage that was calibrated at 200 grams to verify that there had been no change in the welding conditions that could result in weak welds. Weak welds found by probing were usually repairable by rewelding.

A beryllium copper blade that was welded to a steel support by projection welding had inadequate service life because of fatigue failure of the beryllium copper blade in the heat-affected zone. A successful redesign in which the beryllium copper blade was sandwiched between two steel supports is described in the following example.

Example 426. Projection Welding of Two Steel Supports To Hold a Beryllium Copper Blade That Was Sandwiched Between Them (Fig. 7)

The oscillating-contact assembly shown in Fig. 7 was made by sandwiching a beryllium copper alloy 172 blade between two supports made of cadmium-plated cold rolled low-carbon steel strip (ASTM A109), and then projection welding the supports together through holes in the beryllium copper blade so that the welds mechanically held the blade. The steel supports were 0.036 in. thick, and the beryllium copper blade was 0.010 in. thick.



Equipment Details

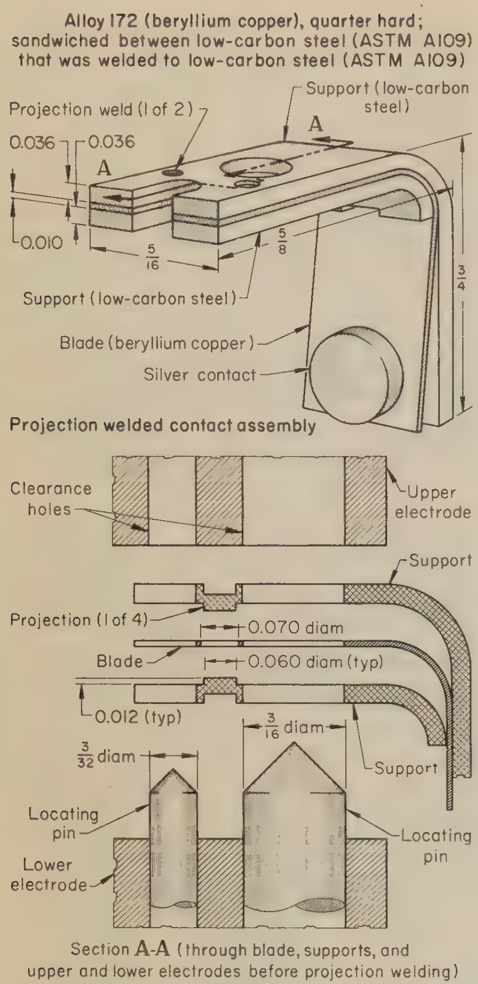
Power supply	120 v, single phase, 60 cycle, 6 amp (max)
Welding machine	Bench type, stored energy, with foot-operated low-inertia head
Rating of capacitor bank	14, 28 or 56 mfd
Storage voltage	675 to 1500 v, dc
Secondary current, max	3000 amp
Energy storage	0-63, 0-32 or 0-16 watt-sec
Pulse width	0.0018 to 0.0166 sec
Electrodes	RWMA class 2(a)
Electrode force, max	15 lb

Conditions for Resistance Spot Welding

Welding current	1900 amp
Welding voltage	2.8 v, dc
Weld energy	27 watt-sec
Electrode force	10 lb
Pulse time	0.005 sec
Production rate	1500 welds per hour

(a) Upper electrode was 3/16 in. in diameter by 1½ in. long, with a 0.060-by-0.080-in. face; lower electrode was a bar 0.080 by 3/8 by 1⅜ in. long, with a 0.060-by-0.080-in. contact surface. Weld strength was significantly greater when the positive electrode was used in contact with the beryllium copper clip.

Fig. 6. Gate module that was assembled by capacitor-discharge resistance projection welding nickel wires to beryllium copper clips in the setup shown. Change in system of supplying and controlling power reduced the number of faulty welds. (Example 425)



Equipment Details

Power supply	480 v, single-phase, 60 cycle
Welding machine	Press type with air and magnetic-actuated electrode force
Rating at 50% duty cycle	75 kva
Welding current, max	30,000 amp
Electrodes	5/8-in.-diam type C, RWMA class 1
Electrode force, max	Air actuated, 600 lb; magnetic actuated, not recorded
Welding controls	Synchronous, with phase-shift heat control
Fixturing	Pins fitted into lower electrode

Conditions for Projection Welding

Welding current	8500 amp, ac
Electrode force	Air actuated, 350 lb; magnetic actuated, not recorded
Squeeze time	30 cycles
Weld time	5 cycles
Hold time	5 cycles
Production rate	360 assemblies per hour

Fig. 7. Oscillating-contact assembly, made by projection welding two low-carbon steel supports through holes in a beryllium copper blade that was sandwiched between the supports (Example 426)

Formerly, the blade itself was projection welded to a single steel support by use of projections in the support. The weld was well formed, but the blade had a life of only 4 to 5 million cycles, compared with the required life of 10 to 15 million cycles. Failure was caused by cracks that originated in the heat-affected zone of the blade.

In the improved design, two projections in one steel support contacted two opposing matched projections in the other support through mating holes in the beryllium copper blade. The projections were 0.060 in. in diameter by 0.012 in. high, and the holes in the blade were 0.070 in. in diameter. There was almost no welding of the beryllium copper blade to the steel supports.

The electrodes were 5/8 in. in diameter with type C (flat) faces, and were made of class 1 material. Two locating pins, made of an electrically nonconductive material and fitted into the lower electrode, passed through matching holes and notches in the workpieces (see Fig. 7) to provide positive location of the assembly. The upper electrode had matching clearance holes for the locating pins.

In operation, the three workpieces were placed on the lower electrode over the two locating pins with the blade between the two steel supports. The welding machine was then actuated to make the weld, and simultaneously a magnetic force system was actuated to forge the weld metal. The forging force closed the gap between the steel supports and expanded the plastic metal against the holes in the blade. The assemblies made in this way proved completely satisfactory, and in service, the silver contact on the blade (see Fig. 7) was worn away before the blade failed in the weld area; failure, if any, occurred elsewhere in the blade.

Five welded assemblies were peel tested by an inspector during each hour. In this test the two steel supports were peeled apart, and it was required that a nugget be pulled from one of the steel supports at each weld.

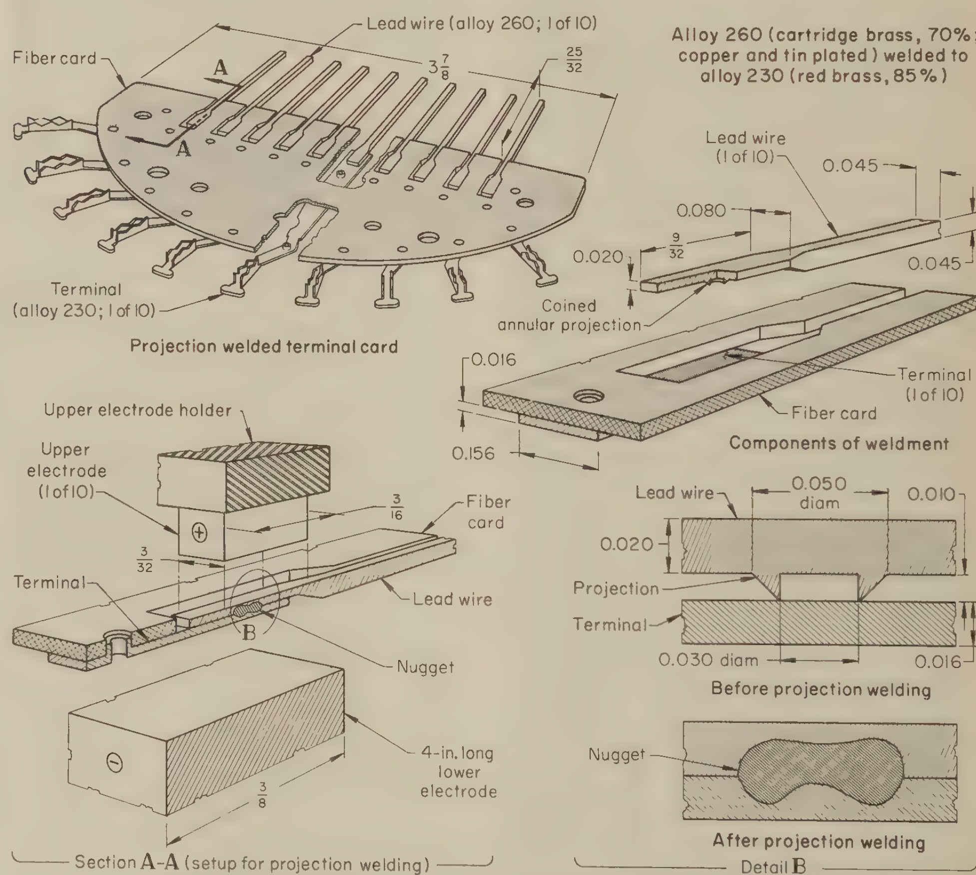
Additional equipment details and welding conditions are given in the table that accompanies Fig. 7. All welding machines in this group had individual connections to a central exhaust system. A flexible tube was located adjacent to the weld area to remove any hazardous fumes and to prevent them from reaching the operator or the adjacent areas.

Low-Zinc and High-Zinc Brasses

The low-zinc brasses are difficult to weld, although easier than copper, and are subject to electrode pickup. Welds made in these brasses may lack strength, principally because of comparatively high electrical conductivity (32 to 56% IACS).

The high-zinc brasses have an electrical conductivity of 27 to 28% IACS and can be both spot and projection welded over a wide range of conditions. Electrode pickup can be a problem unless weld time, welding current and electrode force are properly selected.

Excessive electrode pickup and blowthrough of the weld may occur when long weld times, high energy input and low electrode forces are used. Yellow brasses (alloys 268 and 270) are less subject to electrode pickup than car-



Equipment Details

Welding machine	440-v ac automatic press type, with ten welding heads and ten transformers
Rating at 50% duty cycle	20 kva each
Rating of secondary circuit	4.6 to 6.1 v, 2000 to 4000 amp

Weld time	1 cycle
Hold time	5 cycles, min(c)
Production rate:	
Assemblies per hour	1100
Welds per hour	11,000

(a) Ten upper electrodes, 3/32 by 3/16 in.; one lower electrode, 3/8 by 4 in. (b) 24-stop rotary table. (c) Squeeze time and hold time varied because the upper-electrode holders were attached to the press ram, and times were determined by mechanical motions of the ram.

Fig. 8. Cartridge brass lead wires and red brass terminals that were joined by projection welding, instead of by spot welding, to prevent electrode sticking, using annular projections designed to limit expulsion of weld metal (Example 427)

tridge brass, except when long weld times and high energy input are used. Electrode force should be sufficient to prevent arcing or expulsion of molten metal, to which these alloys are subject because of their 30 to 40% content of zinc, which boils at about 1665 F. As shown in Table 2, the recommended electrode force, when using electrodes having a face diameter of $\frac{3}{16}$ in., is approximately 400 lb.

For weldability ratings, see "Welding index" entries in Table 1.

In projection welding, the projections should be as small as practicable, especially the height. A short weld time and a low-inertia welding head with fast electrode follow-up should be used. Tin plating the workpieces generally will improve weld quality, although expulsion of molten tin from the weld interface may occur.

In the example that follows, in which cartridge brass lead wires were welded to red brass terminals, heat balance was obtained by flattening the wires, which were square in cross section and thicker than the terminals. Spot welding was replaced by projection welding so that large electrodes, which would not stick to the work metal, could be used. Projections that were carefully designed to trap weld metal and limit expulsion were coined on the flat section of the wire.

Example 427. Use of Projection Welding With Annular Projections To Eliminate Electrode Sticking and To Limit Expulsion of Weld Metal (Fig. 8)

A cartridge brass lead wire was joined to a red brass terminal by resistance projection welding as shown in Fig. 8. The terminal was 0.016 in. thick, and the lead wire was 0.045 in. square and was plated with 0.0002-in.-thick copper and with 0.0002-in.-thick tin over the copper. The end of the cartridge brass lead wire was flattened to 0.020 in. thick by 0.080 in. wide by $\frac{9}{32}$ in. long, and an annular projection was coined on one surface. Coining, rather than forming, produced a projection that was strong enough to withstand the electrode force used without collapsing prematurely. The annular projection was designed to prevent expulsion of molten metal.

Originally, the 0.045-in.-sq lead wire was resistance spot welded to the terminal without flattening the end of the wire. Spot welding was not successful, and electrode pickup from the cartridge brass wire was excessive because of the small area of contact between the electrode and the work metal.

Projections of several shapes, including a transverse bead and a longitudinal bead, were tried before the annular projection shown in Fig. 8 was developed. Besides allowing excessive expulsion of weld metal, the transverse bead had to be at the center of the electrode to prevent tilting of the workpiece and contact of workpiece surfaces elsewhere than at the projection. (Circular, square and cross-shape projections provide much more stability than bead-type projections.) The longitudinal bead also caused excessive expulsion of work metal because the volume of weld metal was too great and melting was erratic and inconsistent.

The annular projection had a steep internal slope (about 90°) and a 45° external slope so that, as the projection melted, the molten metal was confined by the remaining metal of the projection.

The welds were made in an automatic welding machine that had a 24-stop rotary-indexing table and ten welding heads, each with a 20-kva transformer. Electrode material was class 2. The lower electrode was made in one piece and was connected to the negative terminals of the transformer secondary circuits. Each of the ten upper electrodes was mounted to a welding head and was connected to the positive terminal of a transformer.

Ten red brass terminals were permanently mounted on a fiber card, and were degreased and cleaned with a rotary wire brush after the card was placed on the indexing table. The cartridge brass wires were cleaned and lubricated by wiping with a felt pad as they were fed into the flattening, coining and cutoff die. In the welding position, the flattened end of each of ten cartridge brass square wires extended beyond a wire-guide groove in the die and over one of the ten terminals fastened to the fiber card. A notch in the card at each terminal helped to position the lead wire. The ten welding transformers had synchronous controls and were fired in sequence.

The equipment for this operation cost about $80,000; cost of replacing electrodes was minor. Equipment details and welding conditions are given in the table that accompanies Fig. 8.

The use of projection welding offers several advantages for the joining of high-zinc brasses, which is often done with close weld spacings and edge distances. The projection defines the size and location of the weld. There is no marking of the parts from electrodes that are misaligned, too large in diameter or have improper face shape. Distortion and sticking of electrodes are minimized because a relatively large area of the workpiece is in contact with the projection welding electrode. Also, localized heating produces a minimum decrease in the hardness and strength of the base metal. Projection welding also permits multiple welds to be made simultaneously at a closer spacing than is possible with spot welds, as is illustrated in the following example.

Example 428. Projection Welding a Cartridge Brass Terminal to a Narrow Phosphor Bronze Blade (Fig. 9)

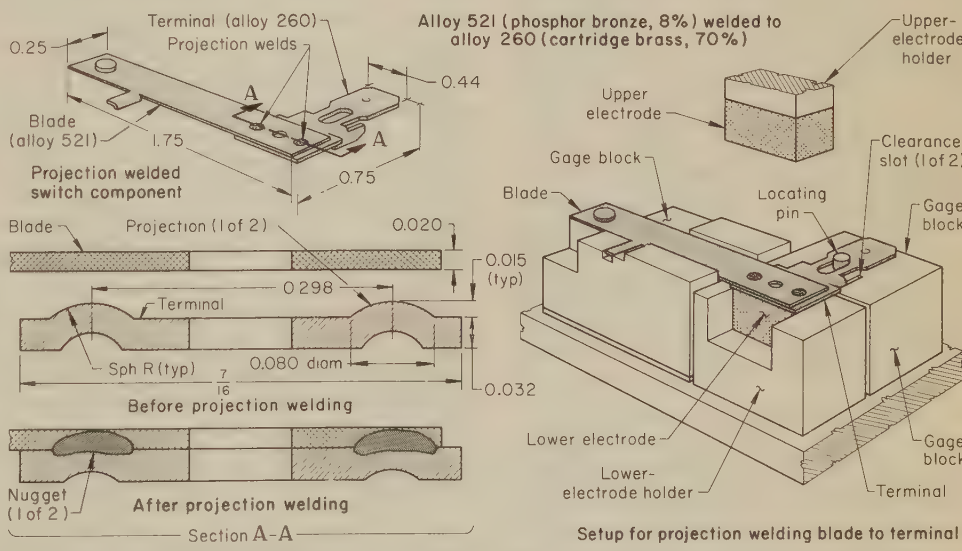
The switch component shown in Fig. 9 was made by projection welding an alloy 260 (cartridge brass, half hard) terminal to an alloy 521 (phosphor bronze, spring temper) blade. The low electrical conductivity of these alloys (28% IACS for alloy 260 and 13% for alloy 521) made them relatively easy to join by resistance welding. Two welds were used for joining the terminal and the blade, and the use of projection welding allowed closer spacing of the welds than normally allowed by spot welding, and made both welds simultaneously.

The terminal, with two spherical projections 0.080 in. in diameter by 0.015 in. high and spaced at 0.298 in., was made in a progressive die. The blade was a flat strip with a hole at one end and a contact fastened to the other end. The slot in the terminal was used for locating the part during projection welding. Before welding, both parts were degreased and bright dipped, then carefully rinsed.

The electrodes were made of refractory metal compositions (RWMA group B) to reduce electrode pickup, and were rectangular in shape, which made them easy to clean and replace. The upper electrode was made of class 13 material (tungsten) and the lower electrode was made of class 11 material (a mixture of copper and tungsten). Both electrodes were fastened to holders made of class 2 material. A gage block supported and located the blade, and a pin located the terminal during welding.

Copper Nickels

The copper-nickel alloys have electrical conductivities of 4.6 to 9% IACS, are readily spot and seam welded with relatively low welding current, and generally do not alloy with the electrode material and cause electrode pickup. Proper preweld cleaning is required to ensure low and consistent contact resistance. Short weld times prevent electrode indentation.



Equipment Details

Welding machine	440-v single-phase ac press type, with synchronous controls
Rating at 50% duty cycle	30 kva
Current, max	22,500 amp
Upper electrode	RWMA class 13
Lower electrode	RWMA class 11
Electrode holders	RWMA class 2
Electrode force, max	750 lb

Conditions for Projection Welding

Welding current	19,200 amp, ac
Secondary voltage	6 v
Electrode force	180 lb
Squeeze time	20 cycles
Weld time	3 cycles
Hold time	5 cycles
Production rate:	
Assemblies per hour	750
Welds per hour	1500

Fig. 9. Switch component that was made by joining a cartridge brass terminal to a phosphor bronze blade, in the setup shown, using closely spaced projection welds (Example 428)

Nickel Silvers

Nickel silvers, which have about the same conductivities as copper nickels, are spot welded as readily as copper nickels (see Table 1), but are more difficult to seam weld. Surface contaminants such as lead and bismuth (which form low-melting eutectics with copper and nickel) or sulfur (which may be introduced in forming) must be removed before resistance welding.

Although cold worked base metal is softened by welding, postweld heat treatment is seldom used except when needed for corrosion resistance.

Bronzes

The phosphor bronzes, except alloy 505, which is not recommended for resistance spot and seam welding, have relatively low electrical conductivity (10 to 15% IACS) and are readily spot and seam welded using low welding currents. Electrode pickup can be reduced by use of a type F (radius) electrode face and frequent redressing to keep the face clean and smooth. Hot shortness can be minimized by supporting the workpieces to prevent strain during welding and by using a greater minimum overlap than recommended by the data in Table 3.

Projection welding of phosphor bronze alloy 521 to alloy 260 (cartridge brass) is described in Example 428. Location of the spot weld with respect to the edge of the workpiece was a factor in preventing expulsion of weld metal in Example 408, in the article on Resistance Welding of Stainless Steel, in which a spring made of copper alloy 510 (phosphor bronze, 5% A) was spot welded to a U-shape workpiece made of type 304 stainless steel.

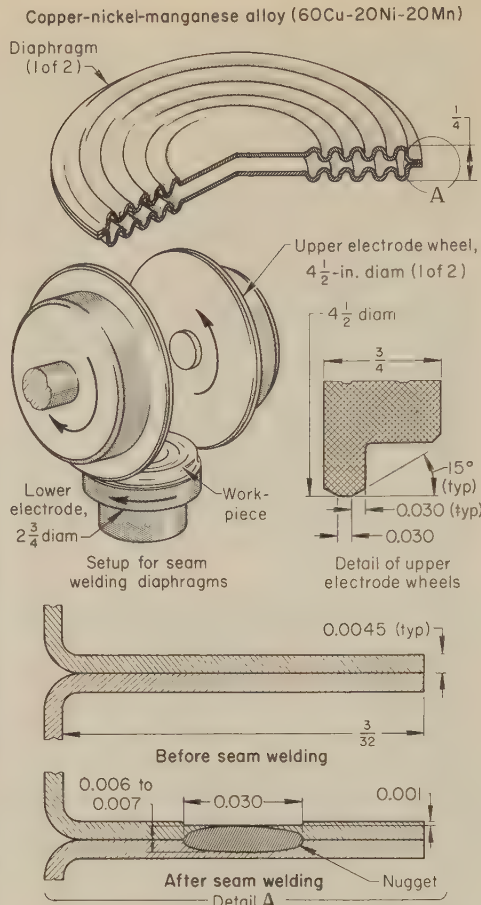
Silicon bronze alloys (7 to 12% IACS conductivity) are the most easily resistance spot and seam welded of all copper alloys. Low welding current and low electrode force (see Table 2) usually are required. Short weld times should be avoided, to prevent shrinkage voids. The surface oxides that develop during annealing must be removed to ensure low and consistent surface contact resistance.

Resistance welding of aluminum bronze is similar to resistance welding of silicon bronze, but with much more electrode pickup and expulsion of weld metal, which can be controlled by careful adjustment of weld time, welding current and electrode force.

Special-Purpose Alloys

Leaded alloys are generally more difficult to weld than those without lead. Poor weld strength, fracturing of metal during welding, and bleeding or fuming of lead from the weld nugget are the major problems.

The copper-nickel-manganese alloy listed in Table 1 has mechanical properties similar to those of alloy 172 (beryllium copper), and both can be precipitation hardened to a tensile strength greater than 150,000 psi. The low electrical conductivity of the copper-nickel-manganese alloy makes it easier to resistance weld than many other copper-base alloys. In the example that follows, this alloy was used as the work metal because it could be resistance seam welded more easily than beryllium copper.



Equipment Details

Power supply	220 v, single-phase, ac
Welding machine	Resistance seam, with two welding heads connected in series
Rating at 50% duty cycle	30 kva
Current, max	21,450 amp
Upper electrodes (2)	4½-in. diam by ¾ in. thick, RWMA class 3
Lower electrode	2¾-in.-diam rotating nest RWMA class 3
Electrode force, max	800 lb per head

Conditions for Resistance Seam Welding

Welding current	1600 amp, ac
Welding voltage	3.5 v
Heat time	2 cycles
Cool time	2 cycles
Welding speed	30 in. per minute
Production rate	120 to 150 assemblies per hr

Fig. 10. Two 0.0045-in.-thick diaphragms, made of a copper-nickel-manganese alloy, that were joined by resistance seam welding to produce a pressure-sensing capsule (Example 429)

Example 429. Resistance Seam Welding of Two 0.0045-In.-Thick Diaphragms Made of a Copper-Nickel-Manganese Alloy (Fig. 10)

A gastight joint around the edge of the capsule shown in Fig. 10 was used to seal the capsule hermetically so that it could be used as the sensing member in an aneroid barometer. The capsule was composed of two diaphragms 0.0045 in. thick arranged so that they would react to any change in external air pressure.

The diaphragms were made of an age-hardenable copper-nickel-manganese alloy (60 Cu, 20 Ni, 20 Mn) with many mechanical properties similar to those of beryllium copper (alloy 172). Beryllium copper was often used for the diaphragms, but because of its higher electrical and thermal conductivities was not suitable for this application, in which the assembly was to be resistance seam welded. The copper-nickel-manganese alloy could be resistance seam welded easily.

Welding was done in a resistance seam welding machine that had two welding heads connected in series with the transformer. The two heads were diametrically opposed and permitted each upper electrode wheel to traverse one half of the circumference of the capsule. Double clamping of the diaphragms against the horizontal rotating-nest lower electrode by the two electrode wheels kept the diaphragms from shifting during seam welding, and therefore made tack welding unnecessary. Alcohol was used for cooling the work metal; water would have been difficult to evacuate from the capsule.

The diaphragms were formed from clean, bright strip; drawing lubricants were removed by vapor degreasing before welding. The welding operation was semiautomatic; the operator loaded and unloaded the workpieces and pressed a button to start the welding machine, which then made a series of overlapping spot welds.

Gas tungsten-arc welding was considered as an alternative process for joining the diaphragms, but was not used. The shorter weld time and the lower operator skill necessary for resistance seam welding were major factors in the choice of that process, as shown in the following comparison of costs per piece.

Cost	Gas tungsten-arc	Resistance seam
Equipment	$0.015	$0.020
Labor	0.050	0.020
Total	$0.065	$0.040

Also, with resistance seam welding, rejects were fewer (less than 1%) and were easier to salvage than if the diaphragms had been joined by gas tungsten-arc welding.

After welding, the work metal in the assembly was age hardened at 700 to 800 F, to a tensile strength of 175,000 psi and a yield strength, at 0.1% offset, of 150,000 psi.

Production rate was 120 to 150 pieces per hour. Additional equipment details and welding conditions are given in the table that accompanies Fig. 10. The relatively large-diameter electrode wheels, with respect to the diameter of the seam weld, allowed a flatter contacting surface and less indentation and distortion of the workpiece than smaller-diameter wheels.

Safety

In resistance welding of copper alloys, a ventilation system may be needed because many copper alloys contain at least small amounts of toxic alloying elements. However, the need for ventilation is less critical for resistance welding operations than for arc welding operations, because a smaller volume of metal is heated and a smaller volume of fumes is generated.

Safety precautions for cleaning and pickling operations are given in the article on Cleaning and Finishing of Copper and Copper Alloys, beginning on page 635 in Volume 2 of this Handbook.

Detailed information and references on safe practices, cautions, contaminants, and hazards in welding are presented in "Safety in Welding and Cutting", American National Standard Z49.1, American National Standards Institute, Inc., 1430 Broadway, New York, N. Y. 10018 or American Welding Society, 2501 N.W. Seventh Street, Miami, Fla.

FLASH AND FRICTION WELDING

CONTENTS

Flash Welding

*By the ASM Committee on Flash, Friction and Stud Welding**

FLASH WELDING is a resistance butt welding process in which two workpieces are clamped in suitable current-carrying fixtures that hold them end-to-end in very light contact. An electric potential is applied that causes current to flow through the workpieces to produce flashing, or arcing, that, in combination with electrical resistance, heats the abutting ends to the fusion point. When the abutting ends reach the proper temperature, the workpieces are suddenly brought together with force sufficient to cause an upsetting action. Upsetting forces plastic metal, together with most of the impurities not expelled by flashing, out of the joint.

Applications. In the aerospace industry, flash welding is used in the production of solid and tubular structural assemblies, landing gears, and rings of various sizes. Wheel rims, headlight rims, frame siderails and control-mechanism linkages are typical of automotive parts commonly joined by flash welding. Other applications include welding of window frames in the automotive and building industries, welding of band-saw blades into continuous loops, and joining of tool steel drill, tap and reamer bodies to low-carbon steel and alloy steel shanks.

The largest flash welding machines are used in the production of line pipe. Machines with capacities of 6000 kva, capable of delivering over one million amperes, are used to weld 40-ft-long longitudinal joints in pipe up to ⅝ in. in wall thickness, in one operation. The pipe is formed from plate in U-bending, crimping and closing presses. The joint is positioned with the aid of locating lugs, and then the entire length is flash welded simultaneously.

Flash welding machines are used in steel-mill pickling lines, cold reduction lines and re-coiling lines to join coils for continuous operation. In wire mills, flash welding is used to produce coils of specified weights. In both steel mills and wire mills, the welded joint is subject to the same reduction as is the base metal, as in Example 446.

Process Capabilities

Any metal that can be forged can be flash welded, and by careful control of welding conditions, many combinations of dissimilar metals can be joined.

Flash welding can be used to produce assemblies that otherwise would require more costly forgings or castings. The process is capable of producing welds with strength equal to, and sometimes greater than, that of the base metal, of joining a wide variety of similar and dissimilar metals in many different cross-sectional shapes, and of maintaining with high accuracy the length and alignment of workpieces.

Most of the examples presented in this article were contributed by members of other Metals Handbook welding committees. The assistance of Taylor-Winfield Corp. also is gratefully acknowledged.

Welds can be made with the longitudinal axes of the workpieces either in line with each other, or at an angle, as in a miter joint.

Generally, the finish or shape of the abutting surfaces is not critical — except on large workpieces, where the ends are beveled to initiate flashing and to promote expulsion of the flashing particles (see Example 435). For welds of high quality, the two ends to be welded should be similar in size and shape.

Economy in Operation and Material. Flash welding is economical both in operation and in use of metal. In applications where flash welding has replaced other joining processes, the production rate has been substantially increased. For instance, in Example 448, the production rate was increased from 144 to 275 welds per hour when torch brazing was replaced by flash welding. In Example 450, the over-all cost of producing steel rings was reduced 19% by changing from gas tungsten-arc welding to flash welding.

Flat or extruded bars of metal are rolled into rings of proper dimensions, which are then flash welded into continuous rings. When rings are produced in this way, less metal is lost by machining than when rings are forged, and less scrap loss is incurred than when rings are cut from plate. The flash welded joint has strength nearly equal to that of the base metal, and generally can be either hot or cold worked in the same manner as can the base metal.

In joining forgings to tubing, material costs and the weight of assemblies can be minimized by using flash welding, as in Example 431.

Weld Strength. With postweld heat treatment, high-quality welds in steel can be produced that are almost as strong as the base metal, even when the weldments are heat treated to a tensile strength of as much as 200,000 psi, for 4130 steel, or 240,000 psi, for 4340 steel. Components that are made of heat treatable steels generally are welded in the annealed condition and are then normalized, quenched and tempered after welding. Flash welding affects or removes any cold worked properties.

Fatigue properties of flash welded joints, after the weld upset is removed, generally are equal to or better than those of joints made by other welding processes. (See the sections in this article on The Heat-Affected Zone, page 498; Hardness of Welds, page 499; and Strength of Welds, page 501.)

Table 1. Maximum Cross-Sectional Areas, and Required Welding-Machine Capacities, for Flash Welding Various Work Metals

Work metal	Maximum area, sq in.	Capacity of welding machine: Kva	Tons
Carbon and low-alloy steels	60	1500	750
Modified 4340 alloy steel ..	33	1600	500

Nickel alloys	25	1600	500
Aluminum alloys	14	1600	500
Titanium alloys	40	1600	500

Sections Welded. A wide variety of cross-sectional shapes can be flash welded, including flat strip, sheet, tubing, bar and plate stock, forgings, extrusions and many combinations of these product forms.

Accuracy. With proper fixturing, the alignment of the welded parts can be held well within the requirements of MIL-W-6873. According to this specification, the maximum mismatch or eccentricity between the welded parts must not exceed 10% of the sheet or tube-wall thickness, and must not exceed 0.008 in. when sheet or tube-wall thickness is 0.080 in. or less. In addition, the angular misalignment (straightness) of the welded parts must not exceed 0.005 in. per inch of length.

The tolerance on the welded length can be less than the sum of the tolerances on the individual parts when proper locating tooling and welding-machine setup are used. There are no uniform standards for tolerances on welded length, and practices vary widely. In general, the tolerance on the welded length is affected by four factors: (*a*) the tolerances on the individual parts, (*b*) the allowance for dimensional changes during heat treating, (*c*) the amount of machining after welding, and (*d*) the care used in loading and locating the parts in the welding machine.

Disadvantages and Limitations

One of the most undesirable features of flash welding is the flashing operation itself, during which molten particles of metal are expelled rapidly from the weld region. It is impossible to protect the welding machine and the surrounding area from these particles, which can burn into slideway bearings, insulation and other critical machine parts. Periodic disassembly of the machine and replacement of insulation and bearings are part of normal maintenance procedure.

Flash welding also presents a considerable fire hazard. Operators must be protected from the flying particles, combustible materials must be kept away from the welding machine and its surrounding area, and a fire-resistant grade of hydraulic oil should be used in the machine.

Removal of the flash and upset metal generally is necessary, and requires additional machinery, such as a flash-and-upset trimmer, and thus adds to the cost of the product. Removal of weld upset from flat workpieces is simple, provided that the mating parts are of equal thickness or cross section; removal of weld upset from contoured workpieces must be done by hand grinding or by chipping. Upset on the inside of butt welded pipe or tubing can restrict fluid flow, reduce fatigue strength, and serve as a point of concentration for corrosion or contaminants. Upset is difficult or impossible to remove from the inside of small-diameter pipe or tubing.

Concentricity and straightness of workpieces during welding is often difficult to maintain, and misalignment can cause rejection or can necessitate postweld machining operations.

Another disadvantage of flash welding is the cost of providing stock to compensate for the metal lost during flashing and upsetting.

Limitations. The size and cross-sectional area of workpieces that can be flash welded are limited by the power and upsetting force available in the machine. Workpiece size is sometimes limited by maximum clamp travel and maximum opening between clamping surfaces. Table 1 gives typical maximum cross-sectional areas, and required welding-machine capacities, for flash welding various work metals.

If a sound flash weld is to be made, the abutting ends should be of essentially the same size and shape. Considerable difficulty is encountered if the cross sections are unequal. (See the section on Heat Balance Between Workpieces, page 494.) In welding extrusions that have different shapes, generally the nonmatching portions must be cut away (see Example 434).

When a small-diameter ring is flash welded, current is shunted around the ring. If shunting becomes excessive, the flashing voltage cannot be maintained and a weld of good quality cannot be made. The welding of small-diameter rings is also complicated by the difficulty of clamping and aligning the flashing surfaces.

Flash welding of T-joints is generally limited. For instance, when the end of a round tube is flash welded to the side of another round tube, the differences in section, heat balance, and resistance to the upsetting force usually result in a weld of poor quality.

In the region of contact with the clamping dies, the surfaces of scaly, rusty, oxidized or otherwise coated workpieces must be cleaned before being flash welded, to ensure proper current flow. On aluminum alloys, which require high welding current, surface coatings such as oxide, paint, oil and anodized films can cause localized hot spots. These hot spots can cause overheating of the clamping dies,

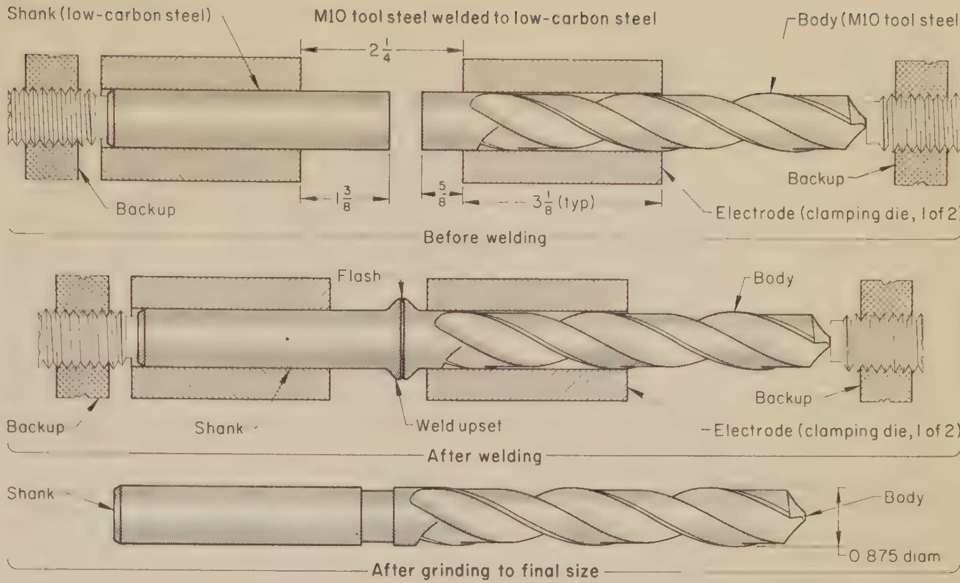
or melting of sections of the dies or workpieces.

Alignment of workpieces made of thin stock, either tubular or flat, sometimes is difficult. If dies are not carefully maintained, poor alignment of the workpieces results and flashing occurs only at the points of contact. During upsetting, the workpieces slip past each other, resulting in a lap instead of a weld. Subsequent trimming may remove the welded region and cause separation.

In flash welding of mitered corners, the shapes of the workpieces may prevent adequate clamping that would ensure a good weld. In many aluminum window frames made from extruded sections, the jamb, header and sill sections are different. In most mitered joints, acceptable welds can be made in legs that, in welding position, are in the same plane as the direction of the upsetting force or platen movement, but poor welds are made in legs that are not in the plane of platen movement. Often, legs not in the plane of platen movement are cut away so that they do not flash or upset. The amount cut away can be such that the legs are in good mechanical contact after the workpiece has been flash welded.



Equipment Details

Metals Welded

Flash welding can be used for joining many ferrous and nonferrous alloys, and combinations of dissimilar metals. In addition to low-carbon steel, metals that are flash welded on a production basis include medium-strength and high-strength low-alloy steels, tool steels, austenitic, martensitic and ferritic stainless steels, aluminum alloys, copper alloys, magnesium alloys, molybdenum alloys, nickel alloys and titanium alloys.

When carbon and alloy steels of high hardenability are flash welded, the as-welded properties of the heat-affected zone deviate substantially from those of the base metal, and postweld heat treatment is necessary to obtain uniformity of properties, especially if the weldment is to be drawn or reduced in section. Heat treating in the welding machine is unlikely to have the proper metallurgical effect. Sometimes the required heat treating process involves a longer heating and cooling cycle than is possible in the welding machine.

Cast iron has never been satisfactorily flash welded in production, although some acceptable results have been achieved in the laboratory.

Low-carbon steels are readily flash welded without preheating. As the carbon and alloy contents increase, preheating or postheating, or both, may be necessary for maximum weld quality. Required upsetting pressure for welding various types of steel is related to the forging strength of the steel at elevated temperatures and to the temperature gradient in the steel in the upset area. Most types of steel are readily welded in both similar and dissimilar combinations, but some combinations require special procedures.

Aluminum alloys are generally flash weldable, but the stock thickness should be greater than 0.050 in. Aluminum extrusions are readily flash welded, but may need special attention at the abutting surfaces (see the section in this article on Miter Joints, page 497).

In general, copper alloys with a high zinc content weld better than those with a low zinc content; the high-leaded copper alloys may give brittle welds. The ductility of welds in some copper alloy rods allows the rods to be flattened under repeated hammering to approximately 15% of the original thickness without indications of fracture at the weld.

Flash welding of lead, zinc, tin, bismuth and antimony, and alloys of these metals, is impractical.

Toxic metals, such as beryllium and beryllium alloys, are not suitable for flash welding without stringent precautionary measures to prevent contamination of air and equipment and danger to personnel by flash particles and dust.

Many combinations of dissimilar metals are easily flash welded if the proper welding conditions and workpiece design are used. Table 2 lists some combinations of metals that have been joined by flash welding.

A common application of flash welding dissimilar metals is the manufacture of large-diameter taps, drills and reamers. A low-carbon or alloy steel shank is welded to a high speed tool steel body to conserve the more expensive tool steel and to provide a soft, tough shank. The following example describes the manufacture of a drill by flash welding a carbon steel shank to a tool steel body.

Example 430. Low-Carbon Steel Shank Flash Welded to an M10 Tool Steel Drill Body (Fig. 1)

The 0.875-in.-diam drill shown in Fig. 1 was made by flash welding a low-carbon steel shank to an M10 high speed tool steel body. This technique conserved the more expensive tool steel and provided a soft, tough shank for insertion into the spindle of the drilling machine. Before welding, the tool steel body was fluted, pointed and hardened. After welding, the weld upset was removed, and the shank and drill body were brought to final size, by grinding.

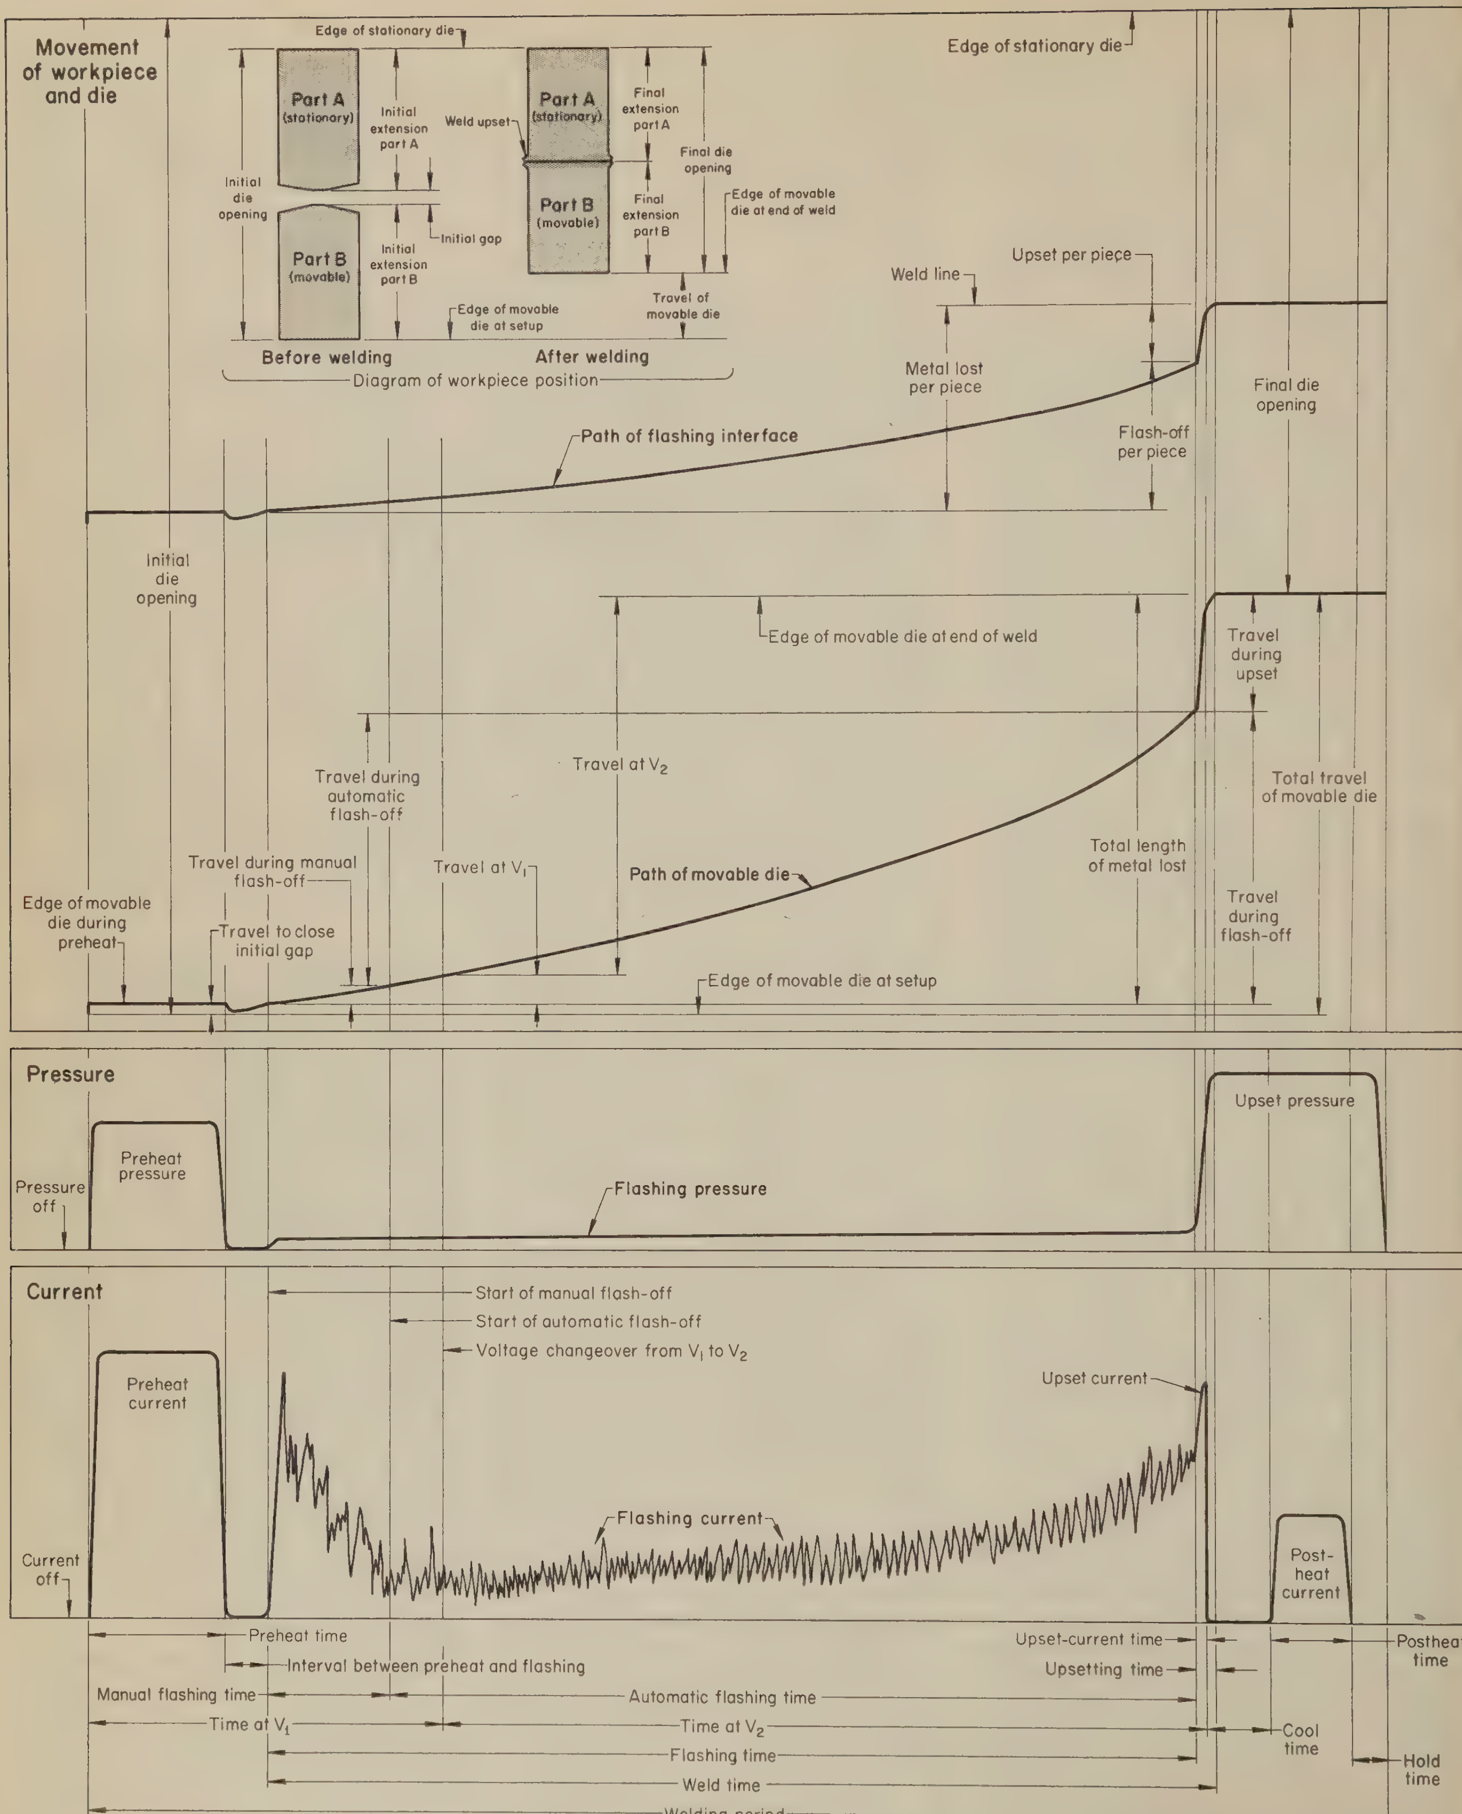
The 3⅛-in.-long air-operated clamping dies were made from RWMA class 4 material (a beryllium-copper alloy having a nominal composition of 1.8% beryllium, 0.3% cobalt, remainder copper; an average electrical conductivity of 18% IACS; and a hardness of Rockwell C 33). Fixtures incorporating backups were fastened to each platen to prevent slippage of the shank and drill body in the clamping dies during upsetting. The platen was moved manually during preheating, flashing and upsetting. Total weld time was about 8 sec.

The platens on the welding machine were inclined at an angle of 35°. This made the welding machine easy to load, and gave the operator full view of the welding operation.

Equipment details and welding conditions are given in the table with Fig. 1.

Fundamentals of the Process

The heat for flash welding is generated by rapidly recurring short circuits of high electrical current at the abutting ends of the workpieces to be welded. The weld is produced by the application of a forging force as the workpiece reaches welding temperature. The upsetting force is produced either manually through lever action, me-



This illustration is intended to define the variables in flash welding. The relationships of the variables to each other do not indicate intrinsic values, and not all functions shown here are used on every flash welding machine or for every flash welding operation.

Fig. 2. Typical flash welding cycle, showing relations of variables and workpiece position before and after welding

chanically through a motor-driven cam, or hydraulically through hydraulic cylinders. The two workpieces are firmly secured by two sets of clamping dies that conduct the welding current. One set of clamping dies is mounted on the movable platen and the other on the stationary platen of the welding machine.

The process is started by bringing the ends of the workpieces into light contact to establish a flashing action. The irregular localized contact between the two lightly touching surfaces results in an extreme localization of heat at the adjoining surfaces. The contact area consists of a series of small short-circuiting contacts in the form of bridges of metal between the two workpieces. These bridges of metal are repeatedly raised to the melting point, broken, and blown out in the form of sparks. This generates the heat necessary to bring a small zone behind the molten surfaces to a temperature within the plastic range.

The movable platen, on which one of the workpieces is held, is advanced to bring new points into contact as metal is expelled during flashing, and continues to move forward toward the stationary platen until the flashing action is continuous over the abutting surfaces. To maintain this flashing, the rate of feed must be properly proportioned to the welding voltage and current. If feeding is too slow, flashing is weak and insufficient heat is generated. If feeding is too fast, the two workpieces stick together prematurely and, if not pulled apart, are joined in a poor weld.

When the correct depth of metal is heated to the plastic range, the speed of the moving platen is suddenly increased, bringing the pieces together under an upsetting force and producing a forged weld. The upsetting action pushes the molten metal, and part of the plastic metal, out of the weld area into a weld upset. In many applications, the upset must be removed after welding, by scarfing or machining.

Figure 2 shows variations during a flash welding cycle, as a function of time. The interrelations among the variables do not represent intrinsic values. Not all of the functions or elements shown in the figure are used on every flash welding machine or for every flash welding operation.

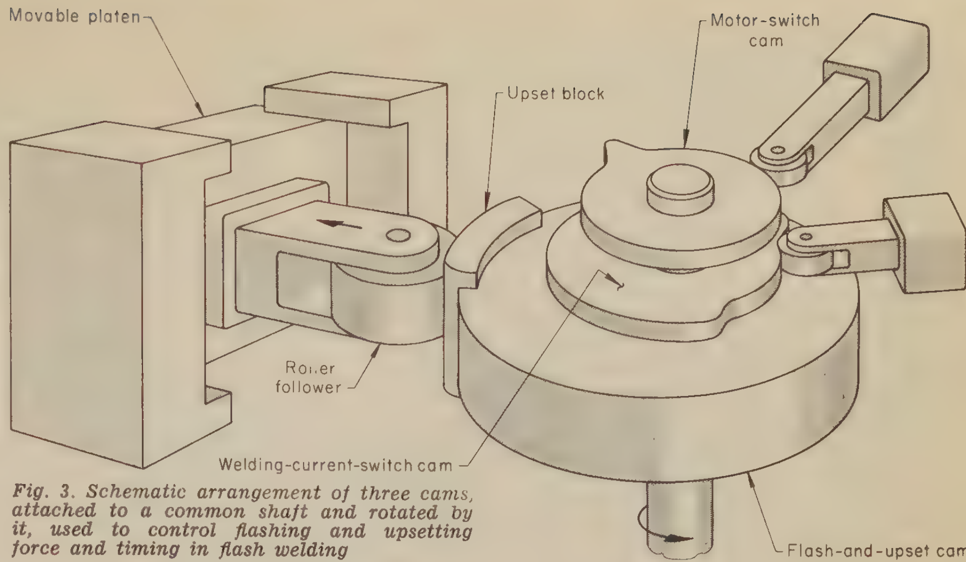


Fig. 3. Schematic arrangement of three cams, attached to a common shaft and rotated by it, used to control flashing and upsetting force and timing in flash welding

Equipment

The machine used for flash welding generally consists of a low-impedance welding transformer, a stationary platen and a movable platen on which the clamping dies, electrodes and other tools needed to position and hold the workpieces are mounted, flashing and upsetting mechanisms, and the necessary electrical, air or hydraulic controls.

Transformer. The transformer is used to supply electrical energy at the voltage and amperage levels needed for the welding operation. The transformer tap switch frequently is a rotary eight-step, knife-type, fully enclosed locking switch, and provides convenient adjustment of the welding voltage to suit the work requirements. Welding transformers are available with primary windings that can be connected either in series or in parallel. This makes the available number of voltage settings twice the number of steps on the tap switch.

Platens. The stationary platen is securely fastened to the machine frame and usually is insulated from it electrically; the insulation is protected from flash and dirt that could cause short circuiting. The movable platen is held in alignment with the stationary platen by bearings and machineways. Stops are provided for quick adjustment of the amount of welding and return travel of the movable platen.

Both platens sometimes are made of a copper alloy such as RWMA class 2 electrode material, and are connected to the transformer secondary by flexible copper bands. Platens are made also of steel or cast iron — frequently with copper alloy inserts. Generally, the clamping dies and electrodes are mounted on the platens. (See page 408 in the article on Resistance Spot Welding for information on classification of RWMA electrode materials.)

Flashing and Upsetting Mechanisms. There are three basic ways of applying the flashing and upsetting forces during flash welding: manually, mechanically through a cam, and hydraulically.

The manually operated mechanism consists of a movable platen operated through a hand-lever-and-toggle arrangement. The toggle mechanism is attached to and insulated from the movable platen. One of the toggle links is a turnbuckle that is used for adjusting the final die opening. The initial die opening is adjusted by a screw-type stop. A pointer on the operating lever indicates on a stationary graduated dial the amount of material that is flashed off and upset. Movement of the lever permits preheating (if desired), flashing and upsetting, in one continuous operation. The operator controls the amount and variation of upset pressure used in the forging action.

A motor-driven cam is used to move the platen when higher production and greater consistency among welds are needed than are possible with manual operation. The cam is operated by the motor through a gear speed-reduction unit with a single-speed or variable-speed drive, or by a variable-speed motor-and-clutch arrangement. Closing and locking of the clamping dies and electrodes are done either manually or by an air or hydraulic cylinder.

Three rotating cams, arranged as shown in Fig. 3, control the operation of the welding machine. Forward movement of the platen is governed by the contour of the flash-and-upset cam, and platen velocity is governed by both the contour and the rotational speed of that cam. The welding-current-switch cam turns the power on and off at the correct time relative to the position of the flash-and-upset cam. The motor-switch cam shuts off the power to the motor or to the clutch at the correct time; this action also is relative to the position of the flash-and-upset cam.

Motor-type flash welding machines are automatic, are the simplest to use, and are predominantly single-purpose, high-production machines without a wide range of flexibility.

When a general-purpose flexible machine is needed that can weld sections requiring more upset pressure than is obtainable with manual or motor-type machines and still can maintain consistency of welds and relatively high production, a machine with hydraulic platen actuation is selected. This machine generally is equipped with hydraulically actuated clamps. Machines with hydraulically actuated platens can be completely automatic, semiautomatic, or manual in operation, depending on how they are adjusted. Completely automatic operation requires little operator skill; semiautomatic and manual operation demand increasing degrees of skill.

Suitability for Application. Different metals have different strengths at flash welding temperature, and in each application the welding current and upsetting capacity of the machine must suit the properties of the metal being welded.

In addition, each machine has mechanical limitations. The clamping space determines the maximum size of workpiece that can be welded, and the clamping-area clearances determine

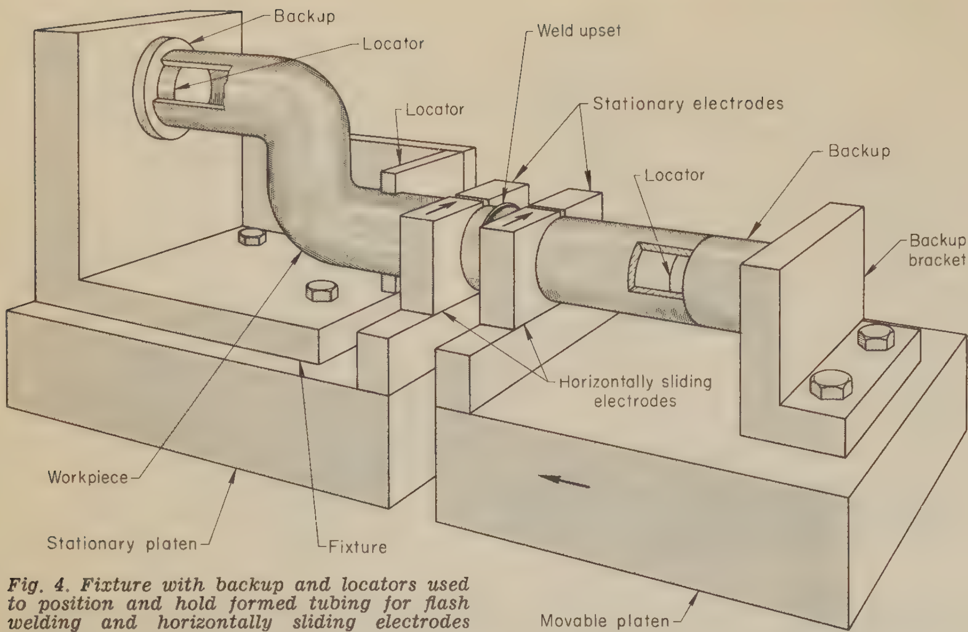

Fig. 4. Fixture with backup and locators used to position and hold formed tubing for flash welding and horizontally sliding electrodes

the size of part or assembly that can be properly clamped. The size and shape of the assembly may not be compatible with the design of the machine. For example, if four tubes are to be welded 90° apart to an X-shape forging, three of the tubes can be welded to the forging with the usual equipment, but a special clamping mechanism with suitable clearance is needed to make the fourth weld.

Clamping Dies and Fixtures

Workpieces must be accurately clamped to maintain alignment, to allow the secondary current to pass into the workpieces, and to apply the upsetting force properly. Generally, the parts of the clamping mechanisms that actually grip the workpieces are the electrodes, often called clamping dies. Fundamentally, the clamping mechanisms allow the dies to move in either the horizontal or the vertical direction. If the clamping dies move in a straight or curved line nearly parallel to the plane of the platen top, the dies are designated as horizontal. If the dies move in a straight or curved line at right angles to the plane of the platen top, the dies are designated as vertical.

In most machines, the principal moving clamping-die member either slides or turns on a pivot. Many workpieces can be welded equally well in either type of clamping die. Pivot-type clamping dies, because of their mechanical advantage, exert more force on the workpiece than do sliding clamping dies.

The use of fixtures, in addition to or in place of clamping dies, is governed by the sizes and shapes of the workpieces, and by the location of features that must be in relation to each other after welding.

Pivot-type clamping dies (or alligator clamps) essentially are levers pivoted in the center; the force is applied at one end, and the clamping-die half is attached at the other end. Because of their circular line of action, pivot-type clamping dies are sensitive to slight variations in stock thickness. This sensitivity is usually decreased by adding a pressure-equalizing mechanism. If an equalizing mechanism is not used, variations in stock thickness will cause variations in the contact area between work metal and electrode, and may damage the contact surfaces because of insufficient area for passage of the secondary current. If one workpiece is clamped incorrectly because it is slightly thicker than the other workpiece, a poor weld can result from the twisting motion that occurs during upset.

When variations in stock thickness are slight, pivot-type clamping dies have an advantage for production purposes, in that workpieces are readily accessible and thus can be easily loaded, positioned and unloaded. Vertically pivoting clamping dies normally are selected for welding joints in sections such as flats and stampings, or for welding small-diameter tubing or solid bars, where current distribution in the work metal permits the transformer to be connected to either the upper or the lower electrodes.

Vertically sliding clamping dies are used where large flat plates or special curved sections are to be welded and, in most applications, eliminate the need for a pressure-equalizing mechanism. With vertically sliding dies, the work is readily accessible, although the high clamping pressure used may require additional apparatus in the form of latches on the open side of the clamping structure.

Horizontally sliding clamping dies usually are selected for welding large solid sections or tubes, into which current must be introduced through all four electrodes. Also, horizontal sliding dies may be used instead of pivoting dies or vertical sliding dies for workpieces that, because of their size or shape, are more easily loaded into the machine from above than from the front side.

Pinch-type dies are used, in welding many nonferrous metals, to contain the heat-affected zone during upsetting and to remove the upset metal. Pinch-type dies have nose inserts (see Fig. 9) shaped to encircle the workpiece and to keep the plastic metal in the weld zone. This minimizes the amount of plastic metal that is extruded out of the weld and, immediately at completion of upsetting, trims any upset that is formed.

Materials for Clamping Dies. Clamping dies or electrodes can be made of any current-conducting metal that is hard enough to withstand the clamping pressures and to resist wear due to scale and oxide on the workpiece. (Best practice is to have the clamping surfaces on the workpiece free from scale, oxide, paint and oil.) When backups are used, the clamping dies generally act only as electrodes and do not resist all of the upsetting force.

The materials commonly used for clamping dies are RWMA class 3, and hardened tool steels such as H11, L6 or O1. (For a description of RWMA classi-

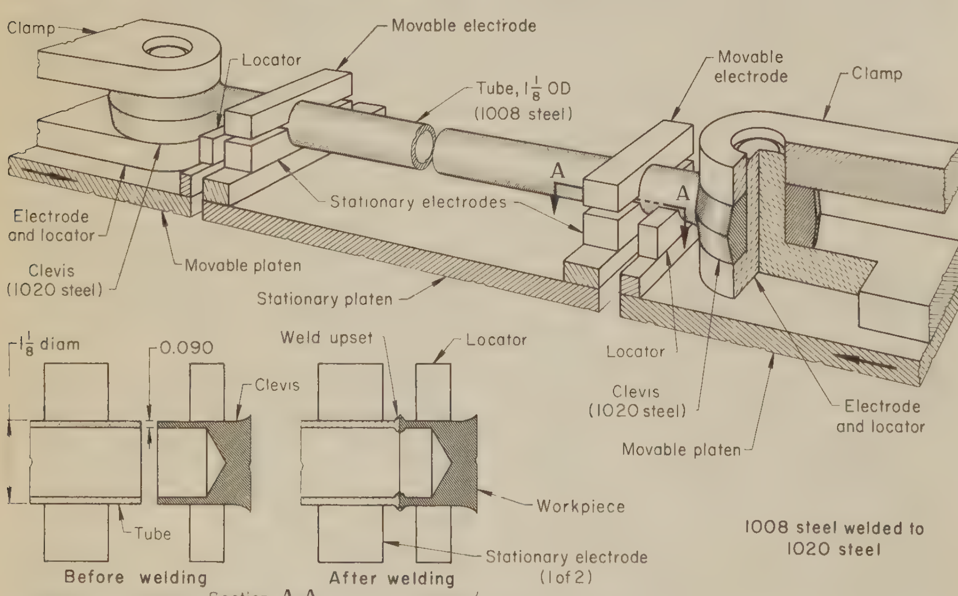

Fig. 5. Setup for simultaneous flash welding of two forged clevises to the ends of a tube, in which a special fixture was used to maintain angular alignment (Example 431)

fications of electrode material, see the section on Electrode Materials, on page 408 in the article on Resistance Spot Welding.) Bronze and other copper-base electrode materials can be used in some applications.

The die half (upper or lower) that carries the current usually is made of a copper-base material. The other half often is made of the same copper-base material, or of hardened steel.

Cooling of Electrodes. The need for water cooling of flash welding electrodes depends on the size of the electrode, die or fixture, the magnitude of the flashing current, and the production rate. When the mass of the electrodes is large compared with that of the workpieces, the heat sink generally is large enough to dissipate the heat generated by the resistance to current flow and the heat absorbed from the workpiece. With high flashing currents and high production rates the electrodes must be cooled.

Electrodes, clamping dies and fixtures used on large flash welding machines usually are water cooled. Those used on smaller machines are less frequently water cooled, unless the flashing current or the production rate is high. Cooling is accomplished by water flowing through internal passages.

Shape and Size of Clamping Dies. Generally, the shape of the clamping-die surface is such that the die encompasses almost the entire workpiece surface. The required area of clamping-die surface depends on the current density needed for heating the workpiece and the pressure needed for holding it. Semicircular dies are used where the line contact provided by V-shape dies gives insufficient surface for the current to flow without burning the workpiece, or for holding the workpiece without marking it. In Example 449, a radiused lower electrode was used to conduct current to a ring-shape workpiece of rectangular cross section.

Table 3 gives the minimum lengths of clamping dies for welding rounds, tubing and other sections of various diameters or minimum dimensions; these data are for welding steels of low and medium forging strength.

Table 3. Minimum Lengths of Clamping Dies, With and Without Backup, for Flash Welding Various Diameters of Workpieces Made From Steels of Low or Medium Forging Strength (a)

Workpiece diameter, in.(a)	Length of clamping die, in. With backup	Length of clamping die, in. Without backup(b)	Workpiece diameter, in.(a)	Length of clamping die with backup, in.	Workpiece diameter, in.(a)	Length of clamping die with backup, in.

			5.50	3.00	9.50	5.00

(a) Diameter of rounds or tubing, or minimum dimension of other sections. (b) Backup is recommended for all workpiece diameters or minimum dimensions over 1.50 in.

Fixtures are used to support workpieces during welding and to provide orientation and alignment of workpiece surfaces that cannot be obtained by the use of clamping dies alone. Generally, fixtures have backup surfaces that absorb all or part of the upsetting force. When fixtures are used, electrodes are positioned adjacent to the joint in the usual manner for carrying current to the surfaces to be welded. The electrodes usually are attached to the clamping mechanism of the machine and are seldom part of the fixture.

The fixture shown in Fig. 4, fastened to the stationary platen of a flash welding machine, located and held a formed tube in alignment during welding. Also, the fixture provided a backup that helped resist the upsetting force. A combination backup and locator also was fastened to a bracket on the movable platen.

Horizontally sliding electrodes mounted to each platen held the abutting ends of the tubes in alignment, in addition to carrying the welding current. Since the electrodes opened in a horizontal plane, the workpieces were loaded and unloaded from the top.

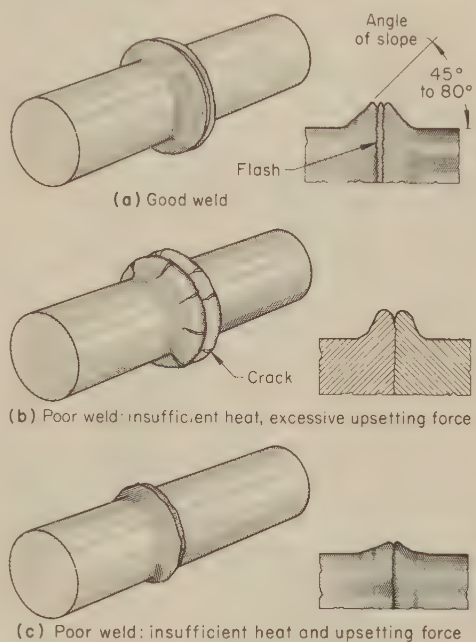

Fig. 6. Shapes of weld upset that indicate weld quality and adequacy of heat and upsetting force used during welding

Miter fixtures are used for welding miter or corner joints in steel and aluminum sash, in screen and door sections, and in structural frames such as those used for refrigerator bases.

The following example describes simultaneous flash welding of two forged steel clevises in angular alignment to the tubular midsection of a brace. In this application, light weight of workpieces, excellent reproducibility of close-tolerance dimensions, and speed were important.

Example 431. Use of a Special Fixture for Maintaining Angular Alignment in Simultaneous Welding of Two Joints (Fig. 5)

Figure 5 shows the use of a special fixture for holding two forged 1020 steel clevises in angular alignment while simultaneously flash welding them to the ends of a length of 1008 steel tubing to produce a brace. Tolerance on center-to-center dimensions of the holes in the clevises was ±0.010 in., and exact angular alignment of the holes was required.

To achieve heat balance between the clevises and the tubing, the clevises were counterbored to approximately the inside diameter of the tubing, and to a depth of about twice the amount of material lost during flashing and upsetting (see section A-A in Fig. 5).

The two joints were welded simultaneously in a synchronized double-end flash welding machine equipped with two 50-kva transformers. Each clevis was positioned on a closely fitting pin that formed part of the lower half of an electrode. Proper alignment was established by placing the tubular section of each clevis in a nest and clamping it with the upper half of the electrode. The tube was positioned by two electrodes that were mounted on the stationary platen. Vertically moving clamps held the tube in place during welding. Both movable platens were actuated by cams that controlled platen motion during flashing and upsetting, and controlled the force applied during upsetting.

Flash welding produced these parts at least cost because of the high production rate and because of the low rate of rejection. Arc welding would have increased the weight of the parts by requiring a tongue-and-socket type of joint. Friction welding would have required a complicated setup to maintain angular alignment. With pinned or riveted construction, the joints would have been weaker and the parts heavier.

Backups are used when the clamping dies cannot provide the workpiece with enough resistance to the upsetting force. This usually occurs either when the length of the workpiece adjacent to the joint is too short for effective clamping, or when the workpiece is unable to withstand the clamping force without being collapsed, scored or otherwise damaged.

A backup often consists of a steel bracket that can be bolted to the platen in various positions. Brackets can have either fixed or adjustable stops for the workpiece.

Heat for Welding

The heat necessary to make a flash weld is generated by flashing, or by a combination of preheating and flashing. Enough heat must be generated to produce a plastic zone deep enough to permit adequate upsetting.

The depth of the plastic zone and the degree of plasticity affect the slope of the upset metal. An upset with a slope between 45° and 80° (as in Fig. 6a) usually indicates that the correct amount of heat has been used and that enough upsetting has occurred. If the slope of the upset is steep and longitudinal cracks appear in the upset (see Fig. 6b), too great an upsetting force has been applied at too low a metal temperature. These cracks are similar to forging cracks, and result from the application of upsetting force before the work metal has become sufficiently plastic. If the slope is much less than 45°, as in Fig. 6(c), the heat and upsetting force have been too low.

The heat generated during flashing is concentrated at the flashing sur-

faces, behind which there is a steep decline in the temperature gradient toward the electrodes or clamping dies. In preheating, the contacting surfaces do not reach as high a temperature as in flashing, and the temperature gradient is not as steep.

Preheating

Preheating of the workpieces usually is done manually by bringing them together under relatively light pressure. Heat is generated by resistance to the flow of current in the metal exposed between the electrodes or clamping dies. Figure 2 shows that the preheat current and pressure are relatively higher than those applied during flashing. The platen is moved only enough to close the initial gap between the workpieces, and pressure is applied so that heating is accomplished by resistance instead of by flashing.

After the preheat temperature is reached, the movable workpiece is withdrawn so that flashing can start. The contact resistance of the ends of the workpieces is the major fraction of the total work-metal resistance, and therefore the metal adjacent to the contact surfaces becomes hotter than the rest of the metal between the dies. The pressure used for preheating is high enough to produce a contact area larger than that needed for sparking, but not so large that the pieces are welded together or deformed.

Preheating has two advantages: (*a*) a proper flashing action can be started more easily on heavy sections that are normally beyond the electrical capacity of a given welding machine, because the elevated temperature of the preheated contacting surfaces reduces the power demand on the machine; and (*b*) a weld can be made with less metal loss than when flashing is used alone, because preheated workpieces do not require as long a flashing action. The faster heating of the contacting surfaces results from the increased resistance of the contacting points, together with shortening of the time required for each point of contact to reach the molten state and rupture. A relatively small amount of metal is lost during preheating as a result of slight upsetting of the semiplastic metal under pressure.

Preheating is often used in order to produce a more even heat balance when the sections of the workpieces adjacent to the weld line are significantly different. Under such conditions, flashing alone may be unable to develop enough heat in the larger workpiece to produce a plastic zone of sufficient depth.

When metals having widely dissimilar elevated-temperature compressive strengths are welded, only the metal with the higher compressive strength is preheated. For example, a piece of stainless steel may have to be preheated before being welded to a piece of low-carbon steel.

Occasionally, the flashing characteristics of two metals are so different that one heats rapidly while the other heats hardly at all. When upsetting occurs, the plastic zone is large in the workpiece at the higher temperature and is very small in the cooler workpiece, and this results in poor bonding. This inequality is likely to occur when high-silicon steel is welded to low-carbon steel, and can be corrected by preheating only the low-carbon steel.

Air-hardening steels and certain other hardenable steels may require preheating before welding, and may sometimes require slow cooling in lime, powdered mica or asbestos feathers after welding. Other steels, with greater hardenability, not only require preheating, but also must be heat treated immediately after welding. For example, when 4150 steel is welded to 1040 steel in small sectional areas, a combination of preheating and postweld heat treatment produces the highest joint properties.

Table 4. Pressures Required for Upsetting Several Ferrous and Nonferrous Metals of Various Thicknesses(a)

Work metal	Thickness, in.	Pressure, psi(b)
Aluminum alloys:		
Soft	Up to 5/8	8,000 to 10,000
High-strength	...	Up to 20,000
Copper, plain	Up to 3/4	5,000 to 7,500
Heat-resisting alloys	...	Up to 35,000
Magnesium alloys	...	6,000 to 8,000
Stainless steels	Up to 2	13,000 to 25,000
Carbon and low-alloy steels:		
1020	Up to 3/8	6,000 to 10,000
	3/8 to 1	7,000 to 10,000
	1 to 2	9,000 to 11,000
	2 to 4	10,000 to 12,000
2340, 3140	Up to 1	10,000 to 12,000
4140, 6145	Up to 1 1/4	11,000 to 18,000

(a) Based on welding temperature obtained without preheating. Pressures may be as much as 50% less if preheating is used. (b) Pounds per square inch of cross-sectional area of weld.

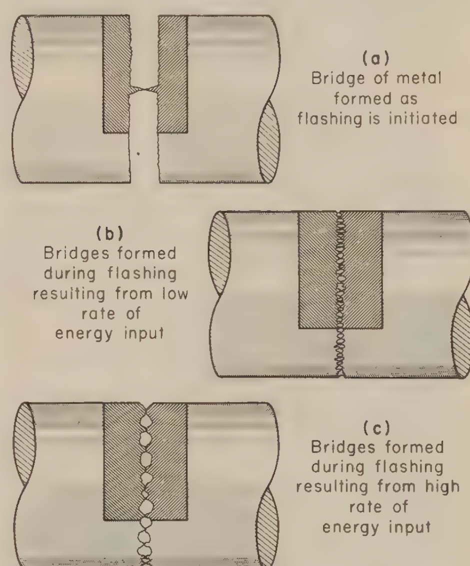

Fig. 7. Bridges of metal produced during flashing, and effects of low and high rates of energy input

Flashing

Flashing derives its name from the rapid expulsion of incandescent particles of molten metal from the bridges, or minute points of contact, between the two workpieces.

The metal in these bridges is heated to the melting point almost instantaneously, and the shape of the bridges, when in the liquid state, is believed to be determined principally by the surface tension, and is apparently characterized by a throat approximately at the center (see Fig. 7a). The incandescent particles of molten metal are thrown out with considerable velocity, which is increased by the action of the strong magnetic field generated by the flow of current. During flashing, the oxygen content of the atmosphere at the weld region is reduced because of oxygen absorption during heating of the bridges, and because of the burning of metal in air. This reduction of oxygen content produces a semiprotective atmosphere.

The primary purpose of flashing is to generate enough heat to produce a plastic zone that permits adequate upsetting. The rate of energy input must be in proper proportion to the travel of the platen or movable die so that constant flashing is maintained until the appropriate amount of metal is flashed off and the required plastic zone is obtained. The relationships of time to the flashing current and to the travel of the movable die are shown in Fig. 2.

Reduction in the rate of energy input produces a decrease in the violence of the flash expulsions, but an increase in their number and continuity, as shown by the number of small craters in Fig. 7(b); higher rates of energy input increase the size and depth of the craters left as the result of the expulsions (see Fig. 7c). Large craters such as those shown in Fig. 7(c) are undesirable because their presence makes it difficult to upset to sound metal.

The rate and duration of energy input also have an effect on the depth of the heat-affected zones. A low rate of input and a long input time result in the greatest depth of heat-affected zone, because there is more time for the heat to flow farther back into the workpiece and to cause metallurgical changes. A high rate of energy input with a short flashing time causes a large flashing gap and increases the possibility of inclusions and porosity in the weld. Inclusions and porosity can be prevented by increasing the amount of upset, but this increases the amount of metal lost in making the weld.

When a welding machine having only single voltage control is used for welding heavy, compact sections, the ease of starting the flashing action sometimes is sacrificed in order to prevent excessively high current from causing an unsatisfactory flashing action. The flashing action can be started more easily and can be accomplished more satisfactorily by using a dual voltage system. With this system, a high secondary voltage (V_1 in Fig. 2) is applied for a short time to initiate flashing. Energy input is then reduced (V_2 in Fig. 2) to provide correct flashing conditions. Dual voltage control normally is used on machines rated at 400 kva or more.

Weld Upset and Upsetting Force

Bonding takes place during the upsetting action, and some metal must be extruded from the weld zone in order to remove slag and other inclusions not expelled during flashing. The extruded

metal must extend beyond the cross-sectional boundaries of the workpiece to ensure that the maximum amounts of slag and inclusions are removed when the weld upset is removed during subsequent machining. When the weld upset is removed, there should be no evidence of the weld. Porosity near the outer surface on an etched section of the weld, or a crevice around the workpiece after the weld upset has been removed, indicates incomplete bonding because of either insufficient upsetting force or insufficient plasticity during upsetting.

A large upset produced by an excessive upsetting force can be detrimental to weld quality, can waste metal, and indicates that most of the plastic metal has been extruded, allowing bonding to take place in metal where plasticity may not have been sufficient to ensure a good weld. Producing a large upset also is equivalent to introducing less total heat into the weld, which can result in poor weld quality. Excessive upsetting force will also bend the flow lines at the weld in a direction 90° from the flow lines in adjacent unwelded metal. Welds made under these conditions have low fatigue strength.

The quality of a flash weld is greatly affected by the upsetting force. During the upsetting action, the force should be sufficient to close all voids, to expel molten metal, slag or other impurities, and to allow complete fusion of the two workpieces.

The ability of the upsetting force to dispel molten metal, slag, and other impurities depends on several factors, including the actual force, the shape of the section, the velocity of upset, and the degree of plasticity of the metal at the time of upset. The shorter the expulsion paths of the inclusions, the easier the inclusions are to expel. The larger the ratio of perimeter to area of section in the workpiece, the more easily can slag and impurities be expelled by the upsetting force applied during flash welding.

The velocity of upset is determined by the construction of the welding machine, the manner and rate at which the upsetting force can be applied, and the amount of upsetting force exerted. For information on machine construction, see the section in this article on Equipment (page 489).

Footnotes for Table 5

(a) Data are based on welding, without preheating, of two pieces with the same welding characteristics. (b) In the views above, the boldface-letter identifications of dimensions are applicable also to flat stock — for which t would be what is shown in these views as the wall thickness of the tubing. When tubing or flat stock has t of 3/16 in. or more, ends should be chamfered as shown in "End preparation" view above. (c) When an initial gap is used between the workpieces at setup, the initial die opening (Dimension A) is increased by an equal amount.

(d) In the views above, the boldface-letter identifications of dimensions are applicable also to bar stock — for which diameter (or least sectional dimension) would be what is shown in these views as the outside diameter of the tubing. When diameter (or least sectional dimension) of bar stock is 1/4 in. or more, ends should be chamfered as shown in "End preparation" view above. (e) Values apply only when ratio of maximum to minimum cross-sectional dimension is less than 1.5.

The relation of time to the magnitude of upsetting force is shown in Fig. 2. Pressure on the platen is relatively constant during flashing, but is increased rapidly for upsetting. The upset pressure usually is constant during cool, postheat and hold times.

Normally, it can be determined whether the welding machine can provide sufficient upsetting force by observing the velocity of platen movement during upset. If the platen moves rapidly (taking only a few cycles to complete the travel during upset), enough upsetting force is available. If the platen moves slowly (taking 15 to 30 cycles to complete the travel), or if it stops before it travels through the total upset, then either the upsetting force is too low or there is insufficient depth of plastic zone in the workpiece.

The necessary amount of upsetting force is related to the temperature of the metal in the upset area, and to the compressive strength of the metal at welding temperature. Table 4 lists the pressures required for upsetting some ferrous and nonferrous alloys without preheating. With preheating, the values in Table 4 may be reduced by up to 50%.

Upsetting Current. The current is allowed to flow after the start of upsetting, to maintain the temperature and to ensure removal of foreign matter from the weld.

If the cross-sectional area to be welded is small compared to the maximum cross-sectional area that can be welded on the machine being used, the duration of current flow should be short — that is, current should stop flowing within one or two cycles after upsetting starts. If the sectional area to be welded approaches the maximum area that can be welded, duration of current flow may have to be relatively long — for example, 20 to 30 cycles after upsetting starts. The exact point of current cutoff is not critical, provided that the current is cut off some time during upsetting but before overheating takes place.

Extension of Workpieces From Dies

The amount of initial extension of the workpiece from the clamping die or electrode is determined principally by the ability of the metal to reach the correct temperature in the plastic range during preheating and flashing. Some of the heat generated by flashing is lost by radiation, and some is lost by conduction to the dies, and the initial extension must be large enough to minimize conduction loss. However, the extension must not be too large, because a large extension decreases the temperature gradient, and thus reduces the effect of the upsetting force and its ability to purge the weld through expulsion of molten metal.

Initial extensions that are larger than required can contribute to misalignment of workpieces after welding. Often, compromise must be made between welding conditions and permissible misalignment, especially in welding sheets or thin workpieces.

The size of the heat-affected zone is partly dependent on the initial and final extensions. It may be desired to harden a workpiece before welding and to retain a specified hardness after welding in a certain portion of the weld zone. By proper manipulation of the initial and final extensions of the workpiece, the desired hardness can be satisfactorily retained.

When workpieces are of the same size, shape and work metal, the initial extensions are made equal. Unequal extensions are used to assist in producing a better heat balance when equal extensions give unsatisfactory results.

Typical dimensional allowances, including lengths of initial and final extensions, for flash welding of steel tubing, flat stock and solid bars are given in Table 5.

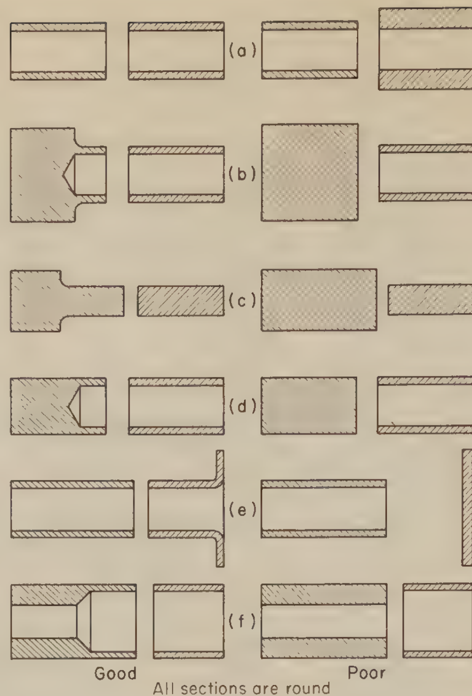

Fig. 8. Examples of good and poor joint design for obtaining heat balance between workpieces in flash welding

Workpiece Design

In designing parts to be flash welded, the following requirements and effects of the process must be considered:

1 An even heat balance should be obtained in the parts, so that the two ends to be welded attain the same degree of plasticity and depth of plastic zone during flashing.

2 The length of metal lost during flashing and upsetting must be added to the initial length of the components if the over-all length after welding is important. In designing components to be miter joined, the angle between the axis of the part and the direction of platen travel must be considered in allowing for metal lost.

3 The parts should be designed so that the reaction to the upsetting force can be resisted in a direction parallel to the line of application of force, and so that it is possible to back up and hold the parts securely during welding.

4 The parts should be designed so that they can be held in accurate alignment during upsetting. This can be done by machining locating surfaces on forgings or, as in Examples 433 and 445, by making use of the unformed ends inherent in roll forming.

5 For sound welds in workpieces to be miter joined, any nonmatching sections must be cut back so as not to interfere with flashing, and the webs must be supported or otherwise strengthened to withstand the upsetting forces (see Example 434).

6 The abutting ends should be designed so that the incandescent particles are not trapped in the weld, and on large pieces, flashing should be started at the center of the cross section of the workpiece (see Example 435).

7 In designing hollow members, consideration should be given to the possible disadvantage of upset at the inner surface. If the part must withstand fatigue loads, the stress-raising effect of the upset is important. Under corrosive conditions the metal in the upset can suffer severe attack.

Good joint design generally results in high-quality welds and consistency in production. Poor design does not necessarily mean that the parts are not weldable, but that the weld quality will be impaired and consistency in production will not be obtained.

Heat Balance Between Workpieces

Because the same welding current and upsetting force are applied to both workpieces, the thermal conditions in the two pieces must be approximately equal. To achieve heat balance, the two workpieces should have the same or nearly the same cross-sectional shape, area of contact, and contour. In general, the ratio of the areas of the two abutting surfaces should not be greater than 5 to 4.

The good designs shown in Fig. 8 are predicated on the provision of similar sections and areas in the vicinity of the weld. In the poor designs shown in Fig. 8, the heavier sections would heat more slowly, making it difficult for both pieces to reach equivalent plasticity for welding. If the thick-wall tube of the poor design in Fig. 8(a) cannot be replaced with a tube of the same wall thickness as the adjoining piece (as suggested for good design), the thick wall should be thinned for a distance from the joint by machining the outer surface of the tube. The inner surface of the thick-wall tube in Fig. 8(f) should be machined for the same reason. In Fig. 8(d), it would not be possible to obtain a weld with the strength of the base metal if the tube were welded to the solid bar, and therefore the bar should be counterbored as shown.

A degree of sectional unbalance is permissible in flash welding. When two tubes or two pieces of solid cylindrical stock are joined, the wall thicknesses of the tubes, or the diameters of the solid stock, should not differ by more than 15%. This allowance will compensate for original part tolerances or applicable tolerances on misalignment or concentricity.

In each example of good design shown in Fig. 8, the optimum length of the altered section is equal to the initial extension. The minimum length is about 125% of the metal lost during flashing and upsetting. Initial extensions for sections made of steels of low and medium forging strength are given in Table 5.

Another means of adjusting the heat balance is by special preparation of the ends of the parts to be welded. With solid bar stock, for example, a chamfered end on one of the pieces (or unequal chamfers on both pieces) will affect the heat balance by reducing the volume of metal extending beyond the clamping die. The metal with the greater heat conductivity should have the steeper chamfer.

When dissimilar metals of the same cross section are to be welded, a satisfactory heat balance can be obtained by adjustment of the initial extension. The metal having the higher thermal conductivity is extended a greater distance than is the metal with the lower thermal conductivity. This moves the weld off-center between the dies, and because of the greater length of slowly heating metal, places the weld line farther from the cooling effect of the clamping dies. Heating of the higher-conductivity workpiece is augmented also by passage of the welding current through a greater length of metal.

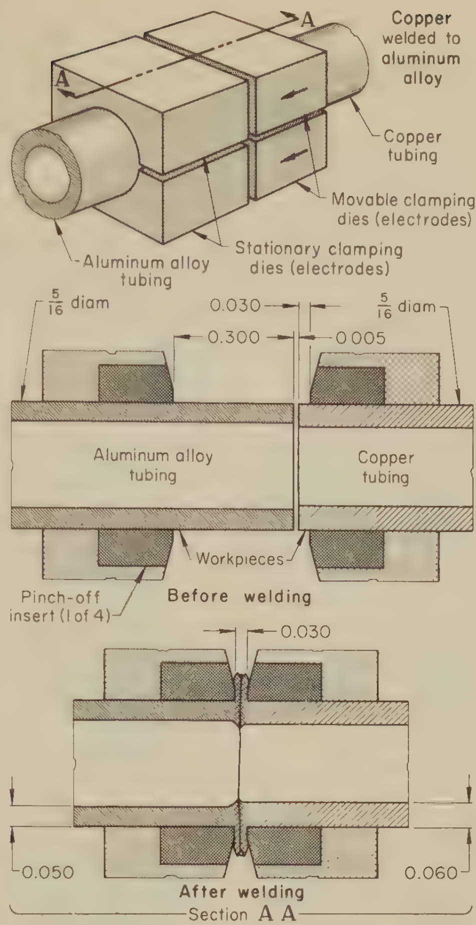
In the following example, the wide difference in the forging temperatures of the work metals was overcome by using unequal extensions of the workpieces from the clamping dies.

Example 432. Use of Unequal Extensions From Dies in Flash Welding of Aluminum Alloy Tubing to Copper Tubing (Fig. 9)

In the manufacture of refrigeration units, a short length of copper tubing was joined to the end of the aluminum alloy condenser tubing. This allowed the connection of the condenser to the remainder of the refrigeration system to be made by a copper-to-copper brazed or soldered joint.

Both tubes had outside diameters of 5/16 in.; wall thickness was 0.050 in. for the aluminum tube, and 0.060 in. for the copper tube. Heat balance would have been better if the wall of the aluminum tube had been thicker than the wall of the copper tube. The unbalance was compensated for by making the initial extension of the aluminum tube from the face of the clamping die ten times that of the copper tube, as shown in Fig. 9. Tool steel pinch-off dies were used to assist in making a better weld and to remove the weld upset from the exterior of the tubes. Flash was removed from the inside by reaming. No special end preparation of the tubing was required.

Welding conditions are given in the table that accompanies Fig. 9.



Flashing current	9000 amp at 4.5 volts
Flashing time	1 sec
Flashing travel	0.200 in.
Upsetting current	19,000 amp
Upsetting time	2 cycles (0.033 sec)
Upsetting travel	0.100 in.
Upsetting force	5000 lb
Clamping force	1000 lb
Total metal lost	0.300 in.

Fig. 9. Use of unequal extensions from dies to compensate for heat unbalance in flash welding copper tubing to aluminum alloy tubing. Pinch-off die inserts were used to remove the weld upset at the end of the upsetting stroke. (Example 432)

As shown in Fig. 10(a), several flash welds can be made simultaneously between two workpieces of the same thickness, even if the weld areas are different. The ratio of the areas should not be greater than 5 to 1. Welding of unequal areas is possible because initial die openings and flashing times used in welding tubing and flat stock (see Table 5) are based on stock thickness. However, simultaneous flash welds between solid round sections (see Fig. 10b) must have equal areas to be of uniformly good quality, because initial die openings and flashing times are different for each workpiece diameter (see Table 5).

Compensation for Metal Loss

In flash welding, some work metal is lost in making the weld. The amount of metal lost varies with the diameter, or least sectional dimension, of solid bars, the thickness of flat stock, or the wall thickness of tubing. To allow for metal lost, each component must be made longer than its final length in the weldment. In addition, the parts must overhang the clamping dies a certain distance, which is also proportional to the least sectional dimension of solid stock or to the wall thickness of tubing. (See the section on Extension of Workpieces From Dies, page 494.) Table 5 gives lengths of metal lost and die spacings for various sizes of steel tubing, flat stock, and solid bars. These values may vary, depending on the specific welding conditions.

In miter joining, the components are set at an angle to the platen, and so the amount by which the workpiece length is increased to compensate for metal that will be lost during flashing and upsetting also must allow for the miter angle. Because metal lost usually is measured parallel to platen travel, the length of the workpiece, measured along its centerline or edge, must be increased by a value equal to the amount of platen travel divided by the sine of the angle between the centerline or edge of the workpiece and the miter-cut end. If there is a gap between the ends of the workpieces after they have been secured by the clamping dies, the gap dimension must be deducted from the platen travel for this calculation.

Parallel Resistance to Upsetting Forces

Parts should be designed so that the reaction to the upsetting force can be resisted parallel to the direction in which it is applied, and so that the parts can be securely backed up and held during upsetting. Suitable backup tooling usually is needed for welding various shapes of forgings and bent tubing, and backups are also used as locators to facilitate loading and to obtain proper alignment of workpieces, as shown in Fig. 4.

There should be sufficient clamping area on the workpiece to permit the necessary clamping force to be applied without distorting the workpiece. Also, the shape of each workpiece should be such that alignment of the workpieces is not affected by the upsetting force.

Flash welding of rings is an application in which the plane of the workpiece that extends between the clamping dies is not always parallel to the plane of the upsetting force. The closed side of the ring also offers mechanical resistance to the normal upsetting force. This resistance can be used to advantage by forming the ring so that the ends are tightly together, or slightly overlapping. In this way, the forces for forging and bending the ring that are exerted through the clamping dies can be reduced. When rings are welded, the metal in the closed side is heated and expands, which causes some slippage in the die. Therefore, the ring should not be

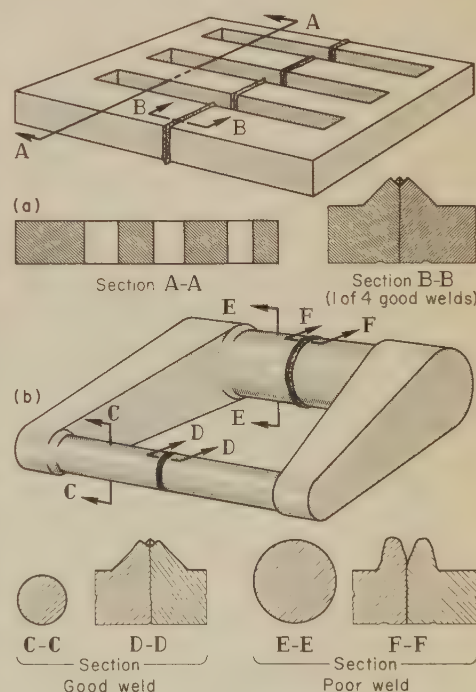


Fig. 10. Quality of simultaneous multiple flash welds of unequal cross-sectional areas. See text for discussion.

clamped completely around its circumference. Sometimes, however, when the material is burned away at least as rapidly as the ring expands, it is possible to use a circumferential clamping mechanism. Another effect of heating the closed side is alteration of the metallurgical properties of the ring after welding.

Care should be taken to avoid interference between the workpiece and the clamping mechanism; this can be difficult when small-diameter rings are being welded. Successful welding of rings depends on the ability of the clamping mechanism to hold the ends in place without slippage during the forging action.

Examples 433 and 445 describe applications in which advantage was taken of the unformed ends of roll formed bands in applying parallel forces during welding.

Not all sizes of rings or cylinders can be welded, because the closed side of the ring shunts the welding current, thus reducing the power that crosses the flashing gap. If the circumference of the ring is less than 25 times the thickness of the section, the shunting effect is so great that it is difficult to maintain flashing, and the closed side of the ring may melt through.

Alignment of Workpieces

Workpieces must be properly aligned to obtain good welds. Misalignment results in poor flashing and incomplete upset. Figure 11 illustrates the effect of good and poor alignment.

Maintenance of alignment and concentricity during flashing and upsetting is difficult in welding thin-wall tubing or workpieces with relatively thin sections. The edges of sheets must be held by the clamping dies so that ripples resulting from previous operations do not cause misalignment. If the edges are bent and do not mate, the sheets will overlap each other, instead of upsetting and welding together. Overlap generally is confined to small local areas along the welded edge, and in these areas poor fusion occurs. Reducing the thickness of the welded sheet by rolling can cause weld failure.

The example that follows describes flash welding of a ring that was roll formed from a stainless steel band. Alignment was maintained by leaving two unformed (flat) ends at the joint to be welded and by using clamping dies that had the same radius as the roll-formed ring.

Example 433. Flash Welding of a 0.078-In.-Thick Stainless Steel Ring (Fig. 12)

The ring shown in Fig. 12 was fabricated from 17-7 PH stainless steel coiled strip 1²¹⁄₃₂ in. wide by 0.078 ± 0.002 in. thick. The strip, annealed and pickled and with a 2B finish, was uncoiled, flattened, pierced with 16 holes ¼ in. square, and cut to a length of 18.08 in. Each length was then roll formed into a ring with a ³⁄₁₆-in.-long flat on each end. These flats helped to keep the ends in alignment during flashing and upsetting. The ends of the band were trimmed to ensure uniform flashing at the start. Then the band was manually loaded and clamped in the flash welding electrodes (see Fig. 12). A clamping force of 4600 lb was exerted on an area of about 1½ sq in.

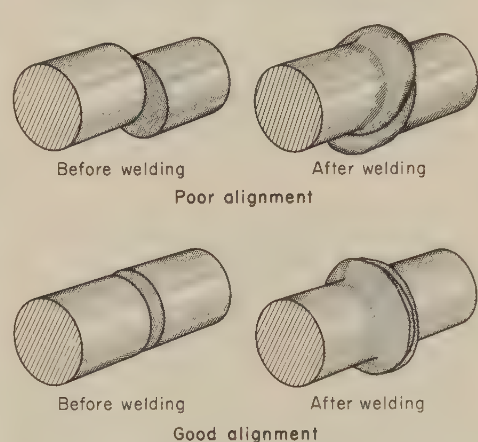

Fig. 11. Effects of alignment of workpieces on welded joint and weld upset

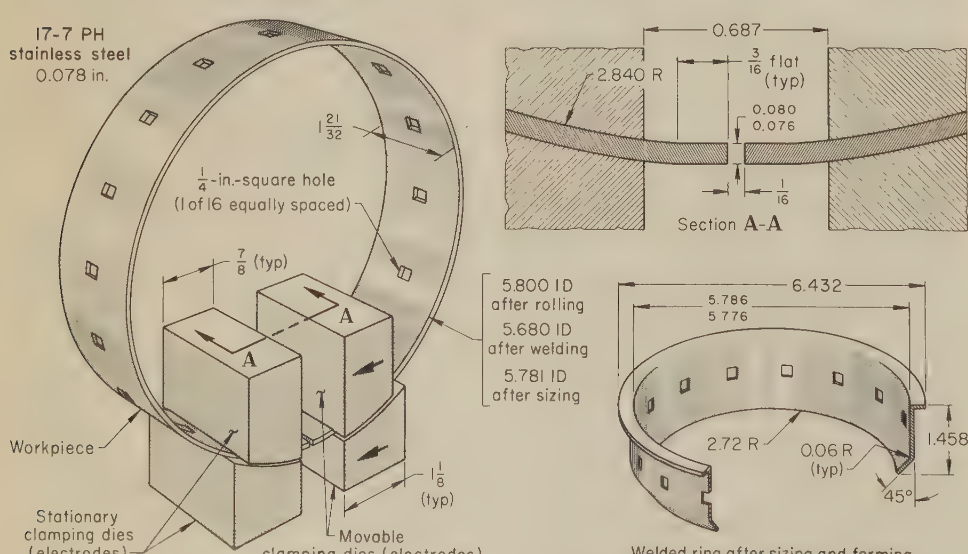
The clamping dies were made of RWMA class 3 electrode material. Power leads from the 50-kva (50% duty cycle) transformer were attached directly to the electrodes. The primary voltage input to the transformer was 220 volts and the secondary output voltage was 4.1 to 6.9 volts in eight steps. The platen speed and travel were controlled by a cam mechanism driven by a synchronous motor. The operation was semiautomatic in that the workpiece was loaded and clamped manually and then the welding cycle was started by the operator. After the automatic flashing and welding cycle was completed, the ring was manually unclamped and transferred to a machine for scarfing the weld upset.

Production rate was one ring in 24 sec, or 150 rings per hour. Flashing and upsetting required 2.58 sec.

The flash welded rings were given an intermediate anneal at 1400 F for 1½ hr, and then were cooled to 60 F within 1 hr. The annealed rings were stretched to an inside diameter of 5.776/5.786 in., and then were formed with a 90° stretch flange and a 45° shrink flange, which proof tested the welded joint. Tension testing of the flash welded joint showed that the metal in the weld zone had a strength equal to that of the base metal.

The rings were given a final heat treatment at 1050 F for 1½ hr, and then were air cooled. This produced a hardness of Rockwell C 40 to 50. Hardness tests indicated that the metal in the weld zone responded to the heat treatment in the same manner as did the base metal. (Costs for flash welding and gas tungsten-arc welding this ring in lots of 40 pieces are compared in Example 450.)



Welding Dimensions and Conditions

Initial die opening	0.687 in.	Total metal lost	0.474 in.
Initial extension per piece	0.312 in.	Flashing current	10,000 amp
Initial gap at joint	0.063 in.	Flashing time	2.50 sec
Final die opening	0.150 in.	Upsetting current	27,000 amp
Flash-off length, total	0.314 in.	Upsetting time	0.08 sec
Upset length, total	0.160 in.	Upsetting velocity	2 in. per sec

Fig. 12. Setup and joint detail for flash welding of a ring made from a roll formed band, prior to sizing and forming. Flats at joint (see section A-A) and use of conforming-radius electrodes kept ends aligned during welding. (Example 433)

Some combinations of joint length and stock thickness are difficult to weld and some are impossible to weld. Table 6 gives the relationships of joint length (sheet width) to sheet thickness that have proved successful in a large number of production jobs.

Relationships of tube diameter to wall thickness that have been successfully welded are listed in Table 7. When the ratio of tube diameter to wall thickness is too large, the clamping dies may deform the tube enough to cause mismatch of the tube ends, producing an incomplete or defective weld in that area.

Diametral tolerances are most critical when extremely thin-wall tubes are being welded, because the ends of out-of-tolerance tubes will not mate accurately at all points around the circumferences of the tubes. A difference in tube diameters also can cause a telescoping action, which reduces the effectiveness of the upsetting action, and thus reduces the properties and quality of the weld.

Standard steel tubing generally is oversize, and therefore the dimensions and tolerances of pieces to be welded should be based on the actual rather than the nominal dimensions. Military specifications require that the ratio of diameter to wall thickness not exceed 30 to 1. Although good welds can sometimes be obtained when this ratio is exceeded, selective assembly or sizing of the tubes may be necessary.

Miter Joints

Flash welded miter joints inherently have less-than-optimum weld quality, because the line of application of upsetting force is not parallel to the centerline of the workpiece, and there are variations in the resistance to the upsetting force in the horizontal plane of the abutting surfaces. However, miter joints have been satisfactorily flash welded in bar stock, flat rectangular sections, solid and hollow extruded sections, contour roll formed sections, and structural sections. Solid, compact sections such as bar stock must be joined at an included angle of not less than 150°, as shown in Fig. 13(a). Poor bonding occurs at the outer corner as a result of the absence of backup material.

Satisfactory 90° welds have been made in thin rectangular sections, and in similar extruded or roll formed sections, where the width of the joint, w, is greater than 20 times the stock thickness, t (see Fig. 13b). Slippage of the workpiece during upsetting is a normal consequence unless the clamping dies are properly designed and unless workpieces are carefully placed in the dies and aligned.

It is impossible to obtain 100% bonding throughout all parts of a flash welded miter joint, because some portions of the weld area are not backed up with cold metal to give support during upset. The lack of backup metal prevents the development of adequate forging pressure, and results in poor bonding at outside corners (see details A and B in Fig. 13). Thus, miter joints are inadvisable for assemblies to be subjected to high stresses in tension or torsion. To safeguard against stress concentration at light and medium loads, the poorly bonded metal at the outside corner of the joint should be removed, as indicated by the trim line in detail B in Fig. 13. When thin rectangular sections are joined at an angle, little heat flows beyond the welding surfaces, because welding time is short; in thin sections, however, a deep zone of plasticity is unnecessary.

Accurate cutting of the ends of workpieces for miter joints is not essential. Slight inaccuracies in straightness or angularity of the abutting ends cause initial point contact at the start of flashing, and help to initiate a smooth flashing action. The values given in Table 5 can be used as a guide in determining dimensional allowances for bar stock, extrusions, tubing and sheet stock.

Extrusions having different cross-sectional shapes, such as the header, the jambs and the sill of a window frame, frequently must be flash welded together in a miter joint. When the ends are prepared for welding, the portions that are not to be welded, or any nonmatching portions of the extrusions, must be cut back for a distance equal to or greater than the length of metal lost during flashing and upsetting, as shown in Example 434. Otherwise, flashing will occur between these portions and other parts of the workpieces or the clamping dies. When properly trimmed, the ends of the extrusions will terminate in the miter exactly at the weld line.

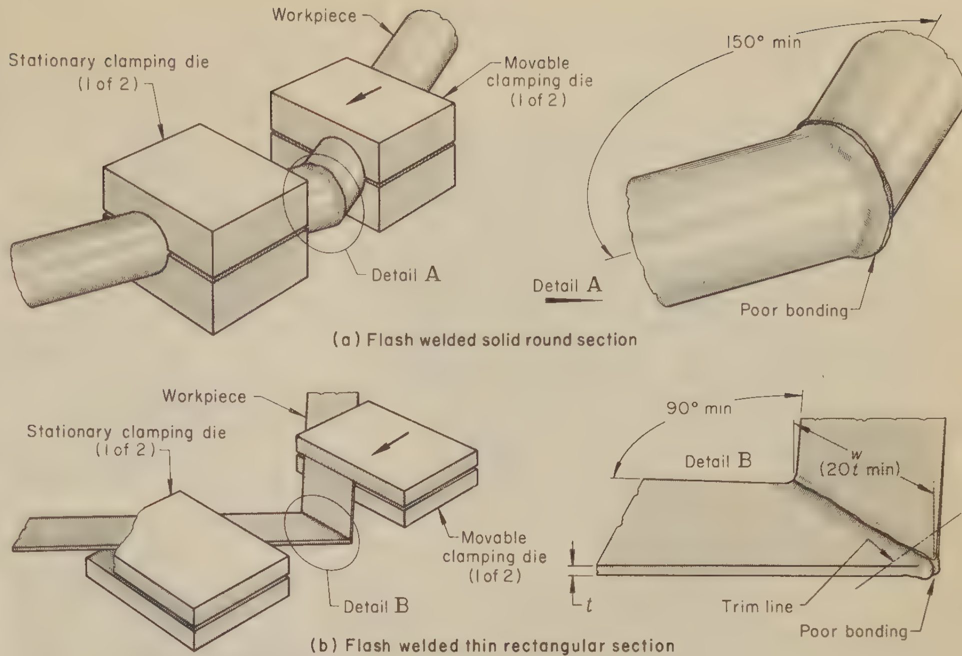


Fig. 13. Setups and dimensional relations for flash welding of miter joints in round and thin rectangular sections. Poor bonding at outer corners results from lack of backup metal.

Table 6. Lengths of Joints Commonly Flash Welded in Various Thicknesses of Flat Sheet

Sheet thickness, in.	Joint length, in.	Sheet thickness, in.	Joint length, in.
0.010	1	0.060	25
0.020	5	0.080	35
0.030	10	0.100	45
0.040	15	0.125	57
0.050	20	0.187	88

Length of joints in stock thicknesses of 0.050 in. and greater can be up to 100 in., depending on material extension, platen travel, die alignment and clamping.

Table 7. Maximum Flash-Weldable Diameters of Tubing of Various Wall Thicknesses

Wall thickness, in.	Max diameter, in.	Wall thickness, in.	Max diameter, in.
0.020	½	0.125	4
0.030	¾	0.187	6
0.050	1¼	0.250	9
0.062	1½	0.375	15
0.080	2	0.500	20
0.100	3		

Adequate support and clamping are important in miter-joint welding of extrusions and roll formed sections that incorporate thin webs, because the plane of the thin web is not in the plane of the upsetting force. Where the length of the thin vertical web is greater than twice the web thickness, the upsetting force is more likely to displace metal from the joint rather than to upset the metal correctly, and a poor weld may result. In applications where a liquid-tight joint is not required between sections having long, thin webs, the webs can be cut back so that, at the end of flashing and upsetting, the webs are in intimate contact but are not welded. Where a liquid-tight joint is required, the webs can be formed so that they are in the same plane as the upsetting action.

In the application described in the following example, after the miter cut was made in the window-frame extrusions to be welded, the end of the web was formed so that it would be parallel to the upsetting force. Also, portions of the extrusions not to be welded were trimmed away so that they would not interfere with other parts of the weldment or the welding operation.

Example 434. Miter-Joint Welding of Window-Frame Extrusions, in Which Weld Strength Was Increased by Preforming Abutting Edges of Thin Webs (Fig. 14)

Aluminum alloy 6063-T5 extrusions were used in making a window frame in which the corners were mitered and joined by flash welding as shown in Fig. 14. Watertight corners were required, and so the thin vertical web sections of the extrusions had to be made part of the welded joints. To provide the strength in the web needed to resist the upsetting force, a V-shape embossment was formed in the end of each web before welding, as shown in Fig. 14; thus, a portion of the web was in line with the platen travel during the later part of flashing and during upsetting. The clamping arrangement shown at the lower right in Fig. 14 was designed to provide adequate support and accurate alignment of the thin web sections.

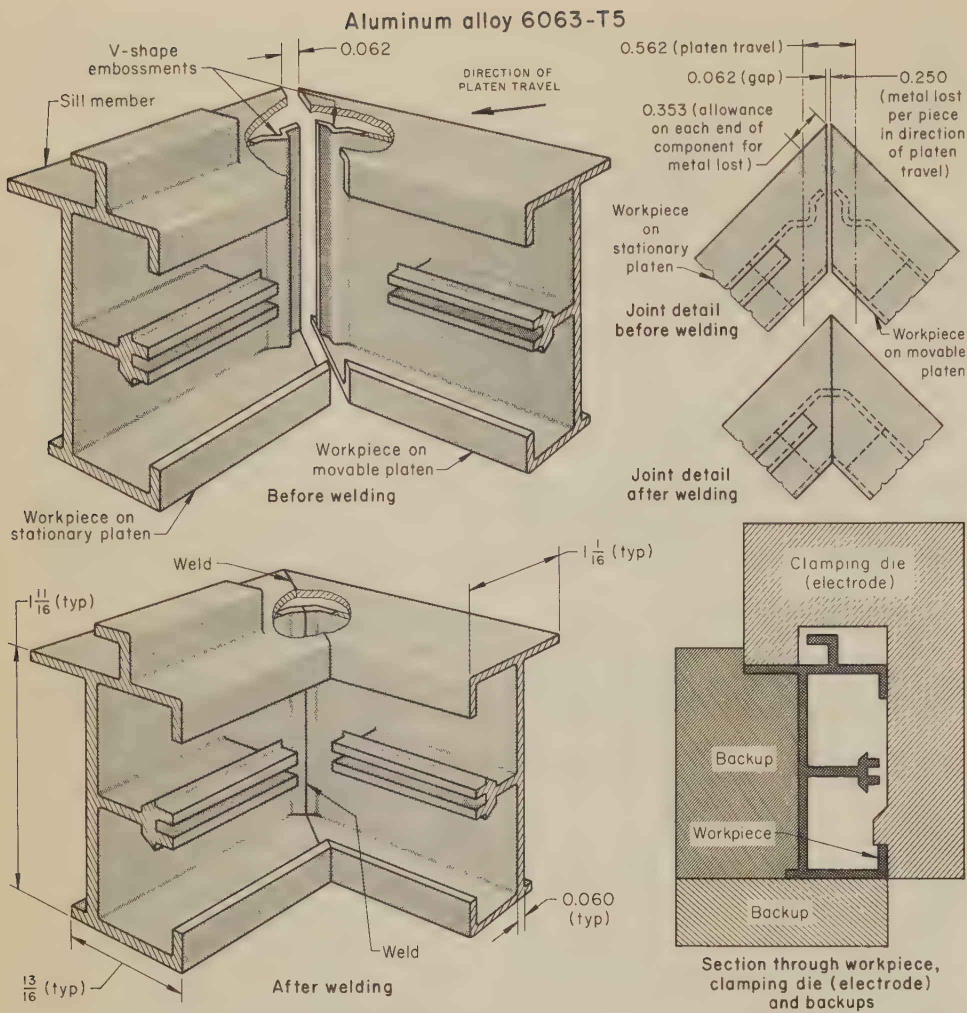
The right-angle projection along the surface of the $1\frac{1}{16}$-in.-wide flange on the sill member was cut back to prevent interference with flashing and upsetting. The inward-pointing projections on the edges of the flanges were short enough to withstand the upsetting force and to provide adequate weld strength, and thus were not cut back. The center bars of the E-shape members were not to be welded, and so were cut back on the ends of each piece.

Production was over 200 frame assemblies (800 welds) per day. The weld area was 0.334 sq in. A 150-kva flash welding machine was used in which platen travel during flashing and upsetting was actuated by a motor-driven cam.

Other welding conditions are given in the table that accompanies Fig. 14.

Expulsion of Flash

Heating of workpieces during flash welding is accompanied by the rapid expulsion of incandescent particles of molten metal. These particles contain slag and oxide that constitute defects



Welding Dimensions(a)		Welding Conditions	
Initial die opening	0.578 in.(b)	Flashing current	13,600 amp at 6.3 volts
Initial extension per piece	0.258 in.	Flashing time	1.8 sec
Final die opening	0.016 in.	Upsetting current	None (power off)
Metal lost per piece	0.250 in.(c)	Upsetting time	3 cycles (0.05 sec)
Flash-off length, total	0.250 in.	Upsetting force	24,000 lb
Upset length, total	0.250 in.	Clamping force	5000 lb

(a) In direction of platen travel. (b) Includes 0.062-in. initial gap between parts at joint. (c) Because of the miter angle, allowance at each end was 0.353 in. instead of 0.250 in.

Fig. 14. Miter joint between window-frame extrusions before and after flash welding, and details of workholding arrangement. V-shape embossments at meeting edges of the thin web sections aided in the production of strong, watertight welds. (Example 434)

if trapped in the weld. Risk of entrapment is lessened when the particles are expelled along the shortest path. On round-section workpieces, the shortest paths lie on radial lines starting at the center of the weld area.

In designing the abutting ends of workpieces, especially of large-diameter workpieces, the mating surfaces can be chamfered as shown in the illustration that accompanies Table 5. This causes the flashing and heating to start at the center of the workpiece and to move progressively toward the outer edges. The chamfered surfaces also help to expel the flash particles during initial flashing.

In the example that follows, the abutting ends of large-diameter workpieces were machined to a point instead of a flat surface. This ensured that flashing would start at the center of the weld area and that the incandescent particles would be expelled along the shortest paths.

Example 435. Welding of Forged Crankshaft Sections on Which Ends Had Been Machined to a Point To Aid in Expulsion of Flash (Fig. 15)

In the production of a 14-ft-long crankshaft for an eight-cylinder engine, two 7-ft-long forged sections of 5046 steel were flash welded together at an 8-in.-diam main bearing. The two surfaces to be welded were machined to a conical shape with a 4° slope from center, as shown in Fig. 15. This caused flashing and heating to start at the center of the shaft and allowed space for the sparks (iron and oxide) to be expelled from the weld area. The opposite side of the cheek on each half of the main bearing was machined to accommodate backups that were mounted on each platen to resist the flashing and upsetting forces. During welding, a fixture mounted on each platen positioned and held each forging, and split-type water-cooled copper electrodes conducted current to the workpieces.

Each half of the crankshaft was placed and clamped in its respective fixture. The electrodes were brought in contact with the bearing surfaces and hydraulically clamped. The two halves of the crankshaft were brought into initial contact by manually actuating the movable platen. Flashing was continued by manually feeding the platen for about half the welding cycle, after which an automatically controlled hydraulic feed was used. When the interfaces were slightly below the melting temperature, upsetting pressure was suddenly applied. The welding current was automatically turned off shortly after the start of upset, but the upsetting pressure was maintained for a short period to permit the workpiece to cool below the solidification temperature, and to maintain alignment during cooling.

The weld upset was removed with a scarfing tool and the weld area was annealed by induction heating. The main-bearing surface was finished to diameter by grinding. The forgings had been quenched and tempered to 270 to 300 Bhn before they were welded.

The welding machine had an input rating of 1750 kva. The output rating of the secondary was 2700 amp at 16 volts during manual feed, and 3000 amp at 12 volts during automatic feed. Platen force during manual feed was 36 tons, and during automatic feed, 94 tons. Two hydraulic cylinders were used — one for manual feed, and the other for automatic feed.

Total welding time was 6 min; upsetting pressure was held for an additional 3 min. Welds were inspected ultrasonically.

Typical Welding Schedules

Flash welding schedules are based primarily on the diameter of bar stock, on the thickness of sheet or plate, or on the wall thickness of tubing, and not on the entire cross-sectional area of the workpiece. Because of the distribution of electrical energy, it is easier to weld a plate 1 in. by 12 in. than a bar 3 in. by 4 in., even though both have the same cross-sectional area. The maximum cross section that can be successfully welded depends primarily on the strength of the work metal at elevated temperature.

Table 8 gives welding schedules for plates, bars and tubes made of various metals and alloys.

The Heat-Affected Zone

In a flash welded part, there are significant metallurgical differences between the highly heated structure at the center of the weld and the unaffected base metal. These differences occur because there is a large temperature gradient in the work metal between the inner edges of the clamping dies or electrodes. The greatest heat is generated at the faces of the weld because of the flashing action, while at the inner edge of the electrodes the metal is essentially at room temperature. The heat-affected zone is the region on each side of the bond line that has been heated during welding to temperatures above or within the transformation-temperature range. The portions of the work metal other than the weld and the heat-affected zone remain relatively cool and conduct heat away from the weld. Consequently, the weld cools at a much higher rate than would be obtained during simple air cooling and, in steel, hardening results, particularly when the welded section is small. There is not only a marked change in microstructure across the weld, but also a variation in hardness — to a small ex-

tent in steels of low hardenability, and to a greater extent in steels of high hardenability.

Solution quenched, annealed or other types of structures appear in alloys not subject to martensitic hardening. In all alloys, the grain size at the weld is large and becomes smaller as the distance from the bond line increases.

In some alloys, the desirable characteristics of flash welds include a narrow hardened or heat-affected zone, and strength and ductility as nearly equal to those of the base metal as possible. A weld with these characteristics can undergo subsequent cold forming or cold reduction to the same degree as can the base metal. Sometimes, weld quality can be improved by welding in an atmosphere other than air. Results of flash welding 4335 steel in six different atmospheres are given in Example 442.

Hardness of Welds

A hardness survey across a flash weld in cold rolled low-carbon steel shows little change in hardness. Therefore, heat treatment is unnecessary for obtaining uniform hardness. When a hardenable steel is flash welded, considerable hardness differentials are produced across the heat-affected zone. If uniform hardness is desired, heat treatment after welding is necessary.

Flash welds in cold rolled low-carbon steel have a coarse structure near the weld and contain some martensite. During flashing, considerable grain growth occurs in the metal at the joint because the temperature is near or above the melting point, which is far above the transformation-temperature range. (Theoretically, all the metal that is melted at the bond line is extruded into the weld upset.) Proceeding from the bond line along the workpiece, the temperature decreases, and any martensite present becomes increasingly finer in appearance. Near the outer edge of the heat-affected zone, where the metal has been heated to a temperature between the lower and upper transformation temperatures, only partial transformation occurs, which results in softening of the steel.

Variations in hardness across the heat-affected zone in cold rolled low-carbon steel are illustrated in Fig. 16(a). The hardness of the metal in the heat-affected zone is lower than that of the unheated base metal because heating has removed the work hardening resulting from cold rolling. The bond line and points near the outer edges of the heat-affected zone are slightly softer than the rest of the heated metal. During a tension test, fracture can be expected to occur near the outer edges of the heat-affected zone because of the slight softening.

After flash welding of hot rolled steel, the metal in the heat-affected zone is harder than the base metal as a result of heat treatment during welding. Therefore, in a tension test of a flash weld in hot rolled steel, fracture usually occurs in the base metal.

A flash weld in an alloy steel containing 0.25 to 0.28 C, 0.60 to 0.80 Cr, 0.80 to 1.00 Ni, and 0.50 to 0.60 Mo has a fully martensitic structure, because of the high hardenability of the steel. The martensite becomes more finely divided as the distance from the bond line increases, because of the decreasing temperature gradient. In a region near the edge of the heat-affected zone where the metal temperature approaches the lower transformation temperature, the original base metal is only partly transformed; after cooling, the microstructure is ferrite and fine-grain martensite.

Variations in hardness across a weld in a Cr-Ni-Mo alloy steel of the composition noted above are illustrated in Fig. 16(b). From the original hardness

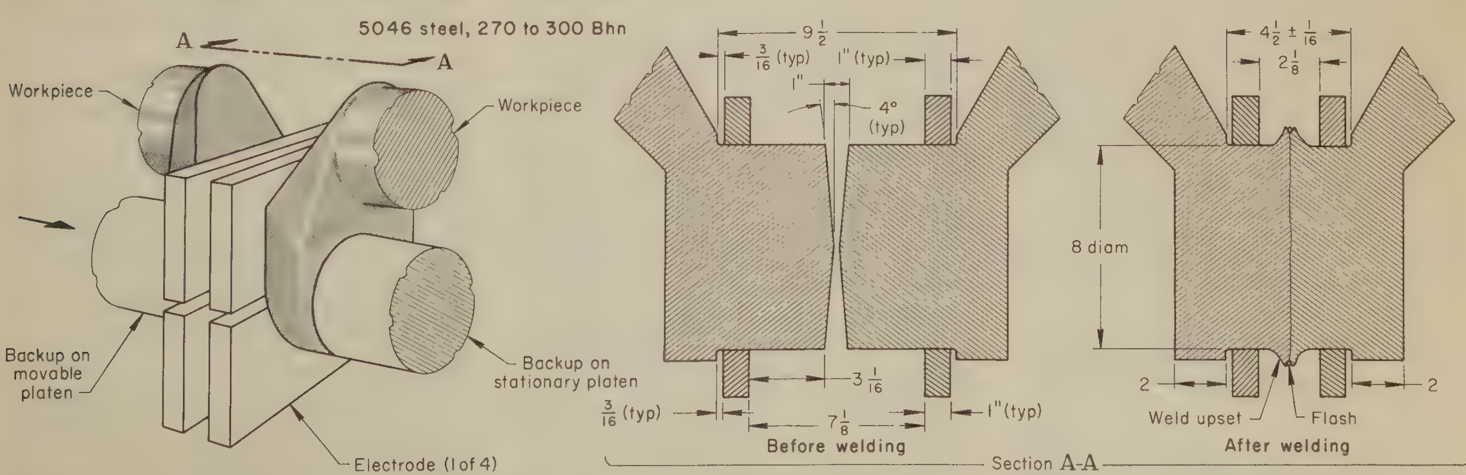

Fig. 15. Setup and joint details for flash welding of two halves of a 14-ft-long crankshaft at an 8-in.-diam main bearing. Expulsion of flash from the thick sections was aided by a 4° conical relief machined on each surface to be welded. Total metal lost, exclusive of the tapered ends, was 4 in. (Example 435)

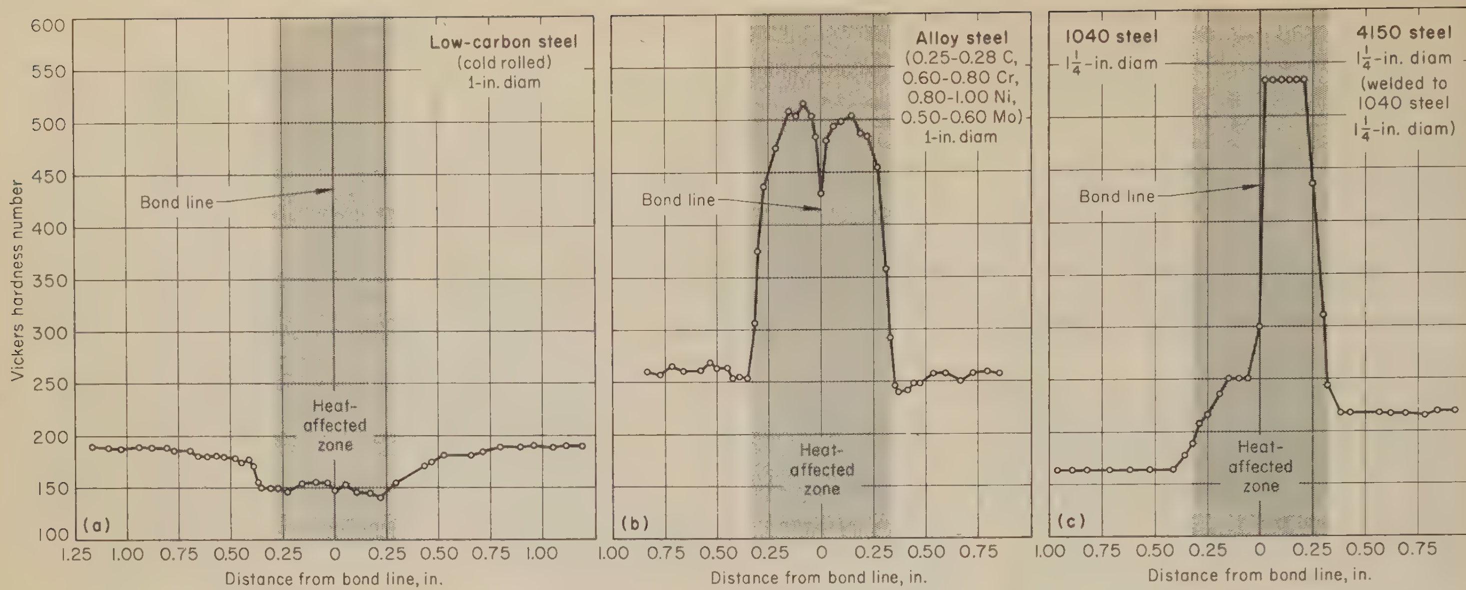

Fig. 16. Variation in hardness across the heat-affected zone and into the base metal for flash welded joints in: (a) *cold rolled low-carbon steel;* (b) *a Cr-Ni-Mo alloy steel; and* (c) *1040 steel welded to 4150 steel*

of the base metal (about 260 Vhn), the hardness rises sharply at the edge of the heat-affected zone and is higher than 500 Vhn (Rockwell C 48 to 50) near the bond line. The dip in hardness at the bond line is probably caused by decarburization. During welding, the regions on either side of the bond line are heated to a temperature high enough to cause full hardening during cooling, and the hardness decreases with the distance from the bond line.

The lowest hardness in the welded joint was just beyond the heat-affected zone where a temperature slightly higher than the tempering temperature (1200 F) of the original base metal had been reached. Had the original tempering temperature been lower, and the hardness of the metal consequently higher, the dip in hardness would have been more noticeable.

A hardness plot taken across the center of 1¼-in.-diam bars of 4150 steel and 1040 steel that were flash welded together is shown in Fig. 16(c). Although similar in carbon content, the two steels differ greatly in hardness within the heat-affected zone, because of the greater hardenability of the 4150 steel. During welding, the 4150 steel was hardened to such an extent that it cracked at the outer edge of the heat-affected zone during cooling. Both of the bars were fully annealed before welding; therefore, there was no dip in hardness between the heat-affected zone and the unheated base metal.

The group of four examples that follows demonstrates the variation in hardness in the heat-affected zones in flash welds between two commonly used alloy steels.

Examples 436 to 439. Variations in Hardness Across the Heat-Affected Zones in Flash Welded Alloy Steel Rings of Four Sizes (Fig. 17)

Figure 17(a) to (d) shows the variations in hardness across the heat-affected zones of four flash welds in alloy steel rings of different inside diameters and cross-sectional areas. All four rings were flash welded in a welding machine with an input rating of 750 kva. The maximum short-circuit output rating of the secondary was 240,000 amp at the highest transformer tap setting. Clamping force and platen movement were hydraulically actuated. The maximum clamping force was 620,000 lb with a hydraulic pressure of 2000 psi. Maximum force on the platen (flashing and upsetting) was 208,000 lb at 1000 psi.

The lower clamping dies, which were attached to the platen and carried the current, were made of RWMA class 3 electrode material. The upper dies were made of an oil-hardening tool steel and were hardened to Rockwell C 42 to 45. Both sets of dies were shaped to the contour of the specific ring being welded, and the upper dies were serrated to resist slippage during upsetting.

Conditions for welding the four different rings are given in the table that accompanies Fig. 17.

Example 436 (Fig. 17a). A ring with an inside diameter of $18\frac{15}{16}$ in. was made from 4130 steel bar stock by roll forming and flash welding. The bar was 1.06 in. square, with a cross-sectional area of 1.12 sq in. After being welded, the ring was machined to a cam contour on one face and was used to apply a brake in the transmission of a military tank. Production rate was 40 rings per hour.

A plot of the hardness across the heat-affected zone of the as-welded ring is shown in Fig. 17(a). Note the sharp drop in hardness at the bond line.

After being welded, the ring was annealed to condition the heat-affected zone for a subsequent sizing operation. The annealing treatment consisted of holding at 1750 F for 1 hr, furnace cooling to 900 F and then air cooling; the hardness after this treatment was 249 Bhn max. Then the base metal and the metal in the heat-affected zone were proof tested by 1% minimum elongation of a section between two gage points. This operation also expanded the ring to size. Before final machining, the ring was quenched and tempered to Rockwell C 26 to 32.

Example 437 (Fig. 17b). A tank-transmission steering-clutch ring $10\frac{11}{16}$ in. in inside diameter was made from 4130 steel bar stock 2⅛ by 5 in. by forming with a compression die in a 500-ton horizontal press and then flash welding. The cross-sectional area of the welded joint was 10.6 sq in. Production rate was 15 rings per hour.

The as-welded hardness of the metal in the heat-affected zone is plotted in Fig. 17(b). Note that the metal at the bond line was only about 2 Rockwell C points softer than the immediately adjacent metal in the heat-affected zone.

After being flash welded, the ring was heated to 1200 F, compression formed for rounding, and expanded (2% max) to size. Then the ring was welded into the tank-transmission assembly, and the entire assembly was quenched and tempered to Rockwell C 26 to 32.

Example 438 (Fig. 17c). A $7\frac{7}{16}$-in.-ID ring (a blank for an internal-reversing ring gear for a transmission planetary-gear system) was made from 4140 steel bar stock 1⅛ by $2\frac{1}{16}$ in. by roll forming and flash welding. The cross-sectional area of the welded joint was 2.3 sq in. Production rate was 30 rings per hour.

The as-welded hardness of the metal across the heat-affected zone is shown in Fig. 17(c). The hardness of the metal at the bond line averaged about 6 Rockwell C points less than that of the immediately adjoining metal.

After being flash welded, the ring was heat treated to obtain increased ductility for sizing. This treatment consisted of holding at 1400 F for 1 hr, cooling to 1250 F, holding at 1250 F for 1 hr, heating to 1330 F, holding at 1330 F for 2 hr, and then air cooling. The resulting hardness was 170 Bhn max. The ring was then expanded to size and proof tested. Before final machining, the ring was quenched and tempered to Rockwell C 32 to 36.

Example 439 (Fig. 17d). A 9.59-in.-ID blank for a ring gear with the same function as that of the ring gear described in Example 438 was made from 1½ by 2¾-in. 4140 steel bar stock by roll forming and flash welding. The cross-sectional area of the joint was 4.12 sq in. Production rate was 20 rings per hour.

As shown in Fig. 17(d), the range of the as-welded hardness across the heat-affected zone was greater than for the ring in Example 438. The maximum hardness was about Rockwell C 41, or ten points higher than the maximum hardness of the ring in Example 438.

Heat treatment prior to sizing and proof testing, and final heat treatment, were the same as for the ring in Example 438.

Full heat treatment can restore a flash welded steel part to the uniform hardness of the unwelded stock, but merely tempering the hard weld metal to the original hardness of the base metal does not result in full homogeneity, because between the hardened weld metal and the unaffected

Fig. 17. Variations in hardness across the heat-affected zones in flash welded rings that were roll formed or compression-die formed to four different inside diameters from 4130 and 4140 steel bars of various cross-sectional areas (Examples 436 to 439)

base metal there is a narrow zone that has been overtempered by the welding heat and that is softer than the original base metal. This softened zone can be brought to uniform hardness only by full heat treatment. The softened zone may or may not be detrimental to the service life of the weldment.

Tempering in a flash welding machine is impractical for two reasons: (*a*) it is difficult to maintain a uniform temperature in the metal between the electrodes; and (*b*) proper tempering of the edge of the heat-affected zone normally cannot be done without overtempering and softening of the areas nearest the bond line.

Strength of Welds

Because flash welds are made from the base metal without any filler metal, the welds can be made to have almost the same properties as the base metal. In welding steel, upsetting diverts the fiber of the steel from its normal direction, and this may have some effect on strength.

In tension tests, yielding often occurs on both sides of the weld before fracture takes place. Fracture occurs in the base metal if it is the softer structure, or in a region softened by the heat of welding if the base metal is hard.

When workpieces are uniformly heat treated after welding, the strength of the weld is theoretically as high as that of the base metal, except where the base metal has a relatively high

Fig. 18. Section of a jet-engine rear-mount ring that was made by flash welding a stainless steel extrusion rolled into a ring (Example 440)

tensile strength. If a flash welded carbon or alloy steel workpiece is heat treated so that it has a tensile strength less than about 150,000 psi, the workpiece is homogeneous throughout and may fracture either at or away from the bond line. At a tensile strength higher than about 150,000 psi, the fracture is more likely to occur at the bond line, presumably because of the removal of some carbon from the steel at the bond line during welding, or the presence of inclusions (see page 505).

In the following example, in which a stainless steel ring was annealed after flash welding, the weld had only slightly less strength than the base metal.

Example 440. Production of a Stainless Steel Ring by Roll Forming and Flash Welding an Extruded Section, in Which the Weld Was Over 98% as Strong as the Base Metal (Fig. 18)

A jet-engine rear-mount ring, a section of which is shown in Fig. 18, was made by roll forming a type 410 stainless steel (AMS 5613) extruded section, and then flash welding it into a continuous ring. The tensile strength of the welded joint was 98.8 to 99.7% that of the base metal.

The ring was welded in a 750-kva, single-phase, 440-volt machine with a maximum secondary output rating of 7500 amp at 16.9 volts. The clamping mechanism and the movable platen were hydraulically actuated. To ensure good conduction of electrical current, the 3-in.-long clamping dies were made of RWMA class 2 copper electrode material, and the clamping surfaces on the workpiece were polished to remove oxide film, scale and other contaminants that could hinder current flow.

The operations for making the ring were as follows:

1. Cut extruded section to length.
2. Roll form in a horizontal three-roll forming machine equipped with rolls shaped to fit the extrusion.
3. Polish end surfaces for electrode contact.
4. Flash weld.
5. Remove flash and polish heat-affected area.
6. Anneal to 187 Bhn.
7. Size, round up, and proof test.
8. Heat treat (if required by customer).

The welded joint in each ring was proof tested in a hydraulically actuated expander that applied uniform pressure on all sections of the ring simultaneously. The proof test consisted of 1% minimum cold expansion of the metal across the weld in a 2-in. gage length. The testing operation also made the ring round and sized it to the specified inside diameter.

Table 9. Effects of Six Different Atmospheres on Strength of Flash Welds in 4335 Steel (Example 442)

Welding atmosphere	Dew point, F	Tensile strength (2 tests) Psi	Tensile strength (2 tests) % of base-metal strength	Fatigue limit Strength, psi	Fatigue limit No. of tests

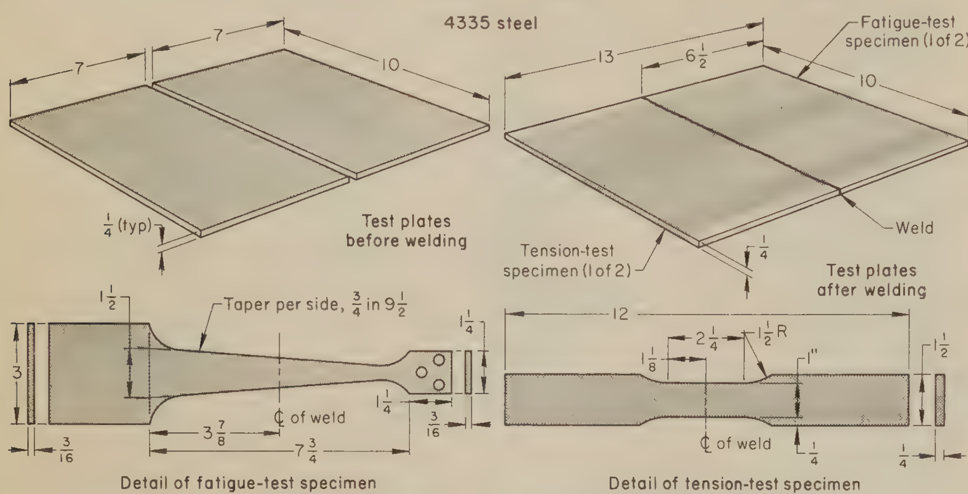
Nitrogen	75	165,000	92	50,000	3
Dry nitrogen, 1% oxygen	20	166,000	92	50,000	3
Air	65	165,000	92	50,000	7



Welding Conditions for All Atmospheres

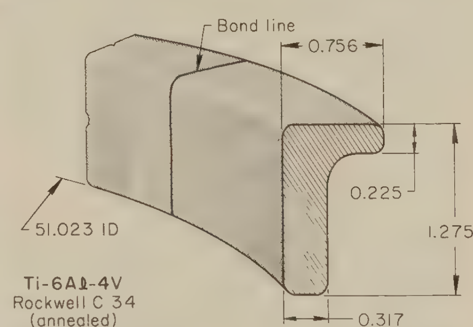
Initial die opening	1.75 in.
Final die opening	0.75 in.
Total flash-off	0.75 in.
Total upset	0.25 in.
Total metal lost	1.00 in.
Voltage, open circuit	6.5 volts
Flashing time	30 sec
Upsetting time	<0.1 sec
Upset-current time	0.3 sec
Upsetting pressure	20,000 psi

One ring from each production lot was tension tested according to AMS 7493, which covers flash welding of martensitic stainless steel. Standard ASTM tension-test specimens were used. The base metal had a hardness of 187 Bhn, tensile strength of 95,100 psi, and 29% elongation. Two test specimens taken across the weld had the following properties: hardness, 187 Bhn; tensile strength, 94,000 and 94,900 psi; joint efficiency, 98.8% and 99.7%; and elongation, 29% and 26%.

Before proof testing, all rings were inspected visually for alignment and for surface defects. Random samples were checked radiographically for internal defects in the heat-affected zone.

The use of an extruded section for the ring instead of a rectangular bar resulted in material savings of $75 per piece. There was an additional saving in machining costs, since there was less metal to remove.

Production rate was seven rings per hour, including polishing the clamping surfaces, flash welding, and removing the weld upset. Welding conditions are given in the table that accompanies Fig. 18.



Initial die opening	2⅛ in.
Final die opening	¾ in.
Metal lost	1⅜ in.
Preheat time	10 sec
Flashing time	10 sec

Fig. 19. Section of a jet-engine ring that was made by flash welding a titanium alloy extrusion rolled into a ring (Example 441)

Some of the alpha-beta titanium alloys can be strengthened by aging at moderately elevated temperatures. The rapid quenching effect of clamping dies used in flash welding suppresses the transformation of the elevated-temperature beta phase that occurs with slow cooling. Aging usually decreases the ductility of the work metal with little or no change in the hardness, as in the following example.

Example 441. Production of a Titanium Ring by Flash Welding (Fig. 19)

The ring shown in Fig. 19 was used, after machining, as a jet-engine inlet-case seal. The workpiece was an AMS 4928 (titanium alloy Ti-6Al-4V) extrusion with a hardness of Rockwell C 34, tensile strength of 145,000 psi, and 14% elongation. The welded joint had the same hardness, but a tensile strength of 151,900 psi, and elongation of 12.5%. Thus the joint efficiency was 105%. The welded area was about 0.5 sq in.

The joint was made in a 750-kva, single-phase, 440-volt flash welding machine with a maximum secondary output rating of 7500 amp at 16.9 volts. Hydraulically actuated clamps, 3 in. in length and made of high-conductivity copper (RWMA class 2), held the roll formed ring during welding. The movable platen was also hydraulically actuated.

The extruded section was cut to length, heated to 1250 F, and then roll formed into a circle in a horizontal three-roll forming machine. To ensure maximum current flow, the contact surfaces of the workpiece at the clamping dies were polished before the ring was placed in the welding machine. After welding, the weld upset was removed, the weld area was ground by hand to the same dimensions as the adjoining area, and the joint was inspected for alignment and for defects. Then the welded rings were heat treated in accordance with AMS 4928.

The joint was proof tested by placing the welded ring in a hydraulically actuated expander and applying uniform pressure to all sections of the ring simultaneously. The circumference of the ring was increased about 2 in., or 1¼%, during this operation, which also made the ring round and sized the inside diameter to specification.

One ring from each production lot was used for destructive tests on the base metal and the welded joint. The tests were conducted according to AMS 7498, which covers flash welding of titanium alloys.

The ring that was made from the extruded section weighed 15 lb, and the bar cost $145. Had the ring been made from a rectangular bar, it would have weighed 36 lb, material cost would have been $270, and machining the welded ring to final contour would have cost substantially more.

Production rate was 35 rings per hour. Welding conditions are given with Fig. 19.

Effect of Protective Atmospheres on Flash Welds

Protective atmospheres can be used to improve the quality of flash welds — especially welds in ferrous metals. Dry hydrogen, dry hydrocarbon gases, and dried inert gases such as helium, argon and nitrogen, have been used for welding ferrous metals. Reducing gases generally are better than dried inert gases. Small amounts of water vapor or oxygen in reducing or inert gases greatly reduce their effectiveness. In flash welding highly reactive metals, only helium or argon can be used as a shielding gas, although some work with these metals indicates that good welds can be made by flash welding in air. In welding aluminum alloys, the use of an inert atmosphere such as argon does not appear to improve weld quality.

The weld strengths of 4335 steel that was flash welded in air, a reducing gas, and inert gases are compared in Example 442. For flash welded 8630 steel, Example 443 compares fatigue life of welds made in air, nitrogen and butane.

High-quality welds can be made only by using optimum welding procedures. Protective atmospheres cannot compensate for the use of poor procedures.

In flash welding, the value of a protective atmosphere depends on how effectively it is applied. Tubular sections are relatively easy to protect by introducing the gas inside the tube and allowing it to escape only through the flashing edges, as was done in Example 444. Long, flat sections are difficult to protect, because they require complete enclosure, which is difficult to design and to work with.

In the following example, steel plates were flash welded in different atmospheres to determine the effects of the atmospheres on strength of welds.

Example 442. Effects of Six Different Atmospheres on Strength of Flash Welds in 4335 Steel (Table 9)

A series of 4335 steel plates was flash welded, under the conditions given in Table 9, in six different atmospheres to compare the effects of the atmospheres on weld strength. Gas atmospheres (except for air) were confined at joint areas by means of a 0.06-cu-ft box-type brass enclosure with asbestos seals. After welding, upset metal was removed and the plates were heat treated to a tensile strength of 180,000 psi. Specimens were then machined for transverse-weld tension and fatigue testing.

Dimensions of the test plates, and of the fatigue-test and tension-test specimens, are shown in the illustration with Table 9.

Results of the tests, which are given in Table 9, show that tensile strength of welds made in dry hydrogen, in butane and in dry nitrogen was 5 to 7% greater than that of welds made in air. When water vapor or a small quantity of oxygen was added to dry nitrogen, tensile strength was not significantly greater than when welding was done in air.

The fatigue-test results were more pronounced. Specimens welded in dry hydrogen showed a 50% increase in fatigue strength over those welded in air; those welded in butane showed a 36% increase. The results for dry nitrogen were inconclusive. However, as in the tension tests, when water vapor or a small amount of oxygen was added to dry nitrogen, there was no improvement over welding in air.

The Krause push-pull fatigue test was used for testing the weld specimens. Ten million cycles were used to determine the limits given in Table 9.

Tests indicate that, compared with air, protective atmospheres improve the fatigue life of flash welds in 8630 steel tubing, as in the next example.

Example 443. Fatigue Life of Welds Made in Air, Nitrogen and Butane

Ambient air, dry nitrogen, and butane were compared as to their effects on the fatigue life of flash welds in 8630 steel tubing. The tubing had an outside diameter of 2⅝ in. and a wall thickness of 0.192 in. For welding in nitrogen and butane, one end of the tubing was sealed, and the gas was introduced from the opposite end at a slight positive pressure to produce a continuous flow across the joint interface. The nitrogen flowed at a rate of about 2.5 cfm, and the butane, at a rate that maintained a constant flame at the flashing edges. No special arrangement was made for welding in air. Dry nitrogen, with a dew point of about 20 F, was supplied in a standard compressed-gas cylinder. The butane was used as it boiled from the liquid state in a standard LP gas tank, and thus was inherently free of water vapor. After welding, the upset metal was removed from the inside and outside of the tube, and the tube was heat treated to a tensile strength of 190,000 to 200,000 psi.

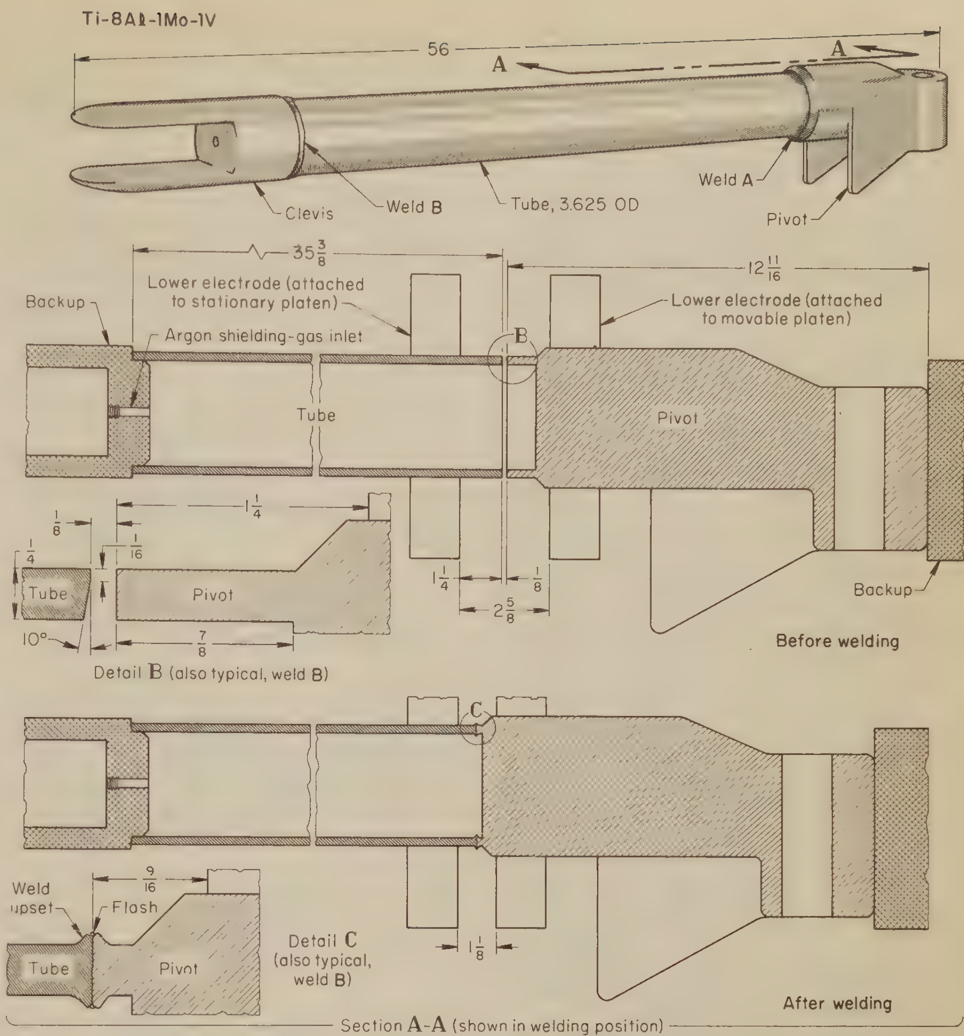
The welded tubes were then subjected to a fatigue test using a rotating beam with constant deflection, which developed a maximum fiber stress of 115,000 psi in the welds. Fatigue life of the welds made in the three atmospheres was as follows:

Welding atmosphere	Dew point, F	Cycles to failure	Number of specimens
Air	65	10,290	9
Dry nitrogen	20	11,050	4
Butane	..	56,800	5

In the following example, titanium alloy forgings were flash welded to each end of a length of tube made of the same alloy. During welding, the heated metal was protected from contamination by purging the inside of the tube with argon gas.

Example 444. Shielding a Flash Weld in a Titanium Alloy by Purging the Inside of a Tubular Section With Argon Gas (Fig. 20)

The components of the drag strut shown in Fig. 20 were made from two titanium alloy forgings (Ti-8Al-1Mo-1V) and a length of tube of the same alloy. The workpieces were joined by flash welding in two setups. During welding, the work metal was protected from contamination by introducing argon into the tube and allowing it to escape through the flashing edges. For the first weld, the argon was fed into the tube through an inlet in the fixture



Initial die opening	2⅝ in.	Total metal lost per weld	1⅜ in.
Final die opening	1⅛ in.	Flashing current	34,100 amp
Initial gap	⅛ in.	Flashing voltage	4 v
Platen travel:		Flashing time	15 sec
Manual flashing	⅛ in.	Upsetting time	10 sec
Automatic flashing	¾ in.	Current flow after start of upset	7 cycles
Upsetting	⅝ in.	Postheat time	7 cycles
Total	1½ in.	Shielding gas	Argon

Fig. 20. Drag strut made by flash welding two Ti-8Al-1Mo-1V titanium alloy forgings to the ends of a tube made of the same material, under the conditions given in the table, and setup for gas shielding and flash welding one of the joints (Example 444)

backup that supported the tube end (see section A-A in Fig. 20). A hole through the clevis forging provided a means for introducing the argon into the tube for the second weld.

The ends of the forgings and the tube were machined in the weld area and cleaned with a solvent before flash welding. The counterbore in each forging provided a weld area that matched that of the tube. The ends of the tube were chamfered as shown in Fig. 20 so that flashing would start near the outer surface.

The workpieces were not preheated, but the flashing current was permitted to flow for seven cycles after upsetting started, to ensure proper upsetting temperature. After upsetting was complete, the welds were postheated for seven cycles.

Weld specimens were tension tested to verify the suitability of the welding conditions listed in the table with Fig. 20. The flash welded joint in the test specimens had an average tensile strength of 142,000 psi; the base metal had a tensile strength of 143,000 psi.

The procedure for qualifying the machine settings followed the requirements of MIL-W-6873, which covers flash welding of carbon and low-alloy steels.

The welding machine had a rating of 800 kva and a maximum upsetting force of 200,000 lb. The platen was cam-actuated through a cam ratio of 1½ to 1.

Suitability of Welds for Forming

The upsetting action that occurs in flash welding not only forces molten metal and oxide impurities out of the weld but also produces a microstructure resembling that of a forging. The grain structure at the bond line is essentially the same as that of the heat-affected zone on either side of the bond line, except for size.

The high ductility of flash welds in low-hardenability metals permits subsequent cold forming operations of varying degrees of severity without postweld heat treatment. Cold rolling, cold bending, spinning, hot forming and wiredrawing also can be applied to flash welded products.

The automotive wheel rim in the following example was made from low-

carbon steel by flash welding at a high production rate. The flash welded band was roll formed cold without prior heat treatment and with no fracturing of the weld that could cause air leaks.

Example 445. Production of a Rim for an Automotive Wheel (Fig. 21)

The rim portion of an automotive wheel, shown in Fig. 21, was made from 1012 steel strip stock by automatically flash welding a ring-rolled band, then progressively roll forming the cross-sectional contours. The surface of the rolled ring was shot blasted before welding.

The input rating of the flash welding machine was 600 kva, 440 volts, single-phase, 60 cycles. The maximum output rating of the secondary was 2000 amp at 15 volts. The current used for this workpiece was 1800 amp at 12 volts.

The movable platen was actuated by a cam mechanism. Clamping dies were made of RWMA class 3 electrode material. An air cylinder, using an air pressure of 70 psi, applied the clamping force on electrodes ⅝ in. wide by 8½ in. long with knurled or serrated surfaces. The unformed flat areas along the abutting edges of the band, which are common in roll forming, extended on both sides of the jaws and facilitated clamping and ensured alignment of the abutting edges.

A strip 43⅛ in. long was sheared from the coil and was automatically transferred to a ring-rolling station, and then to the welding station. The ends of the circular strip were gripped and forced together under high pressure during welding. Metal lost during flashing and upsetting was approximately ⅜ in. The coil stock was 0.130 in. thick and $8\frac{7}{16}$ in. wide.

After the weld upset was scarfed, the band passed through a bath of lubricating oil and into a series of four forming rolls and an expander that progressively formed the band into the cross-sectional shape shown in Fig. 21. After the contour roll forming operation, portions of the finished rim were as much as 25% greater in diameter than the flash welded band.

The completed rim was then degreased, dried and conveyed to a station where an operator placed the spider into the rim. The assembly was moved automatically to a press where the spider was press fitted into the rim for resistance spot welding (for a description of that welding operation, see Example 373, on page 408).

The completed wheel assembly was visually and mechanically inspected for weld integrity and dimensional accuracy. To withstand the forming operations, the flash weld had to be free from pinhole defects caused by sulfur, aluminum, or slag in the steel. Pinholes are also caused by a cold weld or by discontinuous flashing. The finished rim had to have an airtight joint to maintain inflation of the tire.

Production rate was 720 rims per hour. Welding conditions are given in the table that accompanies Fig. 21.

Increased speeds of cold rolling mills and wiredrawing mills have resulted in the production of a higher percentage of off-gage strip and wire while the mills are accelerating and decelerating. The need for uniformity of thickness and for larger coils has led to the adoption of flash welding for joining the ends of several small coils into one large coil before the stock is reduced in thickness or diameter. In these applications, the weld must approach very closely the characteristics of the base metal without varying in uniformity and must be able to undergo the same deformation by cold reduction. In the following example, flash welded joints were reduced in diameter by wiredrawing as easily as was the base metal.

Example 446. Joining of Aluminum Alloy Rods by Flash Welding To Allow a Continuous Wiredrawing Operation

Aluminum alloy 5056-O rods, ⅜ in. in diameter, were joined by flash welding to permit continuous wiredrawing. The high joint efficiency and consistently high quality of flash welds permitted the rods to pass through five drawing operations with a minimum of downtime due to breakage.

The die diameter and reduction in area of the rods for each wiredrawing operation were as follows:

Operation No.	Die diameter, in.	Cross-sectional area, sq in.	Reduction in area, %
1	0.296	0.0688	37.7
2	0.234	0.0430	37.5
3	0.196	0.0302	29.8
4	0.168	0.0222	26.5
5	0.120	0.0113	49.0

Pinch-type dies were used to ensure high-quality welds and to assist in removing the weld upset. The welding conditions were as follows:

Initial die opening ....0.760 in.
Final die opening ....0.010 in.
Flash-off length, total ....0.500 in.
Upset length, total ....0.250 in.
Flashing velocity ....0.25 in. per second
Upsetting velocity ....5 in. per second
Flashing time ....2 sec
Upsetting time ....0.05 sec (3 cycles)
Open-circuit voltage ....12.6 v
Clamping force ....6500 lb
Upsetting force ....3200 lb

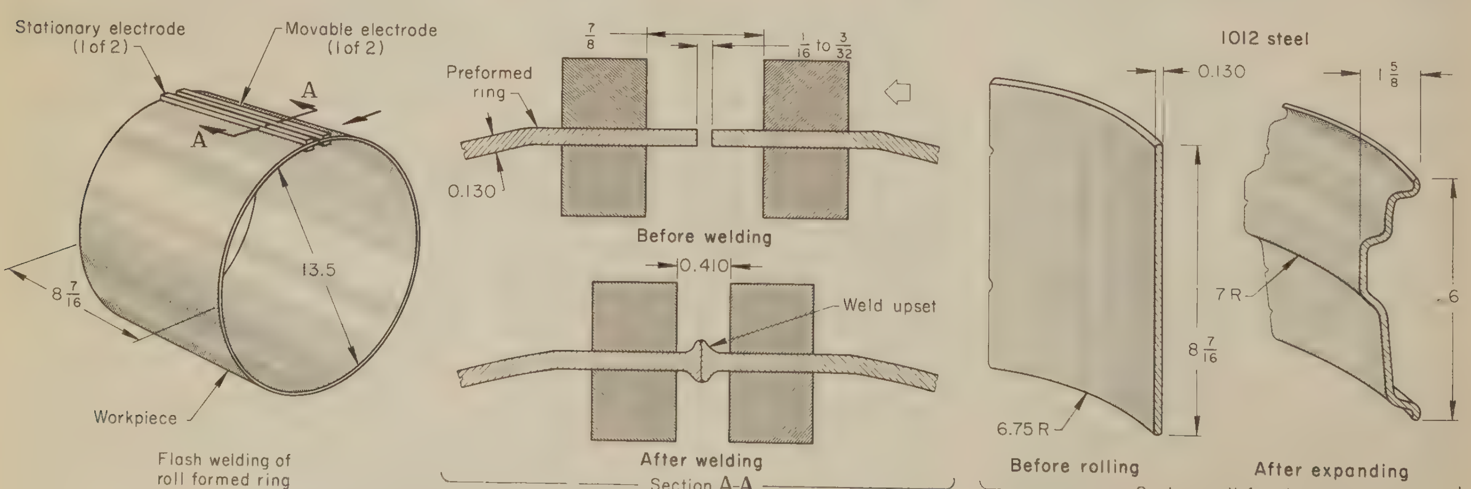
Causes and Prevention of Weld Defects

Common defects in flash welds include: circumferential crevices at the bond line that appear after removal of the upset; cracking caused by brittleness in the heat-affected zone; cast metal in the weld; voids, oxides and inclusions in the weld; and intergranular oxidation and decarburization in the heat-affected zone.

Circumferential Crevices. If either heating or upsetting is insufficient, bonding will not extend across the entire workpiece and into the weld upset, and removal of the weld upset will reveal the presence of an unwelded area in the workpiece at the joint. Such a crevice indicates that a 100% bond has not been obtained, and that the strength of the workpiece may be less than minimum requirements. This type of defect usually can be prevented by the use of greater upsetting pressure or the use of more heat, or both.

Cracking in the heat-affected zone, caused by rapid cooling, can be minimized by releasing the electrodes immediately after upsetting and transferring the workpiece to a furnace for temperature equalization and controlled cooling. After the workpieces have been uniformly heated in the furnace, they can be buried in lime, powdered mica or asbestos feathers to ensure slow cooling. If a furnace is not available and the workpieces are of carbon steel, the weld can be reheated in the welding machine by passing current through the finished weld until a dull-red color is seen. Then the current is turned off, the electrodes are quickly unclamped, and the workpiece is buried in lime or other insulating material for slow cooling.

In the flash welding of parts made of dissimilar steels, such as welding of high speed steel drills to medium-carbon steel shanks, slow cooling must be ensured to avoid cracks in the steel of higher hardenability. New drills made by flash welding normally are fully heat treated after welding. When drills are repaired, or are made longer by flash welding a short drill to a shank extension, rehardening after welding



Initial die opening, ⅞ in.; final die opening, 0.410 in. min.; initial extension per piece, $1\frac{3}{32}$ in.; total metal lost, ⅜ in.; output current, 1800 amp at 12 volts; flashing and upsetting time, 90 cycles (1.5 sec)

Fig. 21. Setup for flash welding, and results of contour roll forming, a 1012 steel band in production of an automotive wheel rim (Example 445)

may not be feasible, and slow cooling is necessary — not only to prevent cracking, but also to minimize brittleness in the weld zone. Such brittleness could lead to failure of the tool in service. In a few applications, the parts to be welded are furnace preheated, welded, and immediately furnace heat treated to prevent cracking.

Cast Metal in the Weld. A certain amount of molten metal forms at the weld faces during flashing and should be extruded from the weld during upsetting, leaving the weld area in a homogeneous condition. However, pockets of molten metal sometimes are trapped in the weld and appear as cast metal under a microscope. Because cast metal is likely to contain small shrinkage cracks and is of lower ductility than worked metal, its presence should be reduced to a minimum.

Cast metal may be trapped in welds between dissimilar alloys that have widely differing hot compressive strengths. The metal or alloy with the lower hot compressive strength upsets to a greater degree, and so entraps cast metal in the weld. Metals with high electrical resistivity become hotter during welding, increasing the probability of formation of cast metal.

Voids frequently are formed when the piece being welded is too large for the welding machine and the upset pressure is insufficient to close all the craters formed during flashing. Sometimes, molten metal formed at the weld interface may be extruded into a void during upsetting, and can be seen under the microscope as a globule of cast metal in the void.

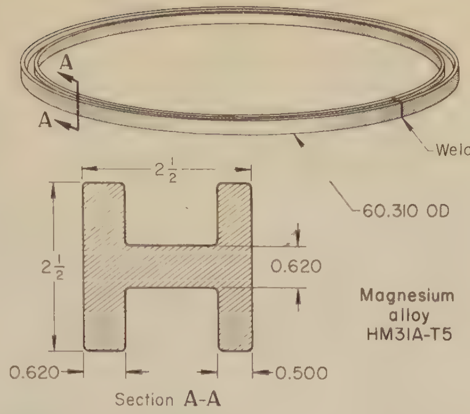
Oxides and other inclusions may be present in joints that have been welded with insufficient upsetting force to expel them, or at too low a temperature to give plasticity to the weld region. Inclusions are very small but they weaken the weld, and heat treatment does not remove them or improve the properties of the weld.

Another type of inclusion is referred to as a penetrator. Penetrators are more prevalent when a high flashing voltage is used, and are caused by large temperature gradients, occluded gas, and nonmetallic inclusions that are trapped in craters in the flashing surface during upsetting. The occurrence of penetrators can be minimized by using the correct voltage, platen speed and flashing gap, and using a protective atmosphere.

Decarburization. During flash welding, high-carbon steel loses carbon along the flashing surfaces, especially when welding is done in air or in an atmosphere of moist gas. The decarburized metal is not entirely expelled during upsetting and some remains in the weld as a zone of weakness.

Intergranular oxidation ("burning") generally is caused by improper material extension during welding of dissimilar metals. Sufficient heat can be developed to oxidize the metal at a point behind the weld. Sometimes, oxidation can cause the workpieces to fall apart in the oxidized region.

Improper contact between the electrode and the workpiece can cause a locally melted or burned area beneath the electrode.



Initial die opening	3¼ in.
Final die opening	1/16 in.
Initial extension per piece	1⅝ in.
Total metal lost	3 3/16 in.

Fig. 22. Ring that was made by flash welding a formed magnesium alloy extrusion (Example 447)

Flash Welding vs Alternative Processes

In some applications, flash welding is the best joining method regardless of the quantity of parts to be produced. Other parts that can be produced by flash welding can be produced equally well by other joining processes, or by forging.

In the following example, the alloy specified was not available as a forging, and flash welding was the only joining process that could produce welds with properties equal to 90% of those of the base metal.

Example 447. Flash Welding of Extruded Magnesium Alloy Rings (Fig. 22)

Flash welded rings, such as the one shown in Fig. 22, were fabricated from H-shape magnesium alloy HM31A-T5 extrusions. The welds were required to have tensile properties equal to 90% of the minimum specifications of the base metal, without subsequent heat treatment. Flash welding was the only joining process that could meet this requirement.

An extruded shape was used instead of a rectangular bar, to minimize finish machining. The magnesium alloy extrusions conformed to AMS 4389, which specifies minimum tensile strength of 37,000 psi and minimum elongation of 4%.

The rings were made in the following seven operations:

1. The extruded shape was formed into an open ring of approximately the finished diameter, with special tooling in a 30-ton hydraulic forming machine at a forming temperature of 750 F.
2. The open ring was band sawed to the proper circumference, allowing stock for flash-off and upset. The as-sawed edges were suitable for welding and needed no further preparation.
3. After preheating the ends of the ring and the steel clamping dies, the ring was flash welded.
4. The weld upset was removed flush with the base metal by snag grinding.
5. The welded ring was heated in a furnace and expanded to size in a sizing and flattening fixture. This operation also proof tested the joint.
6. The weld was inspected using the dye-penetrant method.
7. A ring was machined from each welded ring, and a specimen was cut from it for tension testing across the weld.

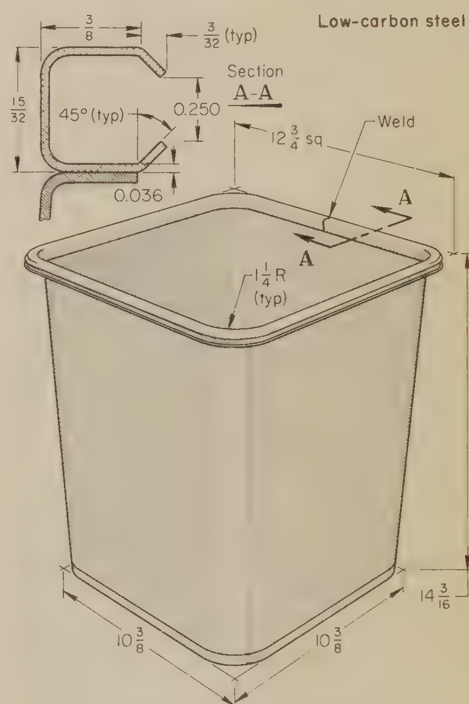
The specification for proof testing the welded joint required that the base metal and the metal in the heat-affected zone be elongated a minimum of 1%. Because the heat-affected metal was more ductile than the base metal, the heat-affected metal required an elongation of about 1½% between gage points to correspond to an elongation of 1% in the base metal.

The welding machine had an input rating of 1600 kva, a maximum secondary output rating of 160,000 amp at 25 volts, and a platen force of 500 tons max. The actual welding current used was 60,000 amp at 9 volts. The clamping dies were made of O1 tool steel machined to the diameter of the ring and the contour of the extrusion. Pinch-type dies were used to obtain more consistent weld quality and to trim the weld upset.

A 500-ton hydraulic press was used to apply pressure on a segmented sizing die.

The tension-test specimen was cut in a boring mill. The results of the tensile test showed that the weld area had mechanical properties between 90% and 100% of the minimum specifications of the base metal. Tensile elongation of the test specimens ranged from 5% to 10%.

In the following example, torch brazing was replaced by flash welding to increase production rate from 144 to 275 pieces per hour. In addition, the improved quality of welded joints obtained by using flash welding greatly reduced the rejection rate.



Comparison of Production Rates

Torch brazing(a)	144 pieces per hour
Flash welding(b)	275 pieces per hour

Conditions for Flash Welding

Initial die opening	1⅝ in.
Final die opening	1¼ in.
Initial extension per piece (max)	¾ in. per side
Flash-off length, per piece	1/16 in.
Upset length, per piece	1/16 in.
Total metal lost	¼ in.

(a) Sequence of operations: position in fixture; apply flux; apply torch to heat; braze; cool and soak off flux; dry and apply rust preventive; belt-sand and grind. (b) Sequence of operations: position in welding machine; weld; belt-sand and grind.

Fig. 23. Wastebasket for which production rate was increased when method of joining contour roll formed top channel was changed from torch brazing to flash welding (Example 448)

Example 448. Change From Torch Brazing to Flash Welding To Increase Production (Fig. 23)

The low-carbon steel top channel for a wastebasket, shown in Fig. 23, was made by bending a contour roll formed section into an open square-shape loop and joining the ends by torch brazing. The channel was then spot welded to the basket body and painted, and a plastic bumper surrounding the basket was installed in the open legs of the channel. The process for making the butt joint was changed to flash welding because, with brazing, two shifts of eight hours each were unable to supply enough channels for one shift of basket production.

The 0.036-in.-thick cold rolled low-carbon steel strip was contour roll formed in a four-pass mill and was cut to length in a flying cutoff shear. The channels were formed two at a time in a powered tube-bending machine, and were then placed in a fixture for brazing. After the metal around the brazed joint had cooled, the loop was placed in hot water to dissolve the flux, or to soften it for removal. After the flux was removed, the part was dried and a rust preventive was applied to the inner and outer surfaces. The excess brazing filler metal was removed from the outer surfaces of the channel with a belt sander, and from the inner surfaces with a thin grinding wheel.

The flux used was AWS type 5 (borax), and the filler metal was RCuZn-C, a low-fuming material.

Both the production rate and the quality of the joint surface after removal of the excess brazing filler metal were important factors in considering another process.

When the joining process was changed to flash welding, the same basic manufacturing sequence was followed. However, since the loops were not dipped in water, a rust-preventive coating was not needed. The time required for cleaning the welded workpiece was greatly reduced, and only two operators were needed for this work, instead of three.

The input rating of the flash welding machine was 110 kva, 220 volts, single phase, 60 cycle, with 20-kva demand at 50% duty cycle. The transformer had a series-parallel winding and four taps. The parallel winding and the No. 4 tap were used, producing the maximum secondary current of 22,000 amp at 4.4 volts.

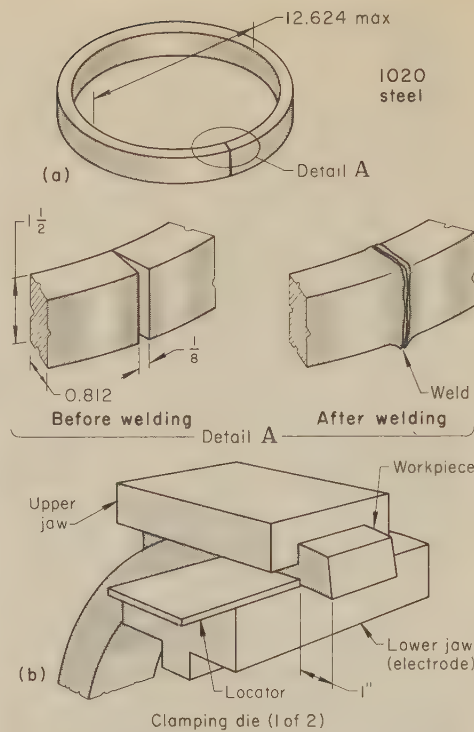
Special air-actuated dies were used to clamp the workpiece in the machine. The movable platen was also air-actuated, and could exert about 125 lb of force. The upper dies were made of RWMA class 3 electrode material, and the lower dies were made of an oil-hardening tool steel.

The flash welded joints were of high quality, and rejections were almost nil. Testing was done by dropping a welded part from a height of 36 in. onto a steel plate. The production rate was 275 pieces per hour, compared with 144 per hour when the joints were brazed. Sequence of operations for both processes, and conditions for flash welding, are given in the table that accompanies Fig. 23.

Forging is a common method of producing rings in any forgeable alloy, but metals that scale easily have a sizable material loss during forging. In the following example, three-roll forming and flash welding of bar stock were used to produce rings of a quality equal to those made by forging.

Example 449. Change From Forging to Three-Roll Forming and Flash Welding To Produce a Ring (Fig. 24)

The fin-ring blank shown in Fig. 24 originally was machined from a forged ring. When the method of manufacturing the blank was changed to three-roll forming and butt welding, flash welding was chosen as the joining process to minimize slag and oxide particles in the joint. Weld quality was checked radiographically.



Sequence of Operations

1 Die cutoff bar to length
2 Three-roll form the ring
3 Press form mating areas
4 Flash weld
5 Remove weld upset
6 Size inside diameter

Welding Conditions

Initial die opening	2 in.
Final die opening	1¼ in.
Initial extension per piece	1 in.
Flash-off length, total	½ in.
Upset length, total	¼ in.
Total metal lost	¾ in.

Fig. 24. Fin-ring blank that was flash welded in the setup shown (Example 449)

Table 10. Time and Costs for Flash Welding vs Gas Tungsten-Arc Welding of Forty Stainless Steel Rings (Example 450)

Item	Gas tungsten-arc welding	Flash welding
Welding time, minutes	3.75	1.7
Total time, minutes(a)	8.00	6.6
Cost Comparison		
Labor ($3 per hour)	$0.40	$0.33
Welding supplies(b)	0.50	None
Work-metal loss	None	0.40
Total	$0.90	$0.73
Savings for 40 rings		$0.17

(a) Includes loading, unloading and scarfing. (b) Includes the cost of 17-7 PH filler wire, inert gas for shielding, and tungsten electrodes.

The rolled ring was made of special-quality 1020 steel that met specification QQ-S-631. Bar stock size was 13⁄16 in. thick by 1½ in. wide by 42½ in. long. In three-roll forming a bar, a short length on each end of the bar cannot be formed, so to maintain alignment during flashing and upsetting, the butted ends were press formed after rolling. Detail A in Fig. 24(a) shows the butted ends of the ring before and after welding.

The input rating of the welding machine was 250 kva, 440 volts, single phase and 60 cycles. The maximum secondary output rating was 84,000 amp at 7.8 volts. The transformer had eight taps, and No. 6 was used for this operation. Heat control was available, but was not used. The machine was loaded and unloaded manually, but the welding cycle was automatic. The maximum available force on the platen was 40,000 lb. The platen opening was 4 in. max and 1¼ in. min.

The workpiece was held in serrated jaws about 3 in. wide (contact area of 2.4 sq in.). The jaws were closed with a cam, which was operated by an air cylinder. The lower jaws, which conducted the current to the work metal, were made of RWMA class 3 electrode material, and were machined to the inside diameter of the ring. A lower locating gage positioned the workpiece on the lower jaws. The upper jaws were made of A2 tool steel and were mounted in a holder fastened to the clamping arm. A slot in the upper jaws that was machined to the outer contour of the ring clamped the workpiece to the lower jaws and prevented mismatch.

The arrangement of the clamping jaws is shown in Fig. 24(b).

The platens on which the lower jaws were mounted were made of an electrically conductive material. The movable platen was actuated by a hydraulic cylinder that had a nitrogen-gas-filled accumulator in the circuit. The platen speed was controlled by a rotary cam.

A two-station die with high speed steel cutters was used to remove the weld upset. The welded ring was sized by expanding it approximately ⅛ in. to an inside diameter of 12.604 ± 0.020 in.

The quality of the finished product was ensured by having the steel mill certify the work metal and by carefully inspecting ring size and alignment of the ends before welding. For each shipment of bar stock, a test coupon containing a welded joint was used to verify that the weld was stronger than the base metal. Also, each weld was examined radiographically.

Average time for flashing and upsetting was 0.26 min. Production rate was 65 welds per hour. Cost for labor and overhead was $0.135 per weld. Sequence of operations and welding conditions are given in the table that accompanies Fig. 24.

Many factors enter into the total cost of a particular welding process. In the following example, manual dexterity of the operator and the differentials between work-metal and welding-supply costs for each method were the principal factors in cost analysis.

Example 450. Comparison of Costs for Flash Welding vs Gas Tungsten-Arc Welding a Stainless Steel Ring (Table 10)

Costs were compared for butt welding the stainless steel ring described in Example 433 and illustrated in Fig. 12 by gas tungsten-arc welding and by flash welding.

Weld properties were not major factors in this comparison, because both welding processes developed heat-affected zones that responded favorably to subsequent heat treatment, and produced equally strong joints.

Many of the manufacturing steps were the same for both processes. The coiled strip was uncoiled, straightened, pierced, sheared to length, formed into a ring and edge trimmed before welding. After welding, both types of welds required comparable time for removal of weld flash and buildup.

The average cost per piece for each welding operation was affected by differences in setup and in level of operator skill. Costs of work metal and welding supplies also affected the total cost, as shown in Table 10. The 50-kva flash welding equipment cost about $10,000 installed, and the arc welding machine and equipment cost about $9000.

The fixture for the gas tungsten-arc welding equipment had space for 40 rings, and 40 was used as the lot size for comparing the costs of the two processes. Costs for making the rings by each process are given in Table 10.

Friction Welding

*By the ASM Committee on Flash, Friction and Stud Welding**

FRICTION WELDING is a process in which the heat for welding is produced by direct conversion of mechanical energy to thermal energy at the interface of the workpieces without the application of electrical energy, or heat from other sources, to the workpieces. Friction welds are made by holding a nonrotating workpiece in contact with a rotating workpiece under constant or gradually increasing pressure until the interface reaches welding temperature, and then stopping rotation to complete the weld. The frictional heat developed at the interface rapidly raises the temperature of the workpieces, over a very short axial distance, to values approaching, but below, the melting range; welding occurs under the influence of a pressure that is applied while the heated zone is in the plastic temperature range.

Friction welding is classified as a solid-state welding process, in which joining occurs at a temperature below the melting point of the work metal. If incipient melting does occur, there is no evidence in the finished weld, because the metal is worked during the welding stage.

A section through a friction weld joining two dissimilar steels is shown in Fig. 1. The steel with the greater forgeability has the greater amount of weld upset. When similar metals are friction welded, the amount of weld upset is about the same on both sides of the bond line.

Applications. Friction welding has been used in high production of hollow precombustion chambers for diesel engines, in welding trunnions to mounting blocks for air and hydraulic cylinders, in welding connectors to piston rods, and in fabricating track-roller hubs and ball-shaft linkages.

In the automotive industry, friction welding is used in fabricating drive shafts, axles, steering shafts and bimetal valves, and for joining hubs to gears. Another application is welding bar stock to small forgings or to plate to produce parts that would otherwise be forged. Blanks for cutting tools are made by welding low-carbon or low-alloy steel shanks to tool steel bodies.

Jet-engine parts are made by welding components made of a heat-resisting alloy to components made of a hardenable or wear-resistant alloy.

Welding Methods. There are three methods of joining workpieces by friction welding: (*a*) conventional friction welding, (*b*) inertia welding, and (*c*) flywheel friction welding.

In conventional friction welding, mechanical energy is converted to heat energy by rotating one workpiece while pressing it against a nonrotating workpiece. After a specific period of time, rotation is suddenly stopped and the pressure is increased and held for another specified period of time, producing a weld.

In inertia welding, the workpiece component that is to be rotated is held in a collet-chuck – flywheel assembly. The assembly is then accelerated to a predetermined speed, at which time the flywheel is disconnected from the power supply and the workpieces are brought into contact under a constant force. Flywheel energy is rapidly converted to heat at the interface, and welding occurs as rotation ceases.

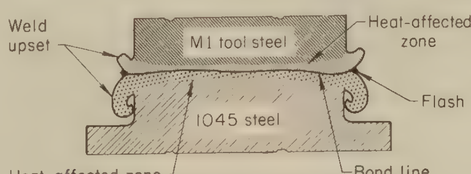
Flywheel friction welding incorporates features of both the conventional and the inertia processes. Flywheels are connected to the drive motor and to the spindle, and are coupled through an integral clutch. The drive-motor – flywheel system rotates continuously and is coupled to the flywheel-spindle system to bring the rotating workpiece to the proper speed. The motor flywheel is disengaged from the spindle flywheel after the desired energy has been extracted. The spindle flywheel, having a low moment of inertia, comes quickly to rest without braking, to complete the weld.

Process Capabilities

Many ferrous and nonferrous alloys can be friction welded. Friction welding also can be used to join metals of widely differing thermal and mechanical properties. Often combinations that can be friction welded cannot be joined by other welding processes because of the formation of brittle phases that would make such joints unserviceable. The submelting temperatures and short weld times of friction welding allow many combinations of work metals to be joined.

End preparation of workpieces, other than that necessary to ensure reasonably good alignment and to produce the required length tolerance for a specific set of welding conditions, is not critical. Frictional wear removes irregularities from the joint surfaces and leaves clean, smooth surfaces heated to welding temperature. In some applications where weld integrity is important, a small projection at the center of one of the weld members is used to ensure proper heating and forging action, and to eliminate center defects. This projection is especially helpful in welding large-diameter bars.

Automatic loading and unloading of the welding machines permit high production rates. For instance, bimetal valves are produced two-at-a-time at a rate of 1200 per hour.



The greater amount of weld upset occurred in the 1045 steel because of its greater forgeability. When workpieces made of the same or closely similar metal are welded, approximately equal amounts of weld upset are formed on both sides of the bond line.

Fig. 1. Cross section through a friction weld joining two dissimilar steels

Other advantages of friction welding include the following:

1. Flux, filler metal or protective atmospheres are not needed.
2. Electric-power and total-energy requirements are a fraction of those needed for other welding processes.
3. The operation is relatively clean, there is little spatter, and no arcs, fumes or scale are developed.
4. The heat-affected zone is very narrow and has a grain size that frequently is smaller than that in the base metal.

Limitations of friction welding are:

1. One workpiece must be round (or nearly round) at the interface and must have a size and shape that can be clamped and rotated. (Hexagon-shape bars have been friction welded to billets.)
2. Workpieces must be able to withstand the torque and axial pressure imposed during heating and forging. (See "Sections Welded", on the next page.)
3. Workholding devices must be strong enough to withstand heavy shock and torque loads.
4. The process is restricted to flat and angular butt welds that are concentric with the axis of rotation (see Fig. 13).
5. Conventional friction welding machines require expensive modifications to be able to weld workpieces that must have final angular alignment.

Economy in Operation and Material. Friction welding can be done at high production rates, and therefore is economical in operation. In applications where friction welding has replaced other joining processes, the production rate has been substantially increased. For instance, in Example 461, production rate was increased from 3 to 30 welds per hour when friction welding replaced pressure gas welding.

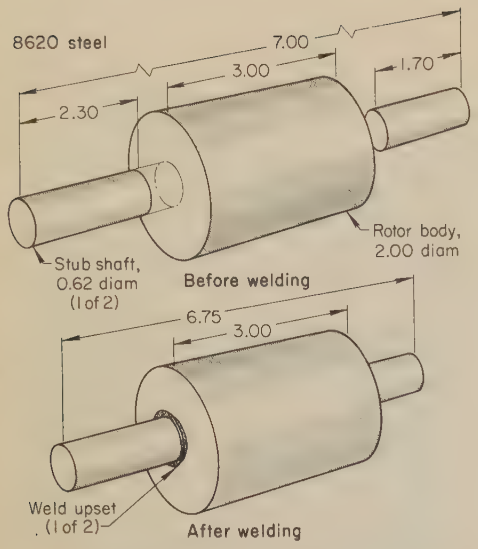
Savings in material also can be realized by the use of friction welding. In Example 454, ¾ in. less metal was needed in friction welding than in flash welding. Also, as described in Example 460, considerable metal was saved by friction welding two pieces of 4140 steel together to make a square-head bolt instead of machining the bolt from a single piece.

Substantial savings in material and machining time can be realized by using friction welding to join stub shafts to large-diameter rotor bodies or other rotating members, or to join components of valve stems — as in the applications described in the two-part example that follows.

Example 451. Changes From Machining Complete From Bar to Friction Welding of Machined Components, for Lower Metal and Machining Costs

Example 451a — Rotor Blank (Fig. 2). A blank for an air-motor rotor (Fig. 2) was made from 8620 steel by joining stub shafts to the ends of the main body by conventional friction welding. In finish machining of the welded blank, the diameter of each of the three pieces was reduced by only 0.060 in., which illustrates the concentricity to which parts can be friction welded. The use of

*For committee list, see page 485. About half of the examples in this article were contributed by members of other Metals Handbook welding committees.



Conditions for Friction Welding	
Spindle speed	2400 rpm
Axial force:	
Heating	2480 lb
Welding	4400 lb
Heat-and-weld time	45 sec per part
Weld area	0.31 sq in. per weld
Metal lost(a)	0.125 in. per weld
Production rate	65 parts per hour

(a) Total axial shortening of the workpieces during welding.

Fig. 2. Rotor blank made by friction welding three pieces instead of by machining from solid bar, to reduce work-metal and machining costs (Example 451a)

friction welding resulted in a 20% material saving and a 39% reduction in machining costs compared with the original method, which was machining from a solid bar.

Time for making the two welds, one at a time, on each rotor blank was 45 sec. The welding machine was manually loaded and unloaded and was equipped with manually actuated chucks for gripping the workpieces. Conditions for friction welding are given in the table that accompanies Fig. 2.

Example 451b — Valve Stem (Fig. 3). The use of friction welding reduced material and machining costs in the manufacturing of the bronze valve stem shown in Fig. 3. Originally, the valve stem was machined complete from a ⅝-in.-diam bar. By friction welding two pieces together and producing a weld upset large enough to provide material from which the flange could be machined to the required final dimensions (see Fig. 3), machining time was reduced 95% and material loss was reduced 98%. The friction weld was made in 7 sec, using a spindle speed of 2200 rpm, a heating pressure of 14,000 psi (about 2100 lb) and a welding pressure of 65,000 psi (about 9750 lb). Total axial shortening of the workpieces during upsetting was 0.150 in. Production rate was 180 valve stems per hour.

Weld Strength. For most metals, the strength of a friction welded joint is about the same as that of the base metal. The metal at the weld interface is hot worked, which refines the grain structure. During the final portion of the weld cycle, upsetting and extrusion of flash ensures removal of oxidized metal that may have been produced during heating. This flash usually appears in the valley at the intersection of the two weld upsets (see Fig. 1).

The relatively large unheated areas adjacent to the joint extract heat quickly from the small mass of the heat-affected zone, thus keeping the zone small in the welded part.

In the following example, the mechanical properties of joints made by friction welding were superior to those of joints made by flash welding.

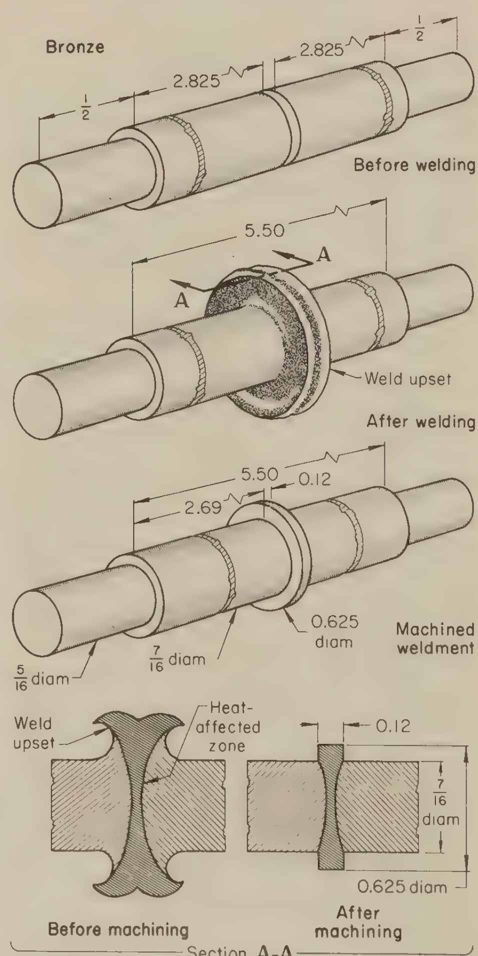
Example 452. Comparison of Properties of Joints Made by Flash Welding and by Friction Welding (Table 1)

A 1026 steel shaft 0.750 in. in diameter was joined to the stub shaft of a worm gear made of 5120 steel by conventional friction welding and by flash welding. Tension tests, rotating-beam fatigue tests and reversed-torsion fatigue tests were made on the weldments. The results of these tests are given in Table 1.

Examination of the microstructures of the welded joints showed a much narrower heat-affected zone and a finer grain structure in the friction welded joint than in the flash welded joint. The friction welded part had a higher tensile strength than the flash welded part.

For flash welding, the shaft had a sheared end and the stub shaft on the worm gear had a specially tapered section that reduced the flashing contact diameter from 0.750 in. to 0.375 in. This tapered section was flashed off during welding. For friction welding, the end of the shaft was used as-sheared but the end of the stub shaft on the worm gear was machined flat. Thus, the need for tapering the end was eliminated by changing from flash welding to friction welding.

In both methods, the worm gear was carburized and hardened before welding, but the stub shaft was flash copper plated,



Work-metal and machining costs were reduced substantially when friction welding replaced machining from bar stock. In the improved method, the center flange was machined from the upset produced by friction welding.

Fig. 3. Friction welded bronze valve stem (Example 451b)

Table 1. Comparison of Properties of Flash and Friction Welded Joints Made Between 1026 and 5120 Steel Bars (Example 452)

Test or property	Flash welding	Friction welding
Tensile strength	70,000 psi	75,000 psi
Bending fatigue time, minutes	32	180
Torsional fatigue time, cycles	1,000,000 (a)	4,000,000 (b)
Metal lost, in. (c)	0.75	0.25

(a) Cycles to failure. (b) Cycles without failure. (c) Axial shortening of bars during welding.

or covered with a tight-fitting cup, to prevent it from being carburized. Thus, the weld areas and the heat-affected zones produced by both welding methods had essentially the same hardness. No heat treatment was needed after welding, because both steels had low carbon contents (although one was a low-alloy steel); the as-welded hardness was acceptable in both the shallow heat-affected zone made by friction welding and in the wider zone made by flash welding.

Line-voltage variations frequently caused a severe drop in the flow of current to the flash welding machine, which resulted in a cold weld. Line-voltage regulators were needed to stabilize the current and shut off the power when the voltage dropped below a predetermined level. In friction welding, line-voltage fluctuations had little effect on the amount of frictional energy produced and voltage regulators were not needed.

The scrap rate for flash welding ranged from 3 to 6%, which was attributed to equipment maintenance, line-voltage variations, and defective components. In friction welding, scrap rate was less than 1%.

Because there is no spatter of weld flash during friction welding, the time required to clean the machines was reduced from 18 hours to less than 5 hours per week. The increased productivity that resulted from less downtime and higher production rate made it possible to use two friction welding instead of five flash welding machines.

Sections Welded. In friction welding, the joint face of at least one of the workpieces must be essentially round. The rotating workpiece should be somewhat concentric in shape because it revolves at a relatively high speed. Workpieces that are not round, such as hexagon-shape workpieces, have been friction welded successfully, but the resulting weld upset is rough, asymmetrical, and difficult to remove without damaging the welded assembly. For a few special applications, welding machines have been modified so that the spindle stops at the same place each time, thus making it possible for workpieces to be oriented to each other.

Solid bars of 1018 steel from ¼ to 4 in. in diameter can be friction welded in the available welding machines. Welding of larger diameters, although feasible, is limited by machine cost.

Wire and tubing of like and unlike metals 1 to 2.5 mm in diameter have been friction welded in special machines to plates 0.2 to 2 mm thick. Wires of unlike metals 1.5 to 2 mm in diameter have been joined.

Tubular sections can be much larger in diameter than the rated capacity of the welding machine for solid bars, and the maximum weldable tube diameter depends primarily on wall thickness. For example, a machine capable of welding a 4-in.-diam 1018 steel bar can weld a 1018 steel tube 30 in. in diameter with a 3⁄16-in.-thick wall. The maximum diameter decreases to about 7½ in. when the wall thickness is 1 in.

The size of section that can be friction welded depends somewhat on the distance the plastic metal must travel to be extruded from the weld interface. Metal in solid bars must travel outward from the center of the bar; metal in tubes can travel both inward and outward from the center of the wall.

Metals Welded

Friction welding can be used to join almost any metal that can be forged and that is not a good dry-bearing metal. The alloying elements that provide dry lubrication (or do not seize under normal operating conditions when without grease or other lubricants) prevent the interfaces from being heated to welding temperature by friction. Metals that contain free-machining additives are likely to be hot short and are generally unsatisfactory for welding.

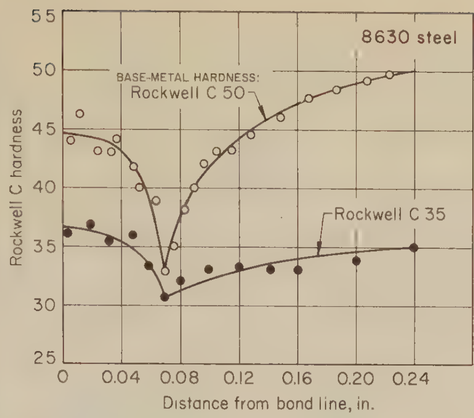
Many similar and dissimilar metal combinations can be friction welded, and in most combinations a sound metallurgical bond is formed. In some combinations, the bond is not as strong as the base metal, and postweld heat treatment may be needed to develop full weld-zone strength in alloy steels and hardenable stainless steels.

Carbon and alloy steels are relatively easy to friction weld. Low-carbon and medium-carbon steels can be welded under a wide range of welding conditions. High-carbon and alloy steels are easily joined but the welding conditions must be controlled within narrower ranges than are permissible for welding low-carbon steels, and the axial pressure must be increased to compensate for lower forgeability.

High speed tool steel can be welded to carbon and alloy steel shanks for making drills, reamers and other cutting tools. Steel balls made of 52100 steel, which is normally difficult to weld, are welded to one or both ends of carbon steel rods to make linkage rods. Frequently the rods are made of 1045 steel and one end is induction hardened before the 52100 steel ball is welded to the opposite end. The weldments are tempered after welding.

Free-machining steels, except those having a high sulfur and low manganese content, can be welded, but the free-machining elements result in undesirable directional properties in the weld zone. Friction welds in free-machining steels have fatigue strength less than 80% that of the base metal and should not be used in applications where high stresses are involved and high fatigue strength is required. Friction welding of free-machining steels should be limited to those with 0.08 to 0.13% sulfur, lead or tellurium. For example, 1141 steel is welded satisfactorily, but 1144 is not.

Heat treated steels can be friction welded with only localized changes in hardness because the heating is confined to a very narrow zone. Also, the rapid quenching restores hardness to the weld zone. For instance, as shown in Fig. 4, when 8630 steel bars were hardened to Rockwell C 35 or C 50 and then were friction welded, the minimum hardnesses (Rockwell C 33 for the Rockwell C 50 steel; Rockwell C 31 for the Rockwell C 35 steel) occurred at about 0.065 in. from the bond line; the heat-affected zone extended about 0.24 in. into the base metal. In welding hardenable steel, the weld upset usually reaches a high hardness because of rapid quenching. Therefore, the weld upset usually must be removed by grinding, or by machining after annealing. In some applications, the upset is removed by hot shearing before it has cooled from the welding temperature to the M_s temperature.



Bars for upper curve postweld tempered at 400 F; those for lower curve, at 1000 F.

Fig. 4. Relation of metal hardness in the heat-affected zone to distance from the bond line after friction welding 8630 steel bars having hardnesses of Rockwell C 35 and C 50

Sintered metals are further compacted during friction welding and have a wrought structure in the weld zone. The joint usually is stronger than the base metal.

The results of friction welding steel forgings and steel castings are about the same as those of friction welding steel bars of similar composition.

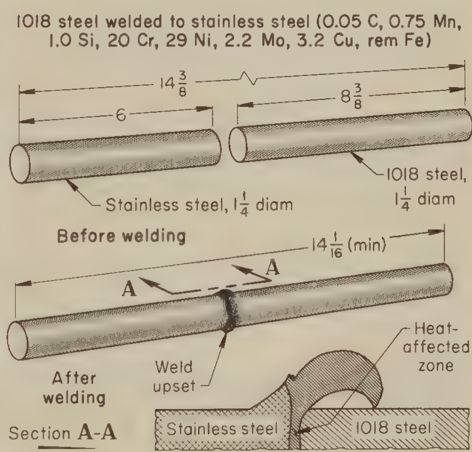
Stainless steels are comparatively easy to friction weld, and good weld properties can be obtained under a wide range of welding conditions. The heat treatable stainless steels are sensitive to heat and pressure and, for good weld properties, require postweld heat treatment in the heat-affected zone. An important application of friction welding of stainless steel is the production of bimetal shafts that are exposed to a corrosive atmosphere or to wear in service. To provide the correct type of resistance where needed, to reduce work-metal cost, or to increase machinability, an alloy that will withstand a corrosive atmosphere can be joined to a metal that is less expensive and easier to machine, as in the example that follows.

Example 453. Comparison of Costs for Making a Pump Shaft by Machining From One Piece of Stainless Steel and by Machining an Inertia Weldment (Fig. 5)

The cost of making the pump shaft shown in Fig. 5 from one piece of stainless steel (0.05 C, 0.75 Mn, 1.0 Si, 20 Cr, 29 Ni, 2.2 Mo, 3.2 Cu, rem Fe) was compared with the cost of making the shaft by inertia welding a bar made of the same stainless steel to a bar made of 1018 steel. In making the bimetal shaft, most of the machining was done on the 1018 steel, which was less expensive and easier to machine than the stainless steel.

When the shaft was made from the two metals instead of from stainless steel only, material cost was reduced by 45% and machining cost was reduced by 10%. Metallographic examination of the inertia welded joint showed good fusion, and when the shafts were field tested in pumps running at 3500 rpm, no failures were reported.

Before welding, the ends of both bars were ground to remove any mill scale. After welding, weld upset was removed as the shaft was machined to size. In order to produce good welds, leaded low-carbon steel was not used. The conditions for inertia welding and the production rates are given in the table that accompanies Fig. 5.



Conditions for Inertia Welding

Flywheel moment of inertia	50 lb-ft^2
Spindle speed	3150 rpm
Weld energy(a)	84,000 ft-lb
Axial force	60,000 lb
Heat-and-weld time	2 to 4 sec
Weld area	1.23 sq in.
Metal lost, max(b)	5/16 in.
Production rate:	
Manual	120 welds per hour
Automatic	360 welds per hour

(a) Calculated from flywheel size (moment of inertia) and spindle speed. (b) Total axial shortening of the workpieces during welding.

Fig. 5. Pump shaft that was made by machining an inertia weldment of stainless steel and 1018 steel, instead of by machining from stainless steel only, to reduce costs (Example 453)

Cast iron in any form — gray, ductile or malleable — has not been friction welded satisfactorily in production. (Joining of ductile iron to steel in laboratories has been reported.) Free graphite gathers at the interface and acts as a lubricant, which limits friction heating. Also, these materials are not forgeable, which is a general requirement for friction welding.

Nonferrous Metals and Alloys. Aluminum alloys are friction welded to similar and dissimilar aluminum alloys, copper alloys to similar and dissimilar copper alloys, and aluminum alloys to copper alloys. Most applications of friction welding these metals are in joining aluminum and copper alloys to steel, although problems are presented by high thermal conductivity, large differences in forging temperatures, and the formation of brittle intermetallic compounds.

Joints between aluminum alloy 6061 and copper have a tensile strength near that of the copper. Joints between aluminum alloy 1100 and stainless steel have a strength near that of the aluminum alloy. Friction welding of other aluminum alloys may develop a joint strength of only 60 to 70% that of the weaker base metal. Even though these

joints are relatively weak, they are useful for pressure sealing and for joining assemblies that require good electrical and thermal conductivity, rather than high strength.

Titanium, titanium alloys, zirconium alloys and magnesium alloys can be friction welded to themselves.

Most nickel-base and cobalt-base alloys, including the heat-resisting alloys, are easily welded to themselves and to alloy steels. The nickel-base alloy GMR-235 can be welded to 1040 steel, Inconel 718 to Inconel 713C, and Inconel 713C to 8630 steel in producing jet-engine parts that require high-strength bonds.

The refractory metals — tungsten, molybdenum, columbium and tantalum — can be welded to themselves. Friction welds between molybdenum rods are ductile enough to withstand substantial reduction by wire drawing.

Conventional Friction Welding

Conventional friction welding requires a machine resembling an engine lathe equipped with an efficient spindle-braking system, a means of applying and controlling axial pressure and a weld-cycle timer and control. The equipment is simple in principle, but the machines are complex when big enough to weld large workpieces.

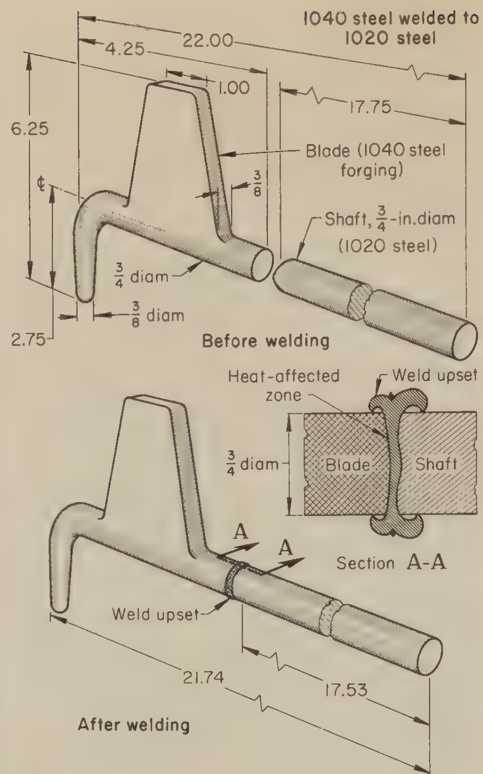
Principle of Operation. The workpiece to be rotated is clamped in the spindle chuck, and the spindle is brought to a predetermined speed. The nonrotating component is clamped in a chuck or fixture mounted to a hydraulically actuated tailstock slide. To heat the workpieces to welding temperature, the tailstock slide is advanced to bring the workpieces in contact under a constant or gradually increasing axial pressure. When the workpieces are at, or slightly above, the welding temperature, the spindle brake is applied, which suddenly stops the spindle rotation. Simultaneously, the tailstock pressure is increased to complete the weld.

The spindle speed, axial pressure and length of time the pressure is applied for a given weldment depend on (*a*) the cross-sectional area of the workpieces to be welded; (*b*) the melting point and thermal conductivity of the work metal; and (*c*) the metallurgical changes that occur during the heating cycle, particularly when dissimilar metals are being welded.

Process variables to be controlled are rotational speed, initial (heating) pressure, length of time that heating pressure is applied, and welding pressure. The time needed to stop the spindle can affect the temperature to which the workpieces are heated, timing of application of the welding pressure, and weld properties.

Rotational speed, or peripheral velocity, is the least sensitive process variable and can be varied over a wide range if heating time and pressure are properly adjusted. However, heating time must be limited to prevent excessive depth of heating. The peripheral velocity recommended for welding most low-carbon, medium-carbon, and high-carbon steels is 400 to 1400 sfm.

Heating pressures used for welding low-carbon and low-alloy steels are from 3000 to 20,000 psi. Welding pressures for these steels are from 5000 to 25,000 psi. Usually, the welding pressure is higher than the heating pressure, but sometimes they are nearly the same.



Item	Welding process Flash	Friction
Cost Comparison		
Production, parts per hour	240	300
Steel savings(a)	...	\$5500
Scrap loss(b)	6 to 7%	½ to 1%
Forging scrap loss	3.5%	1.5%
Fixture maintenance(c)	\$1830	\$1050

(a) For each 100,000 units. (b) From misalignment, burns and other causes. (c) Cost per year.

Fig. 6. Shutdown-control shaft that was made by joining a steel forging to a steel shaft at lower cost by friction welding than by flash welding (Example 454)

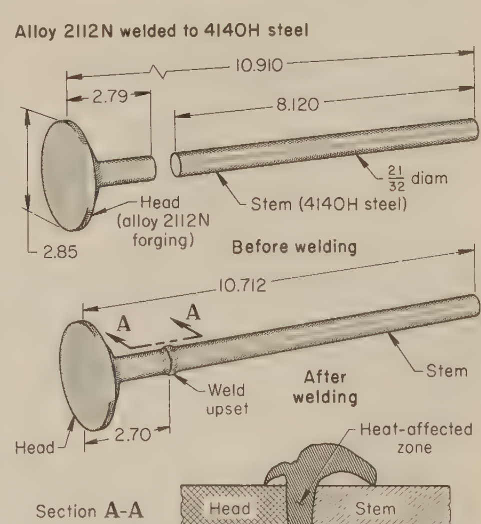


Fig. 7. Diesel-engine exhaust valve that was made by friction welding a heat-resisting alloy to a low-alloy steel (Example 455)

For medium-carbon and high-carbon steels, heating pressures are from 10,000 to 30,000 psi, and welding pressures are from 15,000 to 60,000 psi. Lower heating pressures are sometimes used for large workpieces so that the power requirements do not exceed the capacity of the welding machine.

Heating time varies with the heating pressure, the carbon and alloy content of the steel, and the diameter of the workpiece. Usually, heating time is determined by trial.

The spindle should be stopped rapidly to keep the weld from twisting or tearing. For a workpiece less than ½ in. in diameter, stopping time should be within 1½ sec; a 3-in.-diam bar should be stopped within 3 sec.

Examples of Practice. Only minor alterations in design are needed to adapt to friction welding a workpiece that previously was butt welded by other processes. Generally, in friction welding less metal is lost during heating and upsetting than in flash welding, and it is not necessary, as it is in flash welding, to machine the interface so that heating will start at the center of the workpiece section. Where allowances are made in the size of a forging for differences in metal lost and for welding in the as-forged condition, forging costs can be reduced, as in the following example.

Example 454. Comparison of Friction Welding and Flash Welding of Shutdown-Control Shafts (Fig. 6)

The shutdown-control shaft for a textile loom was made by butt welding a ¾-in.-diam 1020 steel shaft to a forged 1040 steel blade, as shown in Fig. 6. In service, these shafts received severe impact loading and thus required excellent weld quality. Satisfactory joints were made by both flash welding and conventional friction welding, but scrap loss was lower with friction welding than with flash welding because of better accuracy of alignment.

For friction welding, the stub shaft on the forging was ¾ in. shorter than that needed for flash welding because no metal was lost during flashing and the forging was not machined before welding. The over-all length of the control shaft was not held to close tolerances, and therefore, the stub shaft on the blade was friction welded in the as-forged condition. The stub shaft was machined before flash welding so that flashing would start at the center. The shorter forging used for friction welding was easier to produce and required less material. The 1020 steel shaft was used as-sheared for both processes.

The only machining required on the friction welded shaft was removal of the weld upset by grinding. This finished surface served as a bearing journal for the blade end of the shaft.

A comparison of costs for flash and friction welding of the shafts is given in the table that accompanies Fig. 6.

Workpieces made of dissimilar metals are frequently used in order to minimize costs while still providing, where needed, a work metal that meets the necessary service requirements. Many corrosion-resisting and heat-resisting alloys are welded to less expensive alloys to reduce material and machining costs, or to provide a wear-resistant surface. This was done in Example 453 (in which a high-alloy stainless steel was friction welded to 1018 steel), and in the exhaust-valve application described in the example that follows.

Example 455. Production of Diesel-Engine Exhaust Valves by Friction Welding Dissimilar Alloys (Fig. 7)

A large exhaust valve for a diesel engine, shown in Fig. 7, was made by conventional friction welding a head made of a heat-resisting alloy to a low-alloy steel stem. This permitted using the more expensive (heat-resisting) alloy only where required.

The head was forged from alloy 2112N (a 21Cr-12Ni austenitic iron-base alloy used for exhaust valves), and the stem was made of 4140H steel $^{21}/_{32}$ in. in diameter. The initial weld area was 0.34 sq in. Overall length of the part after joining by friction welding was 10.712 in.

A 25-hp friction welding machine was used, although the peak requirement was only 5 hp.

In operation, the valve head was clamped in an air-actuated fixture mounted in the tailstock, and the stem in an air-actuated chuck attached to the machine spindle.

The machine cycle was started, and the spindle was rapidly accelerated to 2700 rpm as the tailstock advanced to bring the workpieces into contact. The pressure of contact initiated a signal in the control circuit that began cycle timing and started a gradual increase in axial pressure by a slope-control unit.

The pressure, applied through the tailstock by two hydraulic cylinders, was smoothly increased to 11,000 psi (about 3740 lb) in 4 sec. The pressure level was maintained for an additional 4 sec, during which time the workpieces were heated to welding temperature.

At the end of the 4-sec heating period, the braking system quickly stopped spindle rotation, and a welding pressure of 32,000 psi (about 10,900 lb) was applied. The resulting weld had a good metallurgical bond that was free of oxides, cast metal structure, porosity, inclusions and other defects. Total axial shortening of the workpieces during welding was 0.195 to 0.200 in.

The weld upset was removed in an automatic lathe prior to heat treating of the valve. After heat treatment, the stem was ground to finished diameter.

The production rate, with an unskilled operator, was 190 to 200 pieces per hour. The total input energy per weld was 6900 watt-sec with a peak power draw of 5 hp, including all losses. The cost per weld, including removal of the weld upset, was less than $0.05. The welding machine cost $20,000, and the semiautomatic loading and unloading equipment cost $3000 (1967).

Inertia Welding

Inertia welding makes use of the kinetic energy of a freely rotating flywheel for all of the heating required to produce a weld.

Welding Machine. The machine is constructed with a horizontal bed and overhead tie bars to contain the axial-pressure and torque reactions and to ensure accurate spindle-to-bed alignment. The spindle is driven by a hydrostatic motor through a change-gear transmission. A hydraulically actuated tailstock retracts on adjustable ways for loading and unloading. A self-centering vise can be attached to the tailstock for clamping cylindrical parts, and fixtures are used for holding asymmetrical parts for which the vise is not suitable. The spindle has a means for mounting a collet chuck, and a draw bar is used for opening and closing the collet.

Flywheel size (moment of inertia of the flywheel or spindle) is adjusted by adding or removing flywheel disks. The spindle speed and axial pressure are adjusted by dials on the control panel.

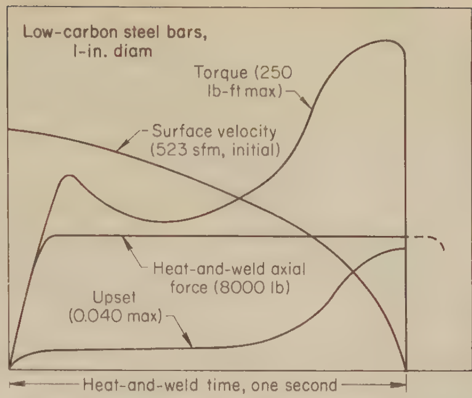

Fig. 8. Variation of surface velocity, torque, axial force and weld upset in a one-second heat-and-weld time in inertia welding

Principle of Operation. In inertia welding, as in conventional friction welding, one workpiece is clamped in a nonrotating vise or fixture and the other workpiece is clamped in a chuck mounted to a rotating spindle.

The drive motor accelerates the rotation of the flywheel-spindle assembly to a predetermined speed, and then the rotating drive power is shut off. The surfaces to be welded are brought together and the kinetic energy of the freely rotating flywheel is rapidly converted to heat at the weld interface as axial pressure is applied. Once the axial pressure, flywheel moment of inertia, and spindle speed have been established for a given workpiece, uniform welds are produced repetitively.

Two characteristics of inertia welding — continuously decreasing surface velocity of the workpiece and continuously changing torque at the weld interface — are illustrated in Fig. 8. Surface velocity begins at some initial value and decreases along an essentially parabolic curve to zero, at which time the weld is completed. Heating and welding time is usually 0.2 to 4 sec. Torque has a peak value of short duration early in the cycle, gradually decreases, and then increases until the velocity has decreased to the value at which welding begins, at which time torque rises sharply. This high torque is accompanied by forging in the weld zone, and is responsible for much of the upsetting. The high-torque phase, present only in inertia welding, refines the grain structure and expels any oxides at the weld interface. The gradually decreasing and increasing part of the torque curve is essential to the formation of good welds. The second (low-torque) phase generally will not develop if initial velocity is too low. Figure 8 is typical for inertia welding of 1-in.-diam low-carbon steel bars.

Other differences between inertia welding and conventional friction welding are input power at the weld interface and heating time. The power needed for the weld itself is not of concern in inertia welding, because whatever power is required can always be supplied by deceleration of the flywheel at the required rate. In conventional friction welding, power is limited by the size of the drive motor.

The high power used in inertia welding is a result of a relatively high, rapidly applied axial pressure. Power demands in conventional friction welding are controlled and limited to motor capacity by applying the axial pressure slowly; usually 2 to 4 seconds elapse before the full pressure is applied. The lower heating rates of conventional friction welding require more energy because much of the heat is conducted away from the weld interface. By rapid application of small amounts of energy, inertia welding produces narrower heat-affected zones than those produced in conventional friction welding.

In inertia welding, intense hot working of the weld zone in conjunction with rapid cooling immediately after hot working results in a very small grain size in the as-welded condition. Subsequent heat treatment will restore the grains to their normal size.

Process Variables. Three variables control the characteristics of an inertia weld: initial peripheral velocity of the rotating workpiece, axial pressure, and flywheel size (moment of inertia).

Table 2. Conditions for Inertia Welding 1-In.-Diam Bars in Combinations of Similar and Dissimilar Metals

Work metal	Welding conditions: Spindle speed, rpm	Axial force, lb	Flywheel size, lb-ft² (a)	Resultant weld conditions: Weld energy, ft-lb	Metal lost, in. (b)	Total time, sec (c)
Metals Welded to Themselves						
1018 steel	4600	12,000	6.7	24,000	0.10	2.0
1045 steel	4600	14,000	7.8	28,000	0.10	2.0
4140 steel	4600	15,000	8.3	30,000	0.10	2.0
Inconel 718	1500	50,000	130.0	50,000	0.15	3.0
Maraging steel	3000	20,000	20.0	30,000	0.10	2.5
Type 410 stainless steel	3000	18,000	20.0	30,000	0.10	2.5
Type 302 stainless steel	3500	18,000	14.0	30,000	0.10	2.5
Copper, commercially pure	8000	5,000	1.0	10,000	0.15	0.5
Copper alloy 260 (cartridge brass, 70%)	7000	5,000	1.2	10,000	0.15	0.7
Titanium alloy Ti-6Al-4V	6000	8,000	1.7	16,000	0.10	2.0
Aluminum alloy 1100	5700	6,000	2.7	15,000	0.15	1.0
Aluminum alloy 6061	5700	7,000	3.0	17,000	0.15	1.0
Dissimilar-Metal Combinations						
Copper to 1018 steel	8000	5,000	1.4	15,000	0.15	1.0
M2 tool steel to 1045 steel	3000	40,000	27.0	40,000	0.10	3.0
Nickel alloy 718 to 1045 steel	1500	40,000	130.0	50,000	0.15	2.5
Type 302 stainless to 1020 steel	3000	18,000	20.0	30,000	0.10	2.5
Sintered high-carbon steel to 1018	4600	12,000	8.3	30,000	0.10	2.5
Aluminum 6061 to type 302 stainless	5500	5000 & 15,000 (d)	3.9	20,000	0.20	3.0
Copper to aluminum alloy 1100	2000	7,500	11.0	7,500	0.20	1.0

(a) Moment of inertia of the flywheel. (b) Total axial shortening of workpieces during welding. (c) Includes heat time and weld time. (d) The 5000-lb force is applied during the heating stage of the weld; force is increased to 15,000 lb near the end of the weld.

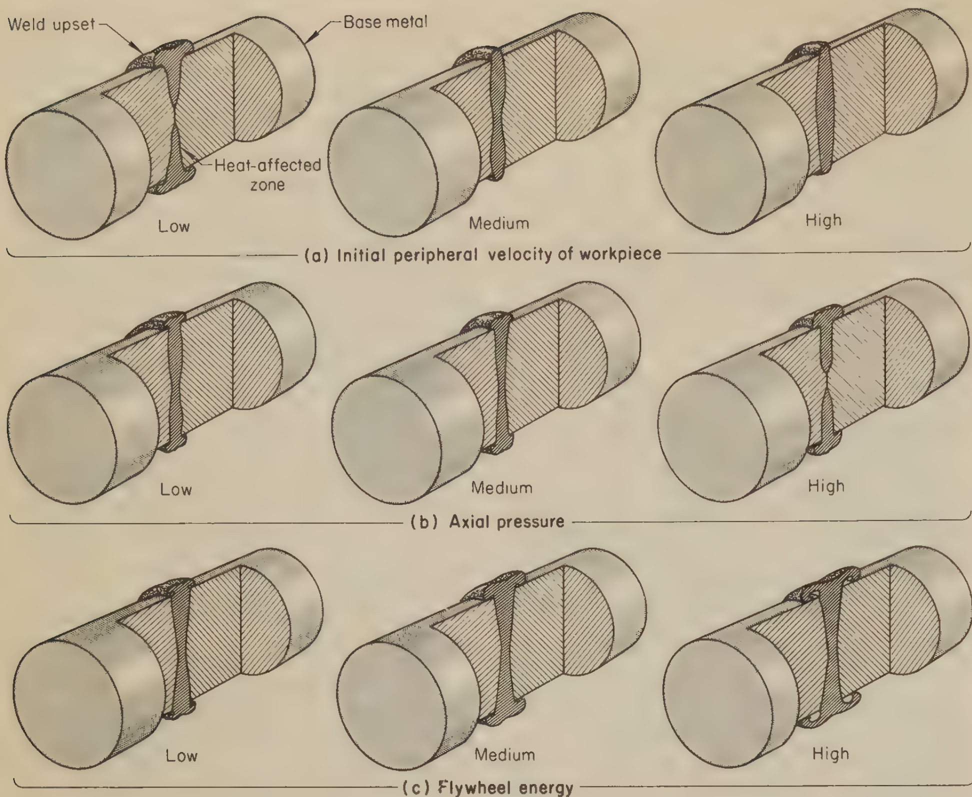

Fig. 9. Effect of low, medium and high levels of the three welding variables on depth and uniformity of heating, and on size and shape of the weld upset, in inertia welding of steel

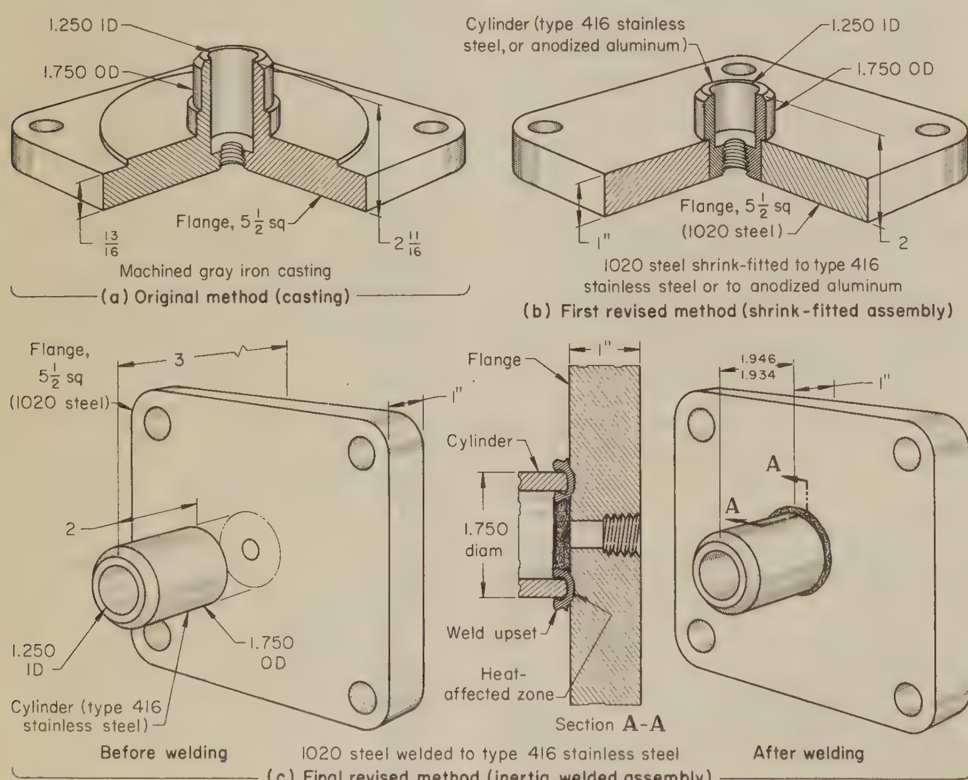


Conditions for Inertia Welding

Machine capacity:		Spindle speed	3900 rpm
Part diameter	0.43 to 1.50 in.	Weld energy(a)	51,800 ft-lb
Spindle speed	8000 rpm max	Axial force	35,000 lb
Axial force	45,000 lb max	Weld area	1.18 sq in.
Flywheel moment of inertia	20 lb-ft²	Metal lost(b)	0.060 ± 0.006 in.

(a) Calculated from flywheel size (moment of inertia) and spindle speed. (b) Total axial shortening of the workpieces during welding.

Fig. 10. Suction-valve cover that was produced by three different processes, using the designs shown. Inertia welding produced the highest-quality part at lowest cost. (Example 456)

For each weld, the minimum energy input required is provided by using the proper combination of flywheel size and spindle speed. Additional energy may be needed if the surfaces to be welded are rough or out of square with the axis of rotation. Very high energy input causes excessive loss of metal, but generally does not affect the strength or quality of the weld.

Table 2 gives representative conditions for inertia welding of 1-in.-diam bars of various metals and alloys, in similar and dissimilar combinations.

Peripheral Velocity of Workpiece. For each combination of work metals, there is a range of peripheral velocity that produces the best weld properties. For welding steel to steel, the recommended initial peripheral velocity of the workpiece ranges from 500 to 1500 sfm; however, welds can be made at velocities as low as 275 sfm. As illustrated in Fig. 9(a), low velocities (less than 300 sfm) can reduce center heating and produce rough, uneven weld upset. At medium velocities (300 to 900 sfm), the heating pattern in steel has an hourglass shape at the lower value and gradually flattens as the upper velocity is approached. The heating pattern is essentially flat and uniformly thick across the workpiece at velocities of 900 to 1200 sfm. At high initial velocities (above 1200 sfm), the weld becomes rounded and is thicker at the center than at the periphery.

Spindle speeds in revolutions per minute for inertia welding 1-in.-diam bars of various metals and alloys are given in Table 2. (For speed conversions — sfm to rpm for many diameters — see the inside back cover of Volume 3 of this Handbook.) The relationship of total time and weld upset to bar diameter is approximately linear.

Axial Pressure. The effect of varying the axial pressure is similar but opposite to the effect of varying the velocity. As Fig. 9(b) shows, welds made at low axial pressure resemble welds made at medium velocity, in regard to formation of weld upset and heat-affected zones. Use of excessive pressure produces a weld that is poor at the center and has a large amount of weld upset, similar to a weld made at a low velocity.

The axial force (in pounds) for welding 1-in.-diam bars is given in Table 2. Axial pressure (in psi) varies as a function of the square root of workpiece diameter. For instance, a 2-in.-diam bar uses 1.414 times the axial pressure needed for a 1-in.-diam bar.

Effect of Flywheel Energy. The flywheel moment of inertia is selected to produce the desired amount of kinetic energy and the desired amount of forging. Forging results from the characteristic increase in torque (see Fig. 8) that occurs at the weld interface as the flywheel slows and comes to rest. This increased torque, in combination with the axial pressure, produces forging as depicted by the upset curve in Fig. 8. Because forging begins at some critical velocity (about 200 sfm for low-carbon steel), the amount of forging depends on the amount of energy remaining in the flywheel, which is a linear function of the flywheel moment of inertia. Large, low-speed flywheels produce greater forging than small,

high-speed flywheels even though they contain the same amount of kinetic energy. Although low, medium and high amounts of flywheel energy produce similar heating patterns, the amount of energy greatly affects the size and shape of the weld upset, as shown in Fig. 9(c).

Examples of Practice. Inertia welding is used in the manufacture of bimetal exhaust valves for internal-combustion engines, bimetal shafts for pumps, and cluster and ring gears for automotive and aircraft applications. The process has been incorporated into the redesign of many parts in order to reduce costs or improve service life, as in the following two examples. Other applications of inertia welding are described in the section on Friction Welding vs Other Processes, beginning on page 516.

In the example that follows, to produce corrosion-resistant parts at low cost, inertia welding was selected over casting or shrink-fit assembly.

Example 456. Use of Inertia Welding Instead of Casting or Shrink-Fit Assembly (Fig. 10)

A high-production part, consisting essentially of a 1¼-in.-ID cylinder with a bolting flange, served as a suction-valve cover. The manufacturing process and design of the part evolved through three successive stages as shown in Fig. 10. The first stage was a one-piece casting (Fig. 10a); the second, a shrink-fitted assembly (Fig. 10b); and the third, the inertia welded assembly shown in Fig. 10(c). The slight differences among the three designs are the results of changes in the design of the mating piece. The inertia welded component was used as-welded, without removing weld upset from either the inner or the outer surface of the cylinder.

Originally, the part was machined from a gray iron casting as shown in Fig. 10(a). Some difficulty was experienced in obtaining the desired finish on the inner surface of the cylinder, but the most serious problem was rusting of the inside of the cylinder. Attempts were made to improve corrosion resistance by burnishing the cylinder wall, and then plating with cadmium, zinc or tin, or phosphate coating. Although phosphate coatings were best on the cast iron surface, none of these coatings proved satisfactory in service.

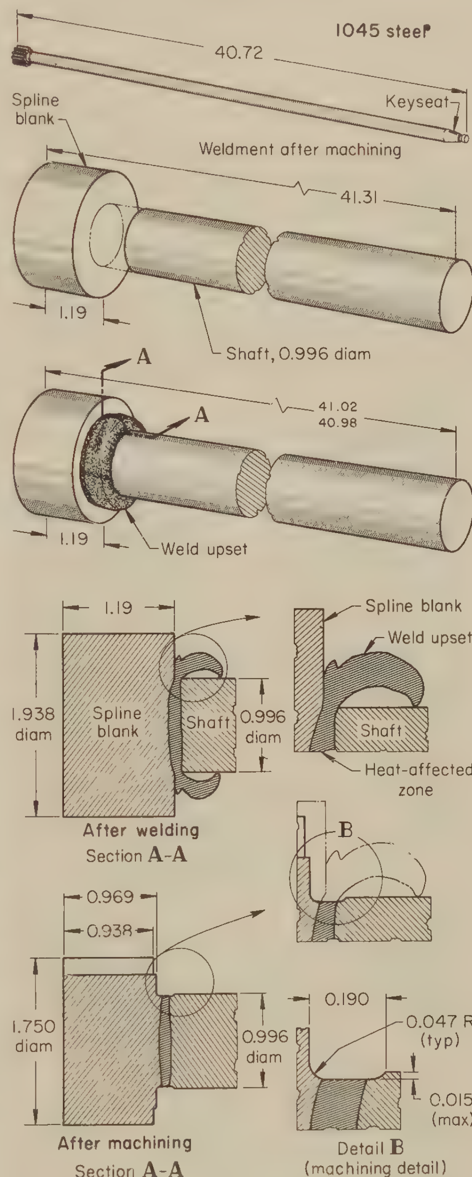
The second method consisted of using for the flange a low-carbon steel plate that was bored to accept a shrink-fitted cylinder (Fig. 10b). Cylinders were made of anodized aluminum alloy or of stainless steel. When the anodized aluminum alloy was used, the cost per part was slightly higher than that of the gray iron casting. Cylinders made of type 416 stainless steel gave excellent results, but cost considerably more than the castings.

In the final design, shown in Fig. 10(c), inertia welding was used to join a type 416 stainless steel tube to a 1020 steel plate. Valve covers made by this method cost 15% less than the original cast iron covers and the corrosion and surface-finish problems were eliminated.

For inertia welding, flanges were gas cut from 1020 steel plate, and the cylinders were saw cut from type 416 stainless steel tubing. Both components were finish machined and the joint surfaces were cleaned carefully before welding.

Conditions for friction welding are given in the table with Fig. 10. With these settings, an upset of 0.060 ± 0.006 in. was a good indication of an acceptable weld. Part specifications required that a 100-psi pressure test be applied to 5% of the weldments, and that 1% of the weldments be examined for weld configuration by sectioning. The test samples were selected on a random basis. Under these conditions, the rejection rate was less than 0.3%, and most rejections were caused by defects in the base metal rather than in the weld.

The manufacture of a long, slender shaft with a spline on one end is described in the example that follows. Use of inertia welding permitted joining a ground and polished steel shaft to another steel part without damaging the polished surface. Changing from forging to inertia welding reduced the over-all cost and eliminated nine manufacturing operations.



Conditions for Inertia Welding(a)

Flywheel moment of inertia	150 lb-ft²
Spindle speed	1850 rpm
Weld energy(b)	87,500 ft-lb
Axial force	21,000 lb
Weld area	0.78 sq in.
Metal lost(c)	0.31 ± 0.02 in.
Production rate	70 welds per hour

(a) In this application, lower-than-normal spindle speeds and larger-than-normal flywheels were used for convenience in changeover from one workpiece to another. (b) Calculated from flywheel size (moment of inertia) and spindle speed. (c) Total axial shortening of the workpieces during welding.

Fig. 11. Drive shaft for which change from forging to inertia welding reduced costs by $12.17 (Example 457)

Example 457. Change From Forging to Inertia Welding To Reduce the Cost of Producing a Long, Slender Shaft (Fig. 11)

The long, slender power-control drive shaft shown in Fig. 11 originally was made from a 1045 steel forging, but was severely warped during forging and heat treating. Nineteen manufacturing operations were needed to complete the forged shaft, including hardening and tempering of the forging to Rockwell C 23 to 30, cleaning by shot blasting, three straightening operations and ten machining operations.

The number of manufacturing operations was reduced to ten when forging was replaced by inertia welding. A spline blank of 1045 steel 1.938 in. in diameter by 1.19 in. long was inertia welded to a 1045 steel shaft 40.12 in. long (see Fig. 11). The shaft had a hardness of Rockwell C 27 and, before welding, was ground and polished to 0.996 in. in diameter. The jaws for holding the shaft were designed so as not to damage the ground and polished surface.

Hardening, tempering, shot blasting, straightening and three grinding operations were eliminated, and the cost of making each shaft was reduced by $12.17, when forging was replaced by inertia welding. Three operations — hardening a bearing surface, deburring, and washing — were included in both manufacturing sequences.

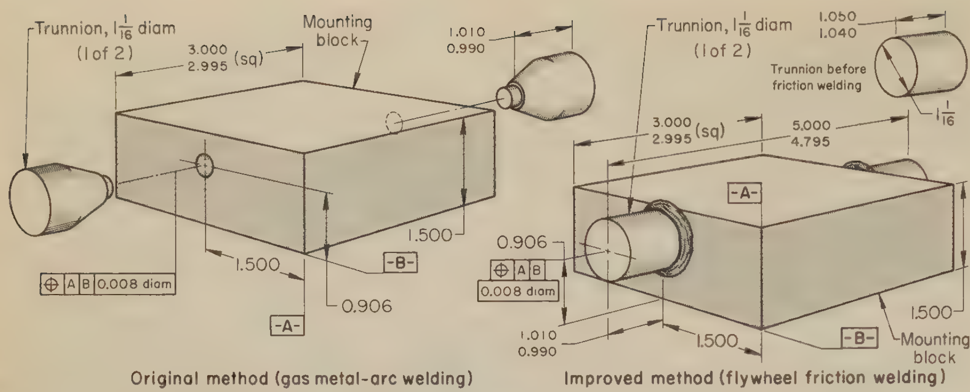
Machining of the spline end of the weldment included removing the weld upset and relieving the area to a minimum diameter of 0.966 in. and to a width of 0.19 in., which eliminated a possible stress raiser. A taper 1.375 in. long, a seat for a Woodruff key, and ⅝-11 threads were machined on the other end of the shaft.

Conditions for inertia welding are given in the table with Fig. 11. These conditions were selected to produce a weld upset of 0.31 ± 0.02 in., which was greater than usual, so that the upset could be machined in the as-welded condition. Failure of the shaft during fatigue testing occurred at the keyseat, not in the weld.

Flywheel Friction Welding

Flywheel friction welding is done with a machine in which mechanical energy is stored in, and released by, a flywheel in amounts predetermined and gaged by flywheel speed. The amount of energy released by the flywheel is determined by its speed when axial pressure is first applied, and by the speed at which the clutch disengages the spindle from the motor. (For additional description of the mechanics of flywheel friction welding, see "Welding Methods" on page 507.)

In operation, one workpiece is clamped in a collet chuck mounted to the spindle and the clutch is engaged, which causes the workpiece to be rotated at a predetermined speed. The mating workpiece is clamped in the tailstock and then brought in contact with the rotating workpiece, and pressure is applied to heat the workpieces. At a predetermined time or spindle speed, the clutch is disengaged and a welding pressure is applied to stop rotation and complete the weld. After the flywheel is disengaged, the heating pressure can be continued or the welding pressure can be applied immediately. Thus both kinetic and direct mechanical energy can be used to heat the workpieces to welding temperature, although the machine is designed with the intent that all heating be derived from the kinetic energy of the freely rotating flywheel, and none from direct mechanical energy.



Conditions for Flywheel Friction Welding	
Flywheel moment of inertia	40 lb-ft²
Spindle speed	1800 rpm
Weld energy(a)	21,800 ft-lb
Axial force	18,000 lb
Time per weld	1 sec
Time, floor to floor	30 sec
Metal lost (b)	0.045 ± 0.005 in.

(a) Calculated from flywheel size (moment of inertia) and spindle speed. (b) Total axial shortening of the workpieces during welding.

Operation	Gas metal-arc welding	Flywheel friction welding
Comparison of Costs per Mount		
Machine two trunnions	$0.90	$0.06
Drill two holes in block	0.12	...
Assemble trunnions to block	0.10	...
Weld	0.85	0.50
Total cost per mount	$1.97	$0.56
Saving per mount		$1.41

Fig. 12. Original and improved methods of welding trunnions to a mounting block to make a trunnion mount for air and hydraulic cylinders. Cost per mount was reduced by 71% when flywheel friction welding replaced gas metal-arc welding. (Example 458)

The variables in flywheel friction welding are rotational speed, flywheel size (moment of inertia), cutout speed and axial pressure. The effects of each variable (except cutout speed) on the weld are the same as in inertia welding. The continuous rotation of the drive-motor – flywheel assembly makes the weld energy almost immediately available as soon as the workpieces are loaded into the collets or fixtures.

In the example that follows, gas metal-arc welding was replaced by flywheel friction welding for joining trunnions to a mounting block. In both of the methods used to join the three components, the location of each trunnion was held to a close tolerance, to minimize the machining necessary to make the trunnions concentric.

Example 458. Joining of Trunnions to Mounting Blocks by Flywheel Friction Welding at Lower Cost Than by Gas Metal-Arc Welding (Fig. 12)

A trunnion mount (see Fig. 12) for air and hydraulic cylinders originally was made by gas metal-arc welding two trunnions to a mounting block. When the joining process was changed to flywheel friction welding, the total cost of making the mount was reduced by 71%.

In the original method, the trunnions were machined from bar stock and then gas metal-arc welded to a mounting block. Each trunnion had a locating boss and a weld chamfer. The block was drilled to accept the trunnions, which were pressed in, and then welded. After welding, the trunnions were machined concentric. Before welding, the blocks were broached square and parallel within 0.005 in. To minimize the machining necessary to make them concentric, the trunnions were held within 0.008 in. of true position. As shown in the table with Fig. 12, the cost of machining and arc welding the trunnions was $1.97 per block.

When the process was changed to flywheel friction welding, the trunnions were saw cut to 1.050 +0.000, −0.010 in. in length and the broached blocks were not drilled. The cost of cutting two trunnions to length and friction welding them to a block was $0.56.

The trunnions were held by a collet chuck mounted to the spindle of the flywheel friction welding machine and the mounting block was located and held in a fixture mounted to the tailstock. The length of each trunnion was held to 1.000 +0.000, −0.010 in., which eliminated the need for facing the ends after welding. Time for each weld was 1 second; floor-to-floor time for each piece was 30 seconds. Additional conditions for flywheel friction welding, and a comparison of costs for the two processes, are given in the table that accompanies Fig. 12.

Joint Design

The mechanics of friction welding restrict its use to flat and angular butt welds that are perpendicular to and concentric with the axis of rotation. Flat joints are the most common and can be classified as: (*a*) bar to bar, (*b*) bar to tube, (*c*) tube to tube, (*d*) bar to plate, and (*e*) tube to plate, as shown in Fig. 13. These classifications refer to the joint itself, and not to the shape of the parts. The joint used in making the rotor bodies described in Example 451 is classified as a bar-to-plate joint because a 0.62-in.-diam rod was joined to a 2-in.-diam rod. Friction welding the cluster gears in Example 463 illustrates a tube-to-plate joint on the OD of the gear and a tube-to-tube joint on the ID.

Joint surface conditions, such as surface finish, squareness and cleanness, are not critical for friction welding because the original abutting surfaces are rubbed off and extruded in the process. As-forged, sheared, gas-cut, abrasive-cut or sawed surfaces are acceptable, but extra heat is needed to remove irregularities and allow uniform heating to occur. Also, if the face of a workpiece is not perpendicular to the axis of rotation, forces are produced that can affect the concentricity of the components after welding.

Projections left by cutoff tools present no problem, and in some applications may even help to heat the center of the bar. However, center-drill holes must be avoided; when the upset metal compresses the air entrapped in a center-drill hole during upsetting, a weld defect usually occurs.

Heavy mill scale, thick chromium plating or a thin carburized or nitrided case acts as a bearing surface and cannot be extruded from the weld area. When deeply carburized workpieces are to be welded, the joint surface, and the adjacent surfaces, must either be machined before welding (or before hardening, if it precedes welding) to remove the carburized metal, or be copper plated or otherwise covered during the carburizing operation to prevent them from being carburized. In Example 463, the weld area was machined before hardening to remove the carburized metal. In Example 451, the end to be welded was copper plated before carburizing.

Tubular Welds. Tube-to-plate welds are not as strong as tube-to-tube welds, because rounding of the end of the tube during heating and upsetting reduces weld effectiveness. Fatigue life of a tube-to-plate weldment increases with removal of the sharp notch at the tube base before the part is put to use. On some metals, when heating is too slow, or when excessive weld energy is applied, the upset metal flows up and around the outside of the tube and forms, in effect, a tube within a tube.

On tubular welds, the upset is extruded equally toward the bore and to-

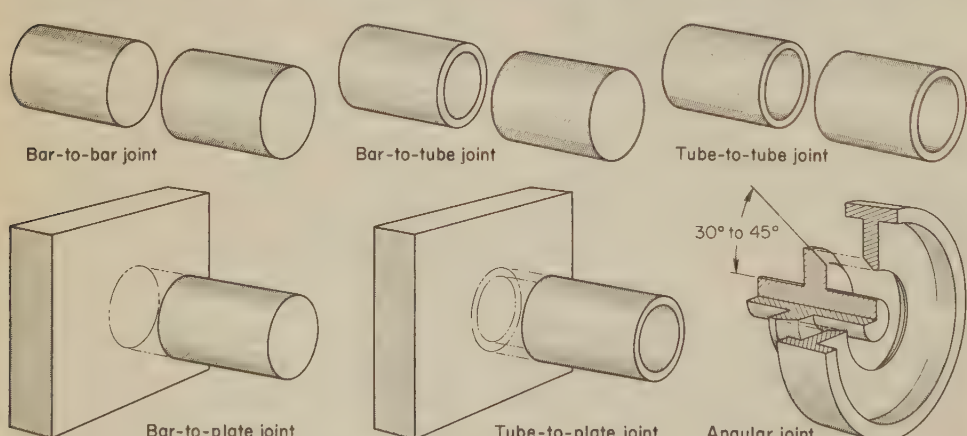


Fig. 13. Types of joints commonly made by friction welding. Bars and tubes, and joint surfaces of angular joints, must be concentric with the axis of rotation; bar, tube and plate surfaces to be welded must be perpendicular to the axis of rotation.

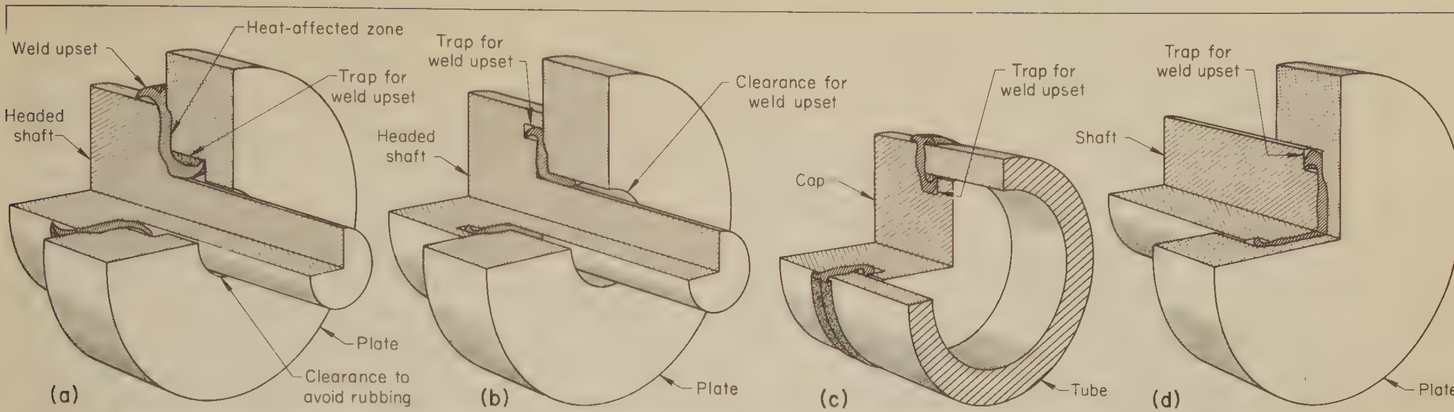

Fig. 14. Recesses used as traps for weld upset in friction welded joints. (See discussion in text, under "Design for Flow of Weld Upset".)

ward the periphery. When weld upset cannot be permitted to remain in the bore and cannot be reached for removal after welding, a trap must be incorporated into the joint design. (See the subsection on Design for Flow of Weld Upset, this page.)

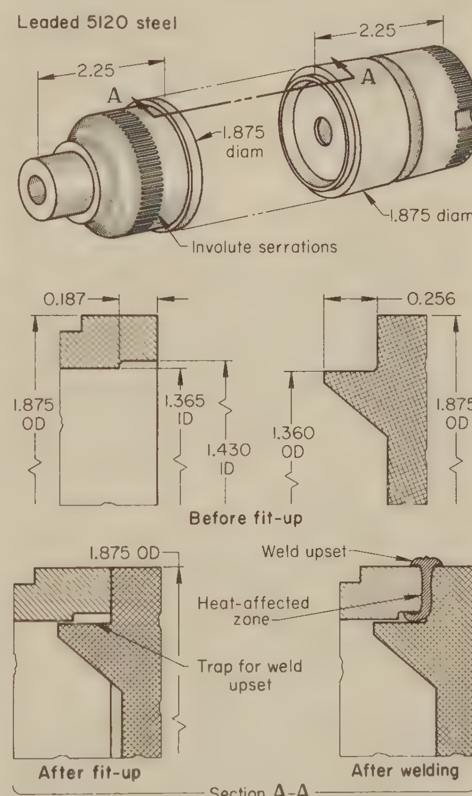
Angular joints (see Fig. 13) are used in welding the inside diameter of one component to the outside diameter of another — for instance, welding the rim of a jet-engine fan to the flange of the hub section or welding a flange to a shaft at some position between the two ends.

The joint can be made where a chamfered shoulder can be mated with an equally chamfered bore in the flange. The interfaces of angular joints must have equal included angles, and the tapered bore in the outer component must have sufficient strength to withstand the axial pressure required to make the weld.

Angular joints are usually designed with faces 30° to 45° from the centerline (an included angle of 60° to 90°) to prevent one part from being pushed through the hole in the other part. Some nickel-base alloys have been welded using smaller angles.

Design for Heat Balance. When similar metals, or dissimilar metals having about the same forging temperature and thermal conductivity, are friction welded, there are no restrictions on the relationship of the cross-sectional area of a bar or tube to the size of plate to which it is welded. Heating rates as high as 100,000 F per second make the weld cycle very short and keep heat losses to the cold metal in the plate adjacent to the weld very low. Thus, bar-to-plate and tube-to-plate welds are feasible for joining similar and some dissimilar metal combinations.

In welding dissimilar metals with widely different forging temperatures and thermal conductivities, adjustment of size or area adjacent to the weld interface may be necessary in one of the workpieces. Area differentials must be determined experimentally because each metal reacts differently. For instance, in welding a nickel-base alloy shaft 1 in. in diameter to an alloy steel shaft, the alloy steel shaft should be $\frac{1}{16}$ to $\frac{1}{8}$ in. in diameter larger than the nickel-base alloy. If the components are tubes, the inside diameter of the alloy steel tube should be $\frac{1}{16}$ to $\frac{1}{8}$ in. less than that of the nickel alloy tube. Thus the alloy steel tube would have a smaller inside diameter and a greater wall thickness and outside diameter than the nickel alloy tube. In making a cutting-tool blank, a tool steel shank can be readily welded to a tool steel body using a bar-to-plate joint, but if the shank is changed to alloy steel, the tool steel body must be modified to produce a bar-to-bar joint.



Conditions for Inertia Welding

Flywheel moment of inertia	10.75 lb-ft²
Spindle speed	2800 rpm
Weld energy(a)	14,300 ft-lb
Axial force	17,000 lb
Heat-and-weld time	0.7 sec
Machine cycle time	4 sec
Weld area	1.36 sq in.
Metal lost(b)	0.020 ± 0.003 in.
Production rate	280 parts per hour

(a) Calculated from flywheel size (moment of inertia) and spindle speed. (b) Total axial shortening of the workpieces during welding.

Joint was designed with a trap that prevented the formation of weld upset on the internal surface of the chamber.

Fig. 15. Components of a diesel-engine precombustion chamber that were joined by inertia welding (Example 459)

When a tube is welded to a thin plate with a hole of the same diameter as the inside of the tube, the hole in the plate frequently is made smaller than the ID of the tube to avoid excessive heating of the plate around the hole. This difficulty does not occur with thick plates because the metal around the hole is not heated through.

Design for Flow of Weld Upset. In applications where the presence of weld upset on one or more work-metal surfaces is undesirable, and where the upset cannot be removed after welding, traps can be incorporated into the joint design, to provide clearance for the flow of weld metal from the interface. When a plate is welded to a shaft extending through a hole in the plate, or a boss on one workpiece extends into a hole in the other workpiece, enough clearance must be provided to prevent rubbing of the shaft or boss against adjacent surfaces. Rubbing of adjacent surfaces parallel to the axis of rotation uses flywheel energy unpredictably and diminishes reproducibility of the weld.

Typical designs of traps for weld upset are shown in Fig. 14. An assembly of a headed shaft and a plate is shown in Fig. 14(a) and (b). In Fig. 14(a), weld upset could not be tolerated on the surface of the plate opposite the joint and could not be removed after welding. A counterbore in the hole in the plate, extending inward from the joint surface of the plate, served as a trap for weld upset, which was permitted to flow out around the head of the shaft. In Fig. 14(b), weld upset was not permitted on the joint surface of the plate, and the trap was formed in the head of the shaft. A surface on the head touched the plate as rotation ceased, and provided a seal.

An end-cap-to-tube weld is shown in Fig. 14(c). A tight internal corner joint free of weld metal was obtained by making the trap in the boss on the end cap. In Fig. 14(d), the step on the joint end of the shaft provided the trap for weld upset, leaving the outside corner formed by the intersection of the plate and the shaft free from upset metal.

Parts that require difficult-to-machine internal recesses or chambers can be made by joining two specially designed and machined parts. Removal of weld upset from the inside surfaces of such parts is difficult; therefore, the joint must be designed with a trap so that weld upset cannot form on the

internal surface. A trap was used effectively in the example that follows.

Example 459. Inertia Welding of a Precombustion Chamber Using a Joint Designed To Prevent Weld Upset From Forming on an Internal Surface (Fig. 15)

Precombustion chambers for diesel engines (see Fig. 15) originally were made by furnace brazing two sections together. The brazed joint was subjected to precombustion temperatures as well as a combustion pressure of about 1700 psi. Precise machining of the joint surfaces and careful inspection of the parts were needed.

When furnace brazing was replaced by inertia welding, close joint tolerances and meticulous inspection procedures were no longer needed, and product quality was improved. The mating surfaces were designed to contain the internal weld upset so that it could not flow into the chamber.

The two components were made of leaded 5120 steel in a multiple-spindle bar machine. The outside diameter of the chamber at the weld interface was 1.875 in., and the width of the weld interface was about 0.22 in. A small enclosed internal cavity, shown in Fig. 15 (section A-A, after fit-up), contained the internal weld upset and prevented it from flowing into the chamber. Involute serrations were rolled onto each part during the machining operation to aid the hydraulically operated welding-machine collet chucks in gripping the workpieces, and mating serrations were machined in the collet pads of the chucks. Dependable holding techniques were needed to prevent undesirable malfunctions, to reduce wear on the gripping surface of the chuck, and to minimize upkeep cost.

In operation, the two sections were clamped in their respective collet chucks, and the tailstock was moved forward until the surfaces to be welded were 0.045 in. apart. The inertia flywheel and spindle were accelerated to 2800 rpm (in about 1.2 sec), the energy source was disconnected from the spindle and, immediately, the two sections were brought into contact under a force of 17,000 lb, which remained constant until rotation stopped. Heat-and-weld time was 0.7 sec. Strength of the welded joint was equal to that of the base metal.

The spindle chuck unclamped automatically and the tailstock retracted to the starting position. Then the tailstock chuck unclamped automatically and the workpiece was removed manually and was placed in an automatic lathe where the weld upset was machined off while the next piece was being welded.

Machine cycle time, exclusive of handling time, was 4 sec. Metal lost was 0.020 ± 0.003 in. Total cost of operation, including overhead, was $0.035 per weld.

Additional welding conditions are given in the table with Fig. 15.

Design for Machine Size. The amount of energy needed for friction welding depends partly on the distance metal must be extruded from the innermost point of the interface of the workpieces. Thus, more weld energy is required, per square inch of weld area, for joining two 1-in.-diam bars than for joining a 1-in.-diam bar to a 1-in.-diam tube. The joints are of nearly equal strength, because the metal at the center of the bar is near the neutral axis and contributes very little to torsional or bending strength.

Some joints can be designed with a center relief in one or both workpieces to eliminate the nonworking but hard-to-weld metal at the center. This also may permit the part to be welded on a smaller-capacity machine, or the length of the welding cycle to be reduced. The size of the center relief must be large enough so that compres-

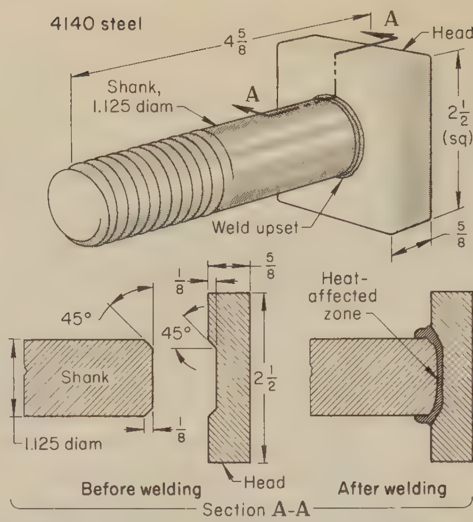


Fig. 16. Square-head bolt that was made by inertia welding to reduce costs from original method of machining from solid bar stock (Example 460)

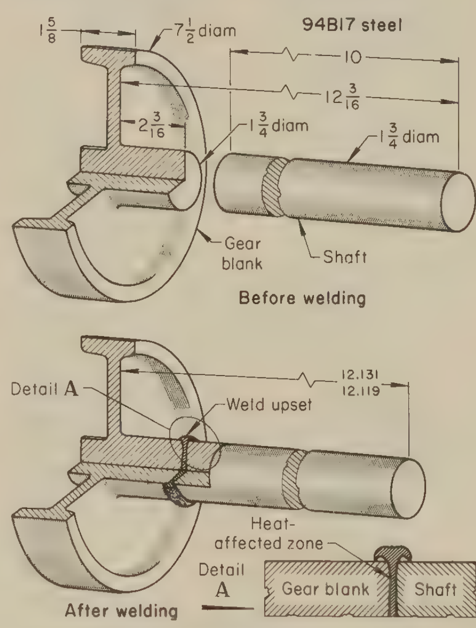
sion of the entrapped air will not cause a weld defect, and to provide adequate space for the weld upset.

Similarly, a bar-to-plate joint can be redesigned as a tube-to-plate or a bar-to-bar joint if desirable to bring it within the capacity of a particular machine. A bar-to-bar joint requires less energy than a bar-to-plate joint.



Conditions for Inertia Welding

Machine capacity:	
Part diameter	0.875 to 2.5 in.
Spindle speed	4800 rpm max
Axial force	160,000 lb max
Flywheel moment of inertia	170 lb-ft²
Spindle speed	2500 rpm
Weld energy(a)	180,900 ft-lb
Axial force	45,000 lb
Floor-to-floor time	2 min (approx)
Weld area	2.4 sq in.
Metal lost(b)	0.062 ± 0.006 in.

(a) Calculated from flywheel size (moment of inertia) and spindle speed. (b) Total axial shortening of the workpieces during welding.

Fig. 17. Gear-blank-and-shaft assembly that was joined by inertia welding. Floor-to-floor time was reduced by 90% compared with original method of pressure gas welding. (Example 461)

Control of Weld Quality

Inspection of friction welds usually consists of visual examination of the weld upset and measurement of the over-all length of the assembly to determine the variation in axial shortening of the members during welding.

Variation in axial shortening, or metal lost, is a good indication of weld quality. Because rotational speed and heating and welding pressures are readily controlled within close limits, the amount of metal lost usually is within ±5% of the nominal value. Therefore, when the lengths of the workpieces are held to close tolerances, the expected variation in the over-all length of the welded assembly can be calculated using the tolerances of the workpieces and weld upset. The nominal amount of metal lost can be determined while making tests to establish welding conditions.

Tension, bend, impact or fatigue tests frequently are used to check weld quality. Sectioning for microscopic examination and for hardness tests is also performed on test samples or on randomly selected production parts.

Proof testing by bending just enough to cause slight yielding in the weld zone has been used for testing friction welded pump shafts. Defective welds are discovered but no harm is done to satisfactory welds. Magnetic-particle inspection can be done on steel parts after the weld upset has been removed.

Friction Welding vs Other Processes

Friction welding can replace or supplement other manufacturing processes to reduce machining and material costs, to permit the use of work metals that meet the application requirements, and to provide reliable joints.

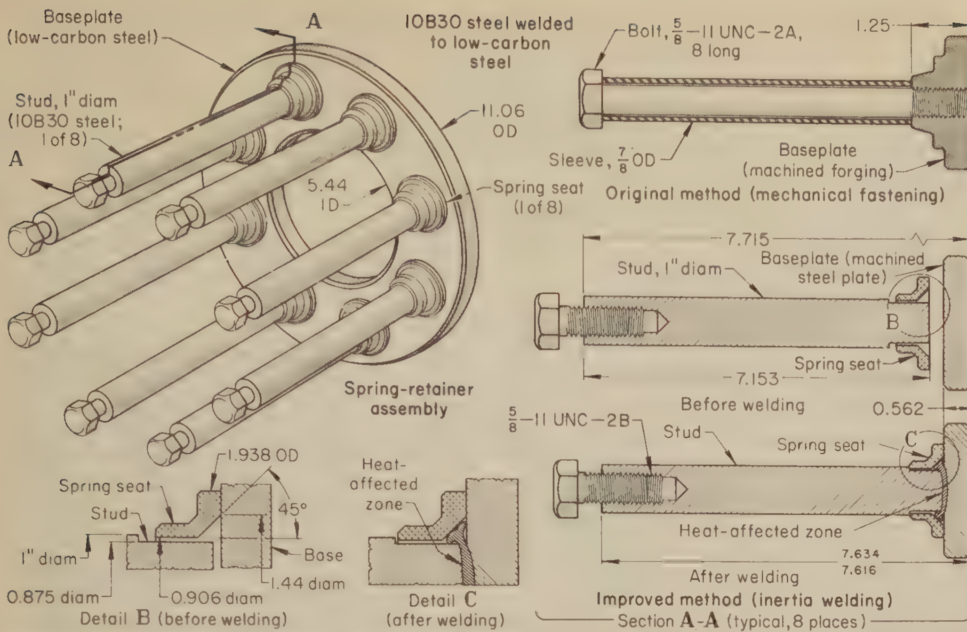
In Example 451, machining and material costs were reduced by friction welding stub shafts to a rotor body instead of machining from solid bar stock. The quality of friction welded parts can be equal to that of parts machined complete from bar stock, as illustrated by the following example.

Example 460. Change From Machining to Inertia Welding That Reduced the Cost of Making Square-Head Bolts (Fig. 16)

The square-head bolt shown in Fig. 16 originally was machined from 2½-in.-sq 4140 steel bar and heat treated to the required mechanical properties. Cost of each bolt was $6.03.

When machining from solid bar stock was replaced by inertia welding a shank to a bolt head, there were no changes in the over-all quality, serviceability and appearance of the bolt, and cost was reduced to $2.707, for a saving of $3.323 per bolt. The welded bolts, when tested in accordance with SAE standard J429, met the requirements for Grade 7 threaded fasteners. Annual production was 1000 bolts.

In the improved method, the two workpieces were made of 4140 steel in an automatic bar machine. The head was faced, recessed and cut off from a 2½-in.-sq bar. The shank was turned, chamfered, threaded and cut to length from a 1¼-in.-diam bar. The mating surfaces of the shank and head had matching contours, as shown in Fig. 16, to assist in alignment. After inertia welding, the bolt was normal-



Conditions for Inertia Welding

Flywheel moment of inertia	8.5 lb-ft²	Heat-and-weld time	1.5 sec per weld
Spindle speed	3900 rpm	Weld area	0.60 sq in.
Weld energy(a)	22,000 ft-lb	Metal lost(b)	0.090 ± 0.009 in.
Axial force	11,000 lb	Production rate	15 parts per hour

(a) Calculated from flywheel size (moment of inertia) and spindle speed. (b) Total axial shortening of the workpieces during welding.

Fig. 18. Spring-retainer assembly made by inertia welding eight studs to a baseplate at lower cost than by tapping a forged plate and inserting bolts (Example 462)

ized, the weld upset was trimmed to a ⅛-in.-radius fillet, and then the bolt was quenched and tempered. About 1⁄16 in. of metal was lost during upsetting.

Sectioning and macroetching the weld zone showed a sound weld. Microscopic examination after heat treatment disclosed an area of transition of finer grain size between the base metal and weld area.

In the example that follows, production time was reduced 90% and rejection rate was reduced slightly when pressure gas welding was replaced by inertia welding for joining a forged gear blank to a shaft.

Example 461. Change From Pressure Gas Welding to Inertia Welding That Reduced Production Time by 90% (Fig. 17)

The 94B17 steel gear-blank-and-shaft assembly shown in Fig. 17 originally was joined by pressure gas welding. The two parts were machined flat at the interface without use of a cutting fluid, and then were chucked in a modified lathe equipped with a hydraulically actuated tailstock and an adjustable oxyacetylene ring burner on the bed. The parts were brought together, heated to slightly below the melting range and held under pressure until the weld was completed. Weld quality was good, and rejection rate was approximately 0.5%. However, 20 min was required for loading, heating, welding and unloading each part.

To increase the production rate, the joining method was changed to inertia welding. No changes in part design or joint preparation were required.

The gear blank was placed in a chuck that was attached to the spindle, and the shaft was chucked in the nonrotating tailstock. The spindle was accelerated to 2500 rpm, the drive mechanism was disengaged, and the workpieces were brought together with an axial force of 45,000 lb. The weld was completed when the flywheel energy was exhausted and the flywheel came to rest.

Although some latitude existed in the selection of machine settings, excellent results were obtained by using the conditions given in the table with Fig. 17. A relatively high axial force was needed to obtain the desired weld upset because of the strength of the 94B17 steel at elevated temperature. Total axial shortening of the workpieces (metal lost) was 0.062 ± 0.006 in.

The change from pressure gas welding to inertia welding reduced floor-to-floor time per assembly to approximately 2 min, and reduced the rejection rate to 0.2%. Weld quality was checked by ultrasonic and magnetic-particle inspection after removal of the weld upset.

Redesign of the workpieces in the following example allowed inertia welding to replace forging and machining. An assembly of equivalent quality was produced at lower cost.

Example 462. Redesign of a Spring-Retainer Assembly for Production by Inertia Welding To Reduce Costs (Fig. 18)

A spring-retainer assembly (see Fig. 18) for a heavy-duty tractor steering clutch originally was made from a forged, machined and tapped baseplate into which hexagon-head bolts were inserted. Spring seats were coined in the base plate prior to machining. The height to which the bolts extended above the baseplate was maintained by a sleeve made of ⅞-in.-OD tubing. When the product design was changed so that studs could be inertia welded to a steel plate, the cost of each assembly was reduced by $0.71.

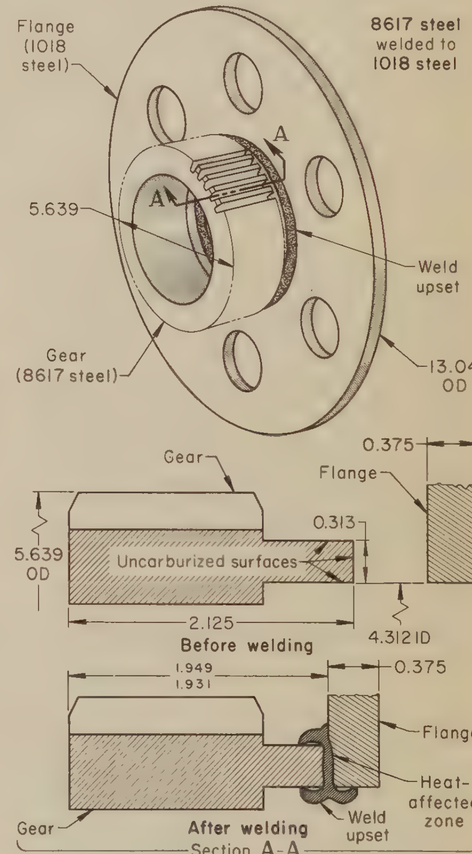
In the improved method, the baseplate was gas-cut from a ⅞-in.-thick low-carbon steel plate. The inside and outside diameters were turned to the dimensions shown in Fig. 18, and were then ground flat to a thickness of 0.562 in. The spring seats were made in an automatic bar machine from 1 15⁄16-in.-diam 1213 steel bar stock. The studs were machined from 1-in.-diam 10B30 cold finished steel that had been heat treated to a hardness of Rockwell C 23 to 30. One end of the stud was tapped with a ⅝–11 UNC–2B thread, and the other end was machined to 0.875 in. in diameter, which produced a weld area of 0.60 sq in. The parts were degreased before being inertia welded.

The baseplate was located by its inside diameter in an indexing fixture that was manually indexed 45° between successive welds. A manually loaded, hydraulically actuated collet chuck was mounted on the spindle for gripping the 1-in.-diam studs.

In operation, the baseplate was secured in the indexing fixture, a stud was clamped in the collet chuck, and a spring seat was placed over the 0.875-in.-diam end of the stud. Rotation of the spindle did not begin until the tailstock had advanced to a position that prevented the spring seat from falling off the end of the stud. The weld upset was not removed, because it was covered by the spring seat. Heat-and-weld time was 1.5 sec per weld, and production rate was 15 assemblies per hour. Additional welding conditions are given with Fig. 18.

Weld quality was checked by visually inspecting the weld upset, and the distance from the bottom of the baseplate to the top of the studs was measured for compliance with a specification of 7.625 ± 0.009 in.

In the example that follows, the method of making a flanged transmission gear was changed from forging to



Conditions for Inertia Welding

Flywheel moment of inertia	668 lb-ft²
Spindle speed	1450 rpm
Weld energy(a)	239,000 ft-lb
Axial force	105,000 lb
Heat-and-weld time	2 sec
Weld area	4.55 sq in.
Metal lost(b)	0.185 ± 0.009 in.
Production rate	63 parts per hour

(a) Calculated from flywheel size (moment of inertia) and spindle speed. (b) Total axial shortening of the workpieces during welding.

Fig. 19. Flanged transmission gear that was made by inertia welding instead of by forging, to reduce costs and avoid distortion of the flange during heat treatment (Example 463)

inertia welding to allow selective hardening of the gear section and so avoid flange distortion. The inertia weldment weighed and cost less than the forging.

Example 463. Change From Forging to Inertia Welding To Avoid Workpiece Distortion (Fig. 19)

A flanged transmission gear originally was machined from a one-piece 8617 steel forging. Hardening of the gear section was required, and distortion of the large-diameter flange necessitated press-die quenching. Although not required functionally, a 0.64-in.-thick by about 1-in.-wide rim was needed to minimize distortion of the 0.335-in.-thick flange during heat treatment. To locate the forging during die quenching, annular surfaces were machined on the flange opposite the gear and on the rim to an axial dimension of 0.100 ± 0.001 in. Because of the cost of alloy steel forgings and the problems from distortion during heat treatment, the gear was redesigned for inertia welding, as shown in Fig. 19.

The flange section was gas-cut from scale-free 1018 steel plate 0.375 in. thick, machined to a 13.04-in. OD and a 4.312-in. ID, and degreased. The gear section was hobbed from 8617 steel tubing and carburized. Before hardening, the carburized case was machined off at the end and sides of the joint area, so that the weld would be made on the low-carbon 8617 core, not on the carburized surface. The area of the weld surface was about 4.55 sq in. The gear section was hardened before welding, and thus heat treatment of the entire part and the resulting distortion of the flange were avoided.

The flange section was held in a nonrotating fixture mounted to the tailstock of the inertia welding machine and the gear was held in a rotating fixture mounted on the spindle. Locating and driving were done on the pitch diameter of the gear. The machine was loaded and unloaded manually. After the gear was welded to the flange, the weld upset was machined from the inside and outside surfaces, and spline teeth were hobbed around the periphery of the flange.

Welding conditions (see table with Fig. 19) and machine performance were checked for each production lot. The weld upset on each part was visually inspected, and random measurements were made to determine whether the length of the gear conformed to the specified 1.940 ± 0.009 in.

Inertia welding and machining produced a part with quality equivalent to that of the machined forging, but at a cost reduction of $4.25 per piece.

Cost of Inertia Welding vs Other Methods of Fabrication

The cost advantages of inertia welding in comparison with other methods of fabrication are shown in the following projections of costs for the production of three different parts.

Drill-to-Shank Welding. Costs for flash welding and inertia welding of 4140 steel shanks to M10 high speed tool steel drill bodies, indicating the savings provided by inertia welding, are given in Table 3.

Table 3. Cost Comparison for Joining M10 High Speed Tool Steel Drill Bodies to 4140 Steel Drill Shanks by Flash Welding and by Inertia Welding

Item	Drill A: Flash welding	Drill A: Inertia welding	Drill B: Flash welding	Drill B: Inertia welding	Drill C: Flash welding	Drill C: Inertia welding
Drill Dimensions, In.						
Diameter	0.547		0.832		1.062	
Over-all length	8.25		9.75		11.00	
Body length	4.25		5.75		6.25	
Welding Conditions						
Metal lost (total), in.	0.400	0.120	0.510	0.175	0.620	0.200
Metal lost (high speed tool steel), in.	0.240	0.030	0.305	0.045	0.370	0.060
Production rate, welds per hour	165	225	138	190	84	160
Scrap rate, %	5	0.5	5	0.5	5	0.5
Costs per 100 Pieces(a)						
Body stock	$38.88	$37.06	$121.10	$115.90	$216.08	$205.96
Shank stock	4.58	4.49	10.93	10.74	21.48	21.00
Welding labor	9.34	6.65	10.72	7.90	17.69	9.38
Cutoff labor	5.00	5.00	6.00	6.00	7.00	7.00
Scrap loss	2.89	0.26	7.44	0.70	13.11	1.21
Total cost	$60.69	$53.46	$156.19	$141.24	$275.36	$244.55
Savings	...	$7.23	...	$14.95	...	$30.81

(a) Values used in calculations: M10 high speed tool steel, $1.30 per pound; 4140 steel, $0.17 per pound; labor plus burden, $12 per hour; labor efficiency, 80%.

Assuming the quantity of 0.547-in.-diam drills (drill A, Table 3) to be about three times that of drills B and C, the average saving per drill would be $0.136 — which, at 300,000 drills per year, would give annual gross savings of $40,800. The inertia welding machine and semiautomatic tooling would cost about $60,000.

Shaft-and-Pinion: One-Piece Forging vs Weldment. Table 4 compares costs for two sizes of each of two designs of pinion-and-shaft one-piece upset forgings made of 8630 steel and equivalent parts made by inertia welding an 8630 steel pancake or upset forging to a 1035 steel tube or shaft. The two designs, identified as designs A and B, are illustrated in Table 4 as the weldments after cutting of gear teeth.

The cost savings shown for the inertia welded pinion-and-shaft assemblies accrue from the use of less expensive forgings, the lower cost of 1035 steel than of 8630 steel for the shafts, and elimination of a drilling operation for the hollow shaft on design A. The inertia welding machine and tooling would cost about $100,000.

Cluster Gear. Following preliminary machining, a heavy gear-and-pinion cluster, upset forged in one piece from 8822 carburizing steel, presented problems in quench hardening after carburizing to provide a case hardness of Rockwell C 60 and a core hardness of Rockwell C 35. A rather severe quench was needed to develop the required core hardness in the heavier pinion section of the forging, and this resulted in excessive distortion and occasional cracking at the intersection of the web and gear. Although increasing the web thickness might have solved the problem, it would have increased the as-forged weight of the one-piece cluster from 130 lb to 152 lb.

To solve the problem and reduce manufacturing costs, investigation was made (*a*) on a change to an inertia welded assembly of a forged gear blank and a forged pinion blank, and (*b*) on the selection of a carburizing steel with slightly higher hardenability for the heavier pinion forging.

The cost of the inertia welding machine, equipped for manual loading and with semiautomatic tooling, was about $225,000. With a machine cycle time of 4 min, production rate was projected at 13.8 assemblies per hour.

Following is a comparison of costs for the two methods of fabrication:

Cost factor	Cost
Original forging, 130 lb at $0.25 per pound	$32.50
Improved forging, 122 lb at $0.23 per pound	28.06
Material saving per piece	$ 4.44
Inertia welding labor and burden, 0.075 hr at $11 per hour	0.82
Cost saving per piece	$ 3.62

(a) Based on unit costs as follows: upset forgings, $0.22 per pound; pancake forgings, $0.19 per pound; bar stock, $0.07 per pound; 1.5-in.-diam tubing, $0.86 per foot; and labor and burden, $11 per hour.

ELECTRON BEAM WELDING

*By the ASM Committee on Electron Beam Welding**

CONTENTS

IN ELECTRON BEAM WELDING, the joint to be welded is heated by bombarding it with a dense stream of high-velocity electrons. The kinetic energy of the electrons is changed into heat on impact with the work.

The electron beam is produced in a high-vacuum environment by an electron gun, usually consisting of a tungsten or tantalum cathode, a grid or forming electrode, and an anode. Electrons are emitted from the cathode, which is heated to about 4600 F or higher. The electrons are gathered, accelerated to a high velocity and shaped into a beam by electrical fields between the cathode, grid and anode. The beam is collimated and focused by passing through the field of an electromagnetic focusing coil, or "magnetic lens". Electron beams can be deflected from their normal path by magnetic deflection coils, usually located below the focusing coil.

The gun, which is sometimes isolated from the welding chamber by a valved aperture, is held at a high vacuum (10^{-4} to 10^{-5} torr, or less) to protect its components, especially the cathode, from oxidation and from short-circuiting through vapors evolved in welding. The vacuum environment also reduces electron scattering by air molecules, thus conserving effective beam energy. Electron guns are rated at about 30 to 175 kv, and for a beam current of about 50 to 1000 ma.

Beams typically are focused to about 0.010 to 0.030 in. in diameter and have a power density of about 10^6 watts per square inch, which is sufficient to vaporize any metal. In the welding process, the beam first creates a hole in the work. As the electron beam advances along the joint, a weld is formed by a combination of three effects that occur at the same time: (*a*) metal on the leading side of the hole vaporizes, and the vaporized metal then condenses to form molten metal on the trailing side of the hole; (*b*) the molten metal on the leading side of the hole flows to the trailing side of the hole; and (*c*) the molten metal thus formed continuously fills the hole and solidifies as the electron beam advances.

Applicability

Electron beam welding is used to weld almost any metal that can be arc welded; weld quality in most metals is equal or superior to that of the best gas tungsten-arc welds. The major advantages of vacuum electron beam welding include:

1. Ability to make welds that are deeper, narrower and less tapered than arc welds, with a total heat input much lower than that in arc welding
2. Superior control over penetration and other weld dimensions and properties
3. A high-purity environment for welding (evacuated work chamber), resulting in freedom from impurities such as oxides and nitrides
4. Higher welding speed
5. High production when a number of parts can be loaded in a chamber, or when the chamber is small enough to permit rapid pumpdown.

These characteristics make possible: minimizing distortion and shrinkage in welding; welding of hardened or work-strengthened metals and frequently without significant deteriora-

Some of the examples presented in this article were contributed by members of other Metals Handbook welding committees.

tion in mechanical properties at the joint; welding of parts that already have been finished to final assembly dimensions; welding in close proximity to heat-sensitive components or attachments; readily making hermetic-seal closure welds on evacuated enclosures; welding of refractory and reactive metals; and welding of combinations of dissimilar metals not usually joinable by arc welding. By projecting the beam several inches to several feet, welds often can be made in otherwise inaccessible locations.

Disadvantages of vacuum electron beam welding include:

1 High cost of equipment. Production-size welding units vary considerably in cost, depending on the accessories included, but a general-purpose unit may cost more than $150,000 (1971 prices).
2 High cost of precision joint preparation and precision tooling, usually higher than for arc welding processes. Because of the relatively small size of the electron beam, joint gaps must be kept to a minimum.
3 Limitations of the vacuum chamber. Work size is limited by the chamber dimensions, and production rate and unit welding cost are adversely affected by the need to pump down the work chamber for each load.

Nonvacuum electron beam welding is not subject to the limitations of the vacuum chamber, can be done at high welding speed, and may permit savings in comparison to arc welding on mass-produced parts of suitable shape. It offers the first two advantages listed on page 519 to a lesser degree than does vacuum electron beam welding, and it completely lacks the third advantage over arc welding.

Penetration is usually less than ½ in., and workpiece shape must permit a working distance of ¾ in. or less.

Process Control

The basic variables for controlling vacuum electron beam welding are:

1 Accelerating voltage
2 Beam current
3 Welding (travel) speed
4 Focusing current
5 Distance from gun to work.

Beam spot size (at the work) is determined by the characteristics of the electron gun, the focusing current (which controls the focal length of the beam), distance from gun to work, accelerating voltage, and beam current.

Increasing the accelerating voltage or beam current increases depth of penetration; the product of these two variables (called beam power) determines the amount of metal melted. Increasing welding (travel) speed without changing another process variable reduces depth of penetration almost proportionately and reduces weld width somewhat. Changing any of the other four basic control variables so as to increase beam spot size reduces depth of penetration and increases weld width, if welding speed is not changed.

Beam deflection can be used to change the impact angle of the beam or to produce controlled patterns of beam oscillation for the effect of greater beam spot size or other special effects, and the beam can be pulsed to reduce effective beam power (page 548).

In nonvacuum electron beam welding, ordinarily all of the five basic control variables except beam current are preset, and control is based on beam current. Beam current may be set at a fixed value for the application and merely turned on and off in relation to workpiece travel, or it may be programed to vary in a predetermined pattern. Beam deflection cannot be used; beam oscillation is seldom used.

Operations

The tooling and welding procedures for each application are developed in preliminary experimental work. Details of the welding sequence may vary somewhat, depending on differences in equipment and on the application requirements. One typical sequence for welding in high vacuum is:

1 Assemble and prepare work and fixtures for welding. This includes cleaning, and may include demagnetizing, preheating and tack welding.
2 Load fixtured work on worktable or workholding mechanism in welding chamber.
3 Start chamber pumpdown.
4 Make preliminary alignment of joint with defocused beam, after pumpdown.
5 After chamber pressure has been reduced to 10^{-4} torr, focus on tungsten target block and set beam parameters.
6 Make final alignment of joint to the beam position.
7 Start welding. Welding is usually performed automatically, but can be performed manually.
8 Terminate the welding cycle.
9 When the work has cooled sufficiently, admit air to the chamber and remove fixtured work.

Step 5 above applies primarily to setting up for a repetitive operation.

For nonvacuum welding, the electron gun and beam transfer column are maintained at established pressure levels. Work-handling and welding operations in this method are ordinarily mechanized for high-speed production, and work and fixturing are prepared before a production run is begun or are done as part of a production-line operation. Beam parameters, alignment of joint with beam position, and transfer and movement of work for welding are set before a production run. Alignment of the joint with beam position is only slightly less critical than for vacuum electron beam welding, because beam spot size and weld width are only slightly larger for nonvacuum welding.

Mechanical Preparation of Joint. A joint for electron beam welding ordinarily has closely fitted, abutting, square groove faces, and filler metal is not ordinarily used. As a general rule, the faces of the joint are machined to a surface roughness of about 120 micro-in. or less.

Surface finish on the weld groove faces may not be critical, depending on part and joint design and the requirements for weld properties. In studies on butt welding of 2-in.-thick aluminum alloy 2219 and Ti-6Al-4V in which the groove faces had surface roughness values of 63, 125, 250, 500 and 1000 micro-in., surface finish had no effect on weld quality, as determined by visual examination and x-ray radiography; all welds were sound. Edge surface finish is much less critical on broad welds than on narrow welds.

Edge roughness is not critical on lap joints in thin metal as long as burrs do not separate the surfaces.

Fit-up. A butt joint is not open, as in arc welding, but has closely fitted, straight surfaces to enable the characteristically narrow electron beam to fuse base metal on both sides of the joint in making a weld. The members of a joint to be melt-through welded also are closely fitted. Fit-up tolerance depends on work-metal thickness and joint design, but is usually 0.005 in. or less. Joint gap is usually smaller for thin work metal and unbacked joints; it may be 0.001 or 0.002 in. max. Interference fits are sometimes used where shrinkage can cause cracking, as in circular joints on hardenable metals.

Joint gap of about 0.002 or 0.003 in. max is commonly used for making narrow welds.

In making deep welds, poor fit-up or excessive joint gap can cause excessive shrinkage, underfill, undercut, voids, cold shuts and missed joints. In most metals, joint gap should not exceed 0.010 in. for narrow welds deeper than about ½ in., although sound welds have been obtained using joint gaps of 0.030 in. by increasing weld width to 0.275 in.

Cleaning. Workpiece surfaces must be meticulously clean for electron beam welding. Inadequate surface cleanness not only causes weld defects, as it does in arc welding, but also increases pumpdown time and can degrade the oil used in the pumps.

Any of the common chemical and mechanical cleaning methods may be used (see cleaning sections in the articles on arc welding processes in this volume). A combination of two or more methods is often used. If workpieces are cleaned in chlorine-containing compounds these compounds should be removed by another cleaning method before welding.

Final cleaning should be done within a few minutes before welding. After final cleaning, the joint faces should not be touched by hands or tools.

Fixturing methods for vacuum electron beam welding are generally like those for gas tungsten-arc welding of precision parts without the use of filler metal, except that the clamping force needed is usually lower, and all materials and moving members must be suitable for use in a high vacuum.

Because total heat input to the weld is much less than for arc welding and because the heat is highly localized, there is less need for heavy fixturing, massive heat sinks, or water cooling. C-clamps suffice for many parts. In some applications, clamping can be supplemented or replaced by small tack welds or by a shallow weld pass (sealing pass) over the joint, with the penetration weld made later at full power. Both basic and specialized fixturing are available.

General-purpose welding positioners and related mechanisms are satisfactory for nonvacuum electron beam welding. Locating and aligning mechanisms are simpler than for welding in a vacuum, because of their accessibility and because beam widths for nonvacuum welding do not necessitate such high accuracy in tracking the joint. Maintenance of work-handling equip-

ment for nonvacuum electron beam welding is greatly simplified by its out-of-chamber location.

Demagnetization. Workpieces and fixtures made of magnetic materials should be demagnetized before welding. Residual magnetism may result from magnetic-particle testing, magnetic chucks, or electrochemical machining. Even a small amount of residual magnetism can cause beam deflection.

Workpieces are usually demagnetized by placing them in a 60-cycle inductive field and slowly removing them. The equipment used in magnetic-particle testing can be used (see Example 484).

Before welding, workpieces should be checked with a gauss meter. Acceptable gauss-meter readings vary from ½ gauss for very narrow, critical welds to as much as 10 gauss for relatively wide welds.

Pumpdown time for the vacuum chamber depends mainly on chamber size, types of pumps used, and vacuum required. Vacuum controls on electron beam welding equipment generally provide a choice of either an automatic or a manual mode of pumpdown. In the manual mode, the operation of the vacuum system is controlled by a manual selection switch on the operator's console, which, step by step, sequences all valves and instrumentation through the entire vacuum cycle. In the automatic mode, a series of relays, limit switches, and pressure sensors overrides the manual selector switch.

For high-vacuum electron beam welding, a pressure of 10^{-4} torr or less is produced by a mechanical-piston pump operating in conjunction with an oil-diffusion pump. The sizes of these pumps depend on the size of the chamber and the pumpdown time required. A 30-cu-ft chamber employing a 21,000-cu-ft-per-minute diffusion pump and a 140-cu-ft-per-minute mechanical pump could be expected to reach welding pressure in less than 3 min; a 300-cu-ft chamber employing a 42,000-cu-ft-per-minute diffusion pump and a 600-cu-ft-per-minute mechanical pump could be expected to pump down in less than 10 min.

For electron beam welding in medium vacuum, the pressure in the work chamber is 2×10^{-1} to 10^{-3} torr. The gun chamber, in which the beam is generated, collimated and focused, is held at 10^{-4} to 10^{-5} torr, as in high-vacuum welding. A small diffusion pump is needed to provide the vacuum in the gun chamber, but a diffusion pump is not needed for pumping down the welding chamber, which can be evacuated with a mechanical pump.

In some applications, however, a blower or Roots pump may be required for high-production welding of small parts in a medium vacuum. Pumpdown times in mass production often range from about 40 sec for a relatively large general-purpose working chamber (4 cu ft), down to less than 5 sec for small chambers.

Preheat and Postheat. Most commonly welded metals can be electron beam welded, even in thick sections, without preheating, because of the extremely narrow width of the heat-affected zone. Hardenable and difficult-to-weld metals may need to be

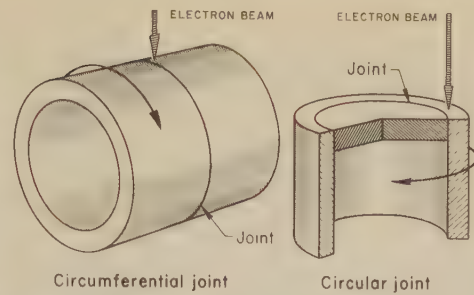

Fig. 1. Circumferential and circular joints in position for electron beam welding

preheated, especially for thick sections and where the weld is restrained.

High-strength alloy steels and tool steels thicker than about ⅜ in. ordinarily must be preheated before electron beam welding, to prevent cracking. Deep circular welds, especially partial-penetration welds, in thick sections of carbon steel containing more than about 0.35% carbon usually need preheating. On the other hand, welds subject to less restraint, such as circumferential welds on cylindrical shapes, can be made on ½-in.-thick, 0.50% carbon steel without preheating.

Preheating, when needed, is usually done before the work is placed in the work chamber. Selection of heating method depends on the size and shape of the work and the preheat temperature; a combination of methods can be used. Torch and furnace heating are widely used; induction and infrared-radiation heating are also used. On small parts or where distortion from localized heating is not a problem, and where increased cycle time can be tolerated, heating is sometimes done with a defocused electron beam; this method can also be used to supplement other methods of heating.

Furnace preheating was used in Examples 483 and 488. The electron beam was used at reduced power to preheat tantalum in Example 491.

When postheating is employed on electron beam welded parts, it is ordinarily done by conventional means after removing the work from the welding chamber.

Postheating was done in 13 of the 42 examples described in this article. Stress relieving was done in Examples 464, 484, 487, 490, 502 and 503, tempering in Examples 464, 473, and 486.

Operating Conditions. A typical vacuum welding sequence is listed in column 2 on the preceding page. Starting and stopping the weld usually requires special consideration, to avoid nonuniformity of the weld at these points and possible burn-through and loss of metal.

One technique that is used to avoid these difficulties is to start the weld at full beam power on a starting tab of the work metal that is tightly fitted against one end of the joint, and to conclude it on a runoff tab at the other end of the joint. Or, the workpieces can be made oversize to provide extra material for starting and stopping. The tabs or the extra material can be machined off after welding. Starting and runoff tabs are used mostly in low-production operations.

Another technique is to start and stop the weld on the work, bringing up the current gradually (upslope) at the beginning of the weld and reducing it gradually (downslope) at the end of the weld. Upslope and downslope at controlled rates and time intervals, as established for a specific application, can be programed into the welding procedure. The use of upslope and downslope is of special value where the weld is a closed path, as in welding circular and circumferential joints.

In many applications of closed-path welds, the weld can be started at full power, with downslope at the end providing a sufficiently gradual termination and a suitable distance of overlap. Downslope of current after overlapping the beginning of the weld on circular welds in thick sections of high-hardenability steels is critical, to avoid porosity and cracking. Other parameters may also be adjusted to avoid these defects.

Downslope alone was used in welding 15 circular and circumferential joints in examples described in this article, and both upslope and downslope were used on five circular and circumferential joints. Upslope is usually rapid; downslope is from a few degrees to a major portion of a revolution.

A "cosmetic pass" is made when needed to smooth or flatten the crown of a weld that is irregular or too high, or to correct undercut or underfill. The beam is usually defocused or reduced in power, or both, in making a cosmetic pass. Filler metal may also be added in making a cosmetic pass intended to correct undercut or underfill.

Cosmetic passes were used on vacuum welds in Examples 471, 474, 497 and 503. Usually, nonvacuum welds are smooth and do not need cosmetic passes (page 528).

Joint Design

Groove and melt-through electron beam welds are made on all basic joint types: butt, corner, T, lap and edge.

Most electron beam welds are square-groove or modified (usually rabbeted) square-groove welds on butt or corner joints (see Fig. 2 and 3); about 80% of the welds in the examples in this article are of this type.

Joints can be straight-line, irregular-outline, circumferential or circular joints. Circumferential and circular joints can be welded by rotating the work in the path of a stationary electron beam, as shown in Fig. 1.

Of the examples of electron beam welded joints in this article, 80% were circumferential or circular, with about the same number of each type.

Factors in Design. Many joints for electron beam welding have rabbeted grooves to make them self-aligning and at least partially self-fixturing, which is of particular importance in batch loading the vacuum chamber for efficient work manipulation.

Most joints are designed to be welded in a single pass with full penetration or penetration to a specified depth (see the section on Welding of Thick Metal, page 538, for the usual ranges of penetration). Depending on the application, welding may be preceded by a sealing pass or by tack welding, and be followed by a "cos-

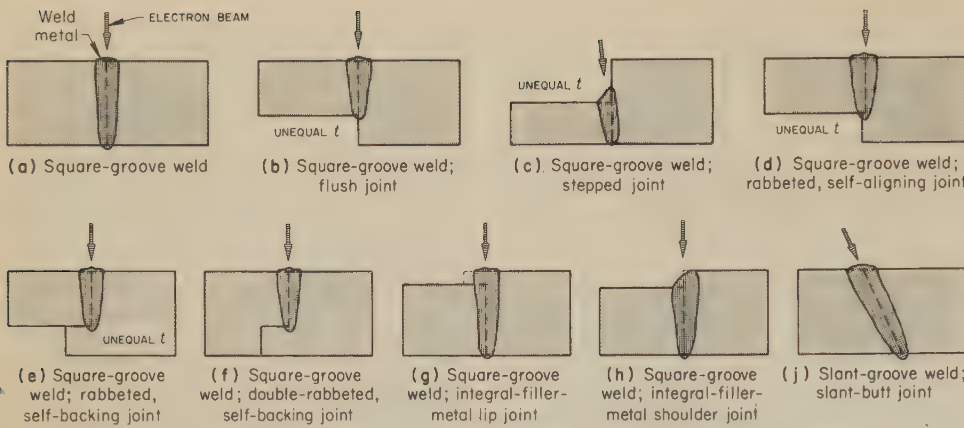

Fig. 2. Nine types of butt joints and welds used in electron beam welding

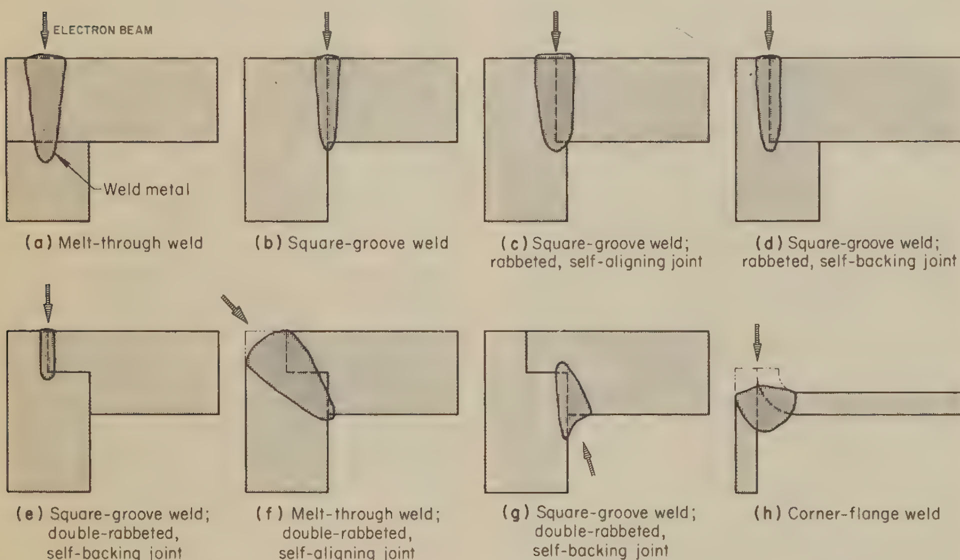

Fig. 3. Eight types of corner joints and welds used in electron beam welding

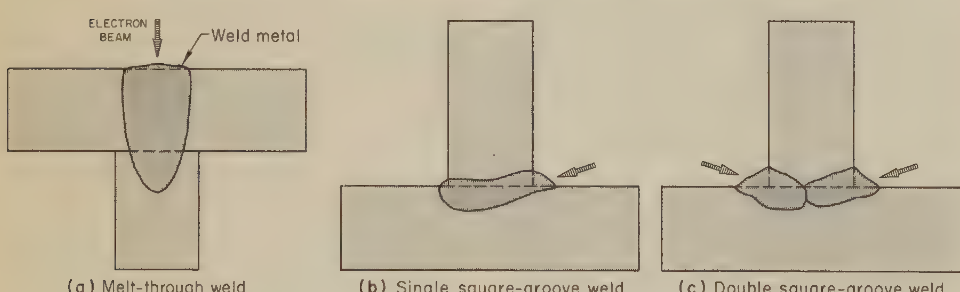

Fig. 4. Three types of electron beam welds in T-joints

metic" or smoothing pass. Most electron beam welds are continuous, but intermittent, spot and plug welds are also made. When filler metal is to be added in making an electron beam weld, either by preplacing wire or strips of filler metal in or at the joint, or by feeding filler-metal wire, a suitable root opening (or, sometimes, a groove bevel) is provided to permit convenient placement or feeding (see "Use of Filler Metal", page 539).

Special joint details are sometimes added to serve as thermal conduction barriers or as heat sinks, in making welds close to heat-sensitive locations in the workpieces. Integral backing or separate backing strips or rings are used to prevent spatter and loss of weld metal, to serve as heat sinks, or to avoid root defects in metal that will not be machined away after welding.

As with arc welding, joint strength, ductility, fatigue life, and avoidance of stress concentration must conform with service requirements.

Common Joint and Weld Types. Figures 2 to 6 show the commonly used joint and weld types for electron beam welding. Different joint preparations, joint designs and welding positions are used to meet special requirements.

Welds in Butt Joints

The basic square-groove weld, which is shown in Fig. 2(a), (b) and (c), needs only the simplest and least expensive joint preparation, and is suitable for either partial or full-penetration welds. Good fit-up and external fixtures are needed. The flush joint (Fig. 2b) is preferred to the stepped joint (Fig. 2c) for joining unequal thicknesses, chiefly because control of conditions for making sound full-penetration welds is less critical than for the stepped joint. A wider beam is used in welding the stepped joint, and the beam angle must be carefully controlled to avoid scarfing the upper edge of the thicker member (angle too small) or missing the bottom of the joint (angle too large), especially if the thinner member is more than about ⅜ in. thick.

Joint (d) in Fig. 2 is rabbeted to make it self-aligning, but the offset is small, to avoid leaving an unwelded seam near the root of the weld (compare Fig. 2e). Joints (d) to (g) in Fig. 2 are self-aligning and may be self-fixturing in circular, circumferential and certain other joint arrangements. Joints (e) and (f) are both self-aligning and self-backing; each, however, leaves an unwelded seam near the root of the weld.

Welds (g) and (h) in Fig. 2 show two ways of providing integral filler metal. The lip of joint (g) provides more filler metal than the shoulder of joint (h), but because it conceals the joint, a scribed line or other means for beam placement and for scanning must be provided before the welding operation can proceed.

The slant-groove weld (also called angular or scarf) shown in Fig. 2(j) is used in butt joints to facilitate fixturing, and where limitations on the beam location would prevent fusion for the entire groove depth if the basic square-groove weld (Fig. 2a) were used. Greater weld depth, as measured parallel to the beam axis, is needed for full penetration of a given work-metal thickness than with the square-groove weld. This type of weld and variations of it are used both in butt joints and in corner joints.

A slant-butt joint can also be welded with beam alignment set at 90° to the surface of the work. This beam angle will permit the production of defect-free welds where fit-up is poor or where the joint opening is larger than can be tolerated when the beam is aligned with the groove. In a related type of weld, the joint has a square-groove or modified square-groove preparation, and the beam is at an angle to the groove. The main reason for using this type of weld is difficulty of access with other types of welds, as in Example 469.

The use of slant-groove welds in circumferential butt joints is described in Examples 486 and 491 on pages 550 and 554, respectively, in this article.

Butt joints are the most common of the five basic joint types used in electron beam welding; about 60% of the electron beam welds described in examples in this article were in butt joints. In welding a flange to a tube, the use of a butt joint in the tube ("welding neck" construction) is preferred to the use of a corner joint, which would concentrate bending stresses at the weld (see Example 464).

Welds in Corner Joints

Eight types of electron beam welds frequently made in corner joints are shown in Fig. 3.

Corner joints are second only to butt joints in frequency of use for electron beam welding; about a fourth of the electron beam welds described in examples in this article were in corner joints. Most are welded from the outside; an inside corner weld is described in Example 499.

Important differences between butt and corner joints are notch sensitivity and suitability for nondestructive testing. (To compare alignment, self-fixturing, and the occurrence of portions of unwelded seam, see Fig. 2 and 3.)

The two simplest and most economical welds in corner joints are the melt-through (Fig. 3a) and basic square-groove (Fig. 3b) welds. Neither is self-aligning or self-fixturing; manipulation of the work for weld (b) in Fig. 3 can be simplified by using a horizontal electron beam and corresponding work orientation (rotated 90° from the orientation shown). The melt-through weld (Fig. 3a), unless made with a fusion zone wide enough to eliminate the unwelded seam completely, is weaker than the square-groove weld and is notch sensitive.

The corner-flange weld (Fig. 3h), usually made only on thin stock, requires precision forming of the 90° bend. Welds in corner joints are subject to high stress concentrations.

Welds in T-Joints

Three types of electron beam welds made in T-joints are shown in Fig. 4. The melt-through or blind weld (Fig. 4a), like melt-through welds in butt or corner joints, leaves an unwelded seam, with resulting low strength, notch sensitivity and corrosion susceptibility. The double square-groove weld (Fig. 4c) is used primarily on sections 1 in. or more in thickness. For types (b) and (c), filler metal is usually added.

Welds in Lap Joints

Three types of electron beam welds made in lap joints are shown in Fig. 5. They are most frequently used in joining thicknesses of about $1/16$ in. or less.

Both the melt-through (Fig. 5a) and the single fillet (Fig. 5b) welds leave an unwelded seam. The major application of a melt-through weld in lap joints is for metal 0.005 in. or less thick; a partially defocused beam or sinusoidal deflection transverse to the travel direction is used to increase weld width at the interface.

The single and double fillet welds (Fig. 5b and 5c) are made with a partially defocused beam to broaden the weld and provide a smooth transition. Especially on thick stock, filler metal may be added to increase fillet size.

Examples 490, 498 and 502 describe electron beam welds in lap joints.

Welds in Edge Joints

Three types of electron beam welds made in edge joints are shown in Fig. 6. Thick sections can be joined by deep, narrow square-groove welds (Fig. 6a). Shallow welds made with a low-power, partially defocused beam are used to join thin sections to each other or to thick sections, as shown in Fig. 6(b) and (c). Shallow edge welds can be made at high speed. Welds of this type are particularly useful on hermetically sealed assemblies, which may be designed for planned salvage by removal of the weld region and subsequent rewelding.

Electron beam welds on edge joints are described in Examples 478, 482, 485 and 501 in this article.

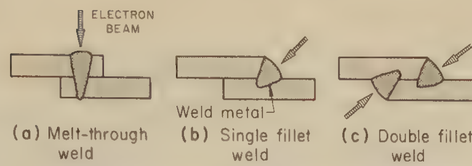

Fig. 5. Three types of electron beam welds in lap joints

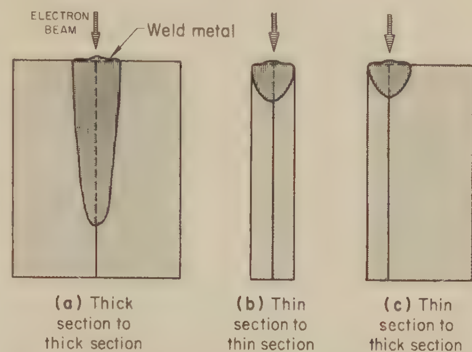

Fig. 6. Three types of electron beam welds in edge joints between members of similar or different section thicknesses

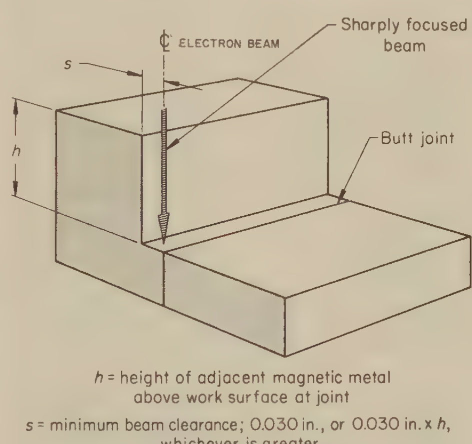

Fig. 7. Joint location and beam clearance for a butt joint near a projecting corner, T or shoulder in a magnetic work metal. For electron beam welding of a straight-line joint of cross section as shown, or a circular or circumferential joint.

Butt vs Corner and T-Joints

The concentration of bending stresses at the weld in corner and T-joints is sometimes avoided by designing the work for a butt joint on a straight section near the corner or T (flange-neck or welding-neck construction). This principle of design is applicable also to butt joints between members having different thicknesses, and it can be applied to straight-line, circular and circumferential joints. Its use is illustrated in Example 464.

In welding such a joint in magnetic metals, if the beam path is too close to the corner, T or shoulder, the beam may be deflected away from the metal that it passes near on its way to the joint, causing it to enter the work at an angle and possibly to miss the lower portion of the joint. To avoid this, the beam clearance should be 0.030 in. or more, depending on the height of the magnetic projection (Fig. 7).

Special Joints and Welds

Many variations of the basic joint and weld types described in the preceding section and illustrated in Fig. 2 to 6 are used to meet the needs of individual applications. Some of these special joints and welds are discussed in the following paragraphs.

Plug and puddle welds are usually made with manual manipulation of the work under a fixed beam at low power. Filler metal used for plug welds is often preplaced at the weld site. Puddle welding is used mainly to fuse shallow defects together locally.

Multiple-Pass Welds. Most electron beam welds produce the desired penetration in a single pass. (Tack welds and cosmetic or smoothing passes are not considered penetration passes.) Welds several inches deep can be made in most metals in a single pass (see the section on Welding of Thick Metal, on page 538). Weld depth obtainable in a single pass can be nearly doubled by welding from both the face and the back of the work, as was done in Example 478, in which weld passes 3 in. deep were made from opposite sides for a full penetration of $5\frac{3}{8}$ in.

In a variation on straight-through two-pass welding from opposite sides, separate welds that meet, or almost meet, can be made at an angle of 90° to each other in a rabbeted square-groove joint, as in Example 488.

Tangent-tube welds are longitudinal welds joining two parallel tangent tubes (or cylinders). The tubes may differ in size; the beam is perpendicular, or nearly perpendicular, to the common axial plane of the two tubes. Added filler metal may be used for reinforcement. Thinner-wall tubes can be joined than by arc welding.

Three-Piece Welds. Welds that join three or more pieces in which there is penetration in a single pass into all of the pieces can be made. Many of the difficulties encountered in welding very thin metal or foil are eliminated by sandwiching it between two thicker sections, as in the melt-through welding of 0.002-in.-thick stainless steel in Example 476. Special types of joints are described in Examples 469 and 473.

Transition joints ordinarily are made with two or more separated welds. An unusual transition-joint design, which was used in welding 1113 steel to 2024-T4 aluminum, is shown in Fig. 53.

Multiple-tier welds are welds made simultaneously in in-line, separated joints (usually butt joints) in a single pass of the electron beam. A more detailed discussion is given in the section on Multiple-Tier Welding, page 541.

Welds using integral filler metal may be of the types shown in Fig. 2(g) and (h), in which an overhanging lip or a shoulder provides filler metal to a butt joint, or both members may be made thicker at the joint than elsewhere.

Examples 464, 465, 480, 484, 487 and 489 in this article describe joints that provided integral filler metal.

Joint Design in Examples of Practice

In addition to those already cited, other examples of practice in this article show various important aspects of joint design.

Heating was minimized in Example 501 by machining slots on either side of the weld groove, which reduced both the amount of heat needed and heat transfer to nearby sensitive components (for a given heat input). This design, which allows slight yielding under shrinkage stress during cooling, thus lowering residual stress, has often been used to make welds that could not otherwise be made. In Examples 465 and 475, the cross section of one member was reduced next to the joint to impede heat transfer.

In Example 487, a ring that was to be welded to a shell was made extra thick to permit welding to a depth sufficient to put any voids near the weld root in a region that would be machined away after welding.

The design of joints between thin and thick sections so that the thick member of the joint provides a heat-sink effect to prevent melting of the thin member is discussed in the section on Welding of Thin Metal, page 536.

The two examples that follow illustrate several aspects of joint design.

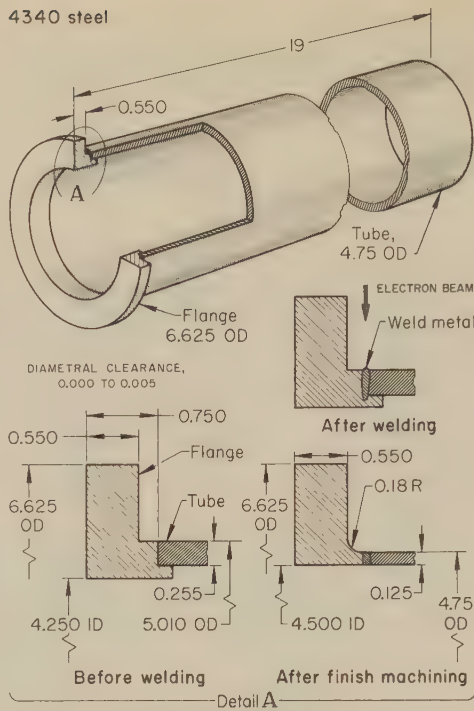
Example 464. Use of an Oversize, Self-Aligning, Self-Backing Butt Joint in a High-Strength Flange-to-Tube Weld on 4340 Steel (Fig. 8)

Joint design was critical in the carefully planned and executed procedure used to produce a flange-to-tube assembly of 4340 steel for an aircraft engine mount. Basically, the procedure consisted of welding an oversize assembly and then machining to finished dimensions, as indicated in detail A of Fig. 8. Process selection, fixturing, welding, heat treatment, inspection and final machining were also important to the success of the application.

Process Selection. Electron beam welding was selected primarily to obtain deep, narrow welds at high speed with low total heat input, for high strength. Tests had shown that high joint efficiencies were obtained in static tensile and fatigue loading. In addition, electron beam welding produced low distortion, and provided excellent control of penetration.

Fusion under a high vacuum promoted weld cleanness, as determined by x-ray radiography. Very clean welds could be obtained by using a vacuum-melted steel; in this application, however, air-melted 4340 steel was used.

Joint Design. The type of butt joint used is shown in detail A of Fig. 8. The normalized, seamless 4340 steel tubing was finish machined on the inside and rough machined on the outside. The flange was of welding-neck design, which located the weld away from major flange bending stresses and simplified nondestructive inspection. The outside of the flange hub was rough machined to the outside diameter of the tube, and the inside diameter of the hub was machined ¼ in. undersize.



Joint type	Circumferential butt; self-backing
Weld type	Square groove
Weld depth-to-width ratio (typ)	3.7
Machine capacity	150 kv at 40 ma
Gun type	Pierce; fixed
Vacuum-chamber size	56 by 56 by 108 in.
Fixtures	Lathe-type positioner with plug and face plate; rotary indexing table
Preheat	None
Welding power	130 kv at 24 ma
Welding vacuum	Less than 10^{-4} torr
Beam focal point	0.250 in. above work surface
Welding speed	31.4 ipm (2 rpm)
Weld time	30 sec
Production rate	12 pieces (one load) per hour
Postheat	Stress relieve (950 F for ½ hr); quench and temper to a tensile strength of 150,000 to 172,000 psi (see text)

Fig. 8. Flange-to-tube assembly that was precision welded for a critical application, using an oversize, self-aligning, self-backing butt joint and controlled penetration (Example 464)

The overlapping lip, made by cutting a recess in the hub, served for alignment and weld backing. The lip was sufficiently thick (0.125 in.) to permit controlled-penetration welding beyond the inside diameter of the tube, so that any root voids would be in the region to be machined away after welding and so that there would be no weld spatter on the interior of the tube. Diametral clearance was zero to 0.005 in., for accurate axial alignment.

Joints were cleaned by vapor degreasing and wiping with acetone. The parts were then demagnetized and assembled.

Fixturing. To permit welding in the horizontal-rolled pipe position, a lathe-type positioner was used. With a plug at the tailstock to fit the tube and a face plate at the headstock aligned by three tooling holes in the flange face, the joint was precisely located for rotation under the electron beam gun. Fit-up tolerances, including mismatch, were held within 0.005 in. Fixtures were vented to prevent any buildup of air pressure in the tube during welding.

By mounting the fixtured assemblies on a rotary-indexing fixture, a batch of 12 assemblies could be welded in one hour during one pumpdown. All fixtures were made of nonmagnetic stainless steel.

Welding. Machine settings for the welding operation were determined on test pieces, to obtain a fusion pass that would penetrate the joint up to 60 to 70% of the backing-lip thickness. Partial penetration, as shown in detail A of Fig. 8, eliminated the possibility of weld spatter damaging the interior of the tube. The table with Fig. 8 summarizes machine settings and other welding conditions. During weld starting and stopping, beam energy was regulated by upslope and downslope current control, which made necessary slightly more than one full revolution of the work to complete the weld.

Heat Treatment. Immediately after a batch was welded, the parts were stress relieved at 950 F for ½ hr, and heat treated to a tensile strength of 150,000 to 172,000 psi, by heating to 1550 F for 1 hr, quenching, and tempering at 1250 F for 2 hr.

Inspection. Before final machining, all welds were inspected visually and by magnetic-particle testing. After final machining, the joints were inspected by radiographic and ultrasonic examination. Acceptable defects were limited to 5% of minimum thickness, or approximately 0.006 to 0.007 in. in size.

Final Machining. The flange was rebored to the same inside diameter as the tube. The outside tube surface and the flange hub were machined to finished wall thickness, as shown in detail A of Fig. 8. Roughness was held to 63 micro-in., and tolerances required concentricity over the tube length within 0.005 in.

Example 465. Joint Design, Equipment and Procedure for Welding Controlled-Strength Joints Between 8620 Steel and GMR-235 at a High Production Rate (Fig. 9)

Supercharger impellers for diesel engines were produced in batches of 24 by electron beam welding. A typical impeller, as shown in Fig. 9, was made by welding a shaft of vacuum degassed, nonleaded 8620 steel bar to a wheel hub of cast nickel-base alloy GMR-235 (8 to 12 Fe, 14 to 17 Cr, 4.5 to 6 Mo, 2 Ti, 2.5 to 3.5 Al, 0.15 C, rem Ni).

Before welding, shaft bearing surfaces were carburized, and the shaft was hardened and tempered. The objective was to obtain consistent joints of high weld integrity with low distortion. Concentricity requirements on machined bearing surfaces were 0.005-in. TIR after welding.

Joint design used was basic to the welding operation and to the end use of the part. Because the wheel was to be exposed to high temperatures, the joint was made at the end of an annular hub to provide a heat barrier. The depth of the joint provided a weld of sufficient strength for normal operation, but also of relative weakness, so that, if a seizure took place, the unit would rupture in this location and in this way prevent more extensive damage.

A small chamfer was cut on the inside edge of the joint (joint detail, Fig. 9) to facilitate x-ray inspection. Complete joint penetration caused the chamfer to be filled; incomplete penetration was indicated by a void line on the radiograph.

A rabbeted, self-aligning, self-backing joint preparation was used, as shown in Fig. 9. The joint was designed with a small diametral clearance of 0.007 to 0.017 in., to permit a sliding fit, so that abutting joint surfaces could be held together by the fixtures with uniform end pressure, to prevent blowout (expulsion of metal from the joint) during welding. A tack weld was made at 180° from the starting point.

Fixturing consisted of two 24-spindle rotating positioners, each spindle being separately spring-loaded to provide constant axial pressure on each joint before, during and after welding, regardless of the slight expansion and contraction that occurred. While one batch of 24 units was being welded in sequence, a second batch was being fixtured to avoid loss of machine time.

Welding Equipment. The principal features of the electron beam welding machine adapted to this operation were:

1 A relatively large vacuum chamber (30 by 36 by 24 in. deep) capable of handling the 24-unit fixtures
2 A movable electron beam gun capable of travel from one unit to the next during one vacuum pumpdown

3 A vacuum pumping system capable of relatively fast pumpdown
4 An observation system that would permit accurate beam alignment and continual monitoring of the complete welding operation on the 24-piece load. The beam was aligned with a 20-power telescope mounted outside the chamber. The chamber was also fitted with three glass viewing ports 18 in. in diameter, located at 90° with respect to each other, for oblique viewing with the unaided eye.

Observation of the complete operation was important during both initial setup and production welding. During initial setup, it was used to observe the effects of varying techniques and machine settings, in determining optimum welding conditions. During production, it was used to detect, as soon as possible, any deviations in the operation. Optical surfaces that were directly exposed to the operation required frequent cleaning because of metal-vapor deposition.

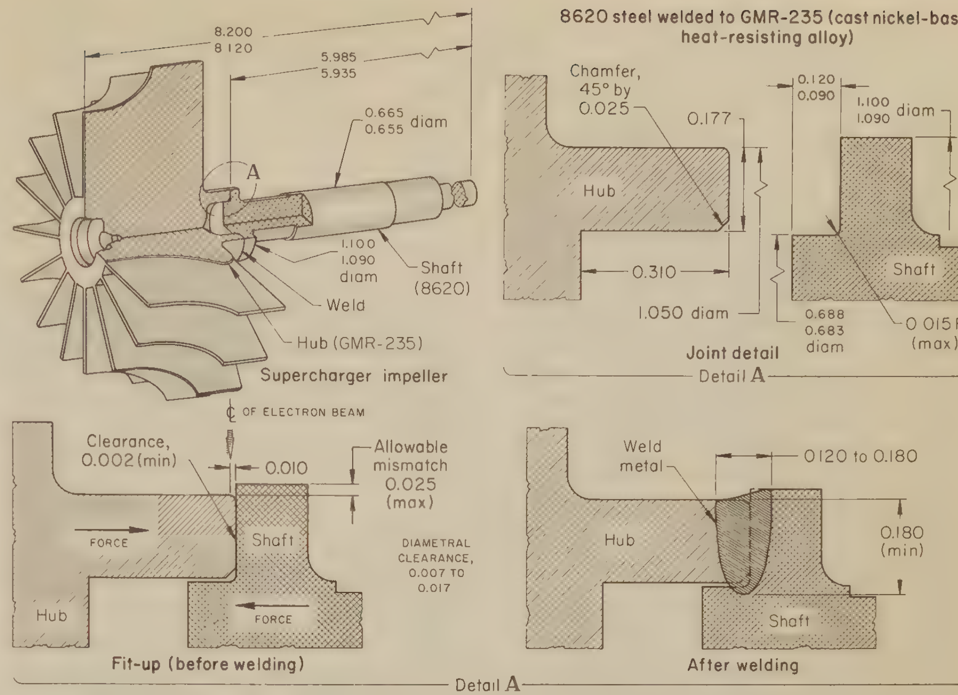
Welding Technique. The welding procedure was one often used in welding dissimilar metals. Cracking and porosity were controlled by directing the beam about 0.010 in. off the joint on the side of the GMR-235 component. Because this affected the relative amount of melting of each alloy, the beam focal point was set at the midsection of the joint, making the beam wider at the joint surface. To suit these conditions, a relatively low welding speed was used. The wide beam and low speed aided in accurate indexing of successive parts.

This type of beam alignment and focus required careful fitting of the abutting joint surfaces. If the joints were not tightly closed, blowouts occurred, with attendant loss of concentricity, and with undercutting and porosity. Careful fit-up was accomplished by adjusting the spring tension on the spindles of the fixture.

Weld quality was also affected by the alignment of the beam with respect to the axis of the part. Variations in alignment could be observed through the port facing the axial direction, and corrections could be made as needed.

The part was welded automatically in one pass. Current downslope was automatically started at overlap and continued to taper out over a 120° arc. Beam oscillation was not used.

Details of the equipment, machine settings, and welding conditions are given in the table with Fig. 9.



Joint type	Circumferential butt; rabbeted, self-aligning, self-backing	Welding vacuum	10^{-4} torr
Weld type	Square groove	Pumpdown time	8 min(b)
Machine capacity	60 kv at 500 ma	Beam spot size	0.040-in. diameter
Gun type	Pierce; movable; square filament	Beam focal point	At midjoint depth
Maximum vacuum	5×10^{-6} torr	Working distance	2.5 in.
Fixtures	24 unit, multiple spindle, spring loaded(a)	Welding speed	14.5 ipm
Welding power	26.5 kv at 52 to 54 ma	Number of passes	One, plus 120° downslope
		Production rate	80 parts per hour(c)

(a) Two fixtures; one was being loaded while the other was being used. (b) Pumpdown time for a fully loaded chamber. Time for an empty chamber was about 4 min. (c) From loading to unloading of a batch of 24 units; based on a 50-min hour.

Fig. 9. Supercharger impeller that was made by electron beam welding of a shaft and a wheel of dissimilar metals. Joint design, operating conditions, and equipment selection were important for meeting end-use requirements at a high welding rate. (Example 465)

Welding in High Vacuum

Much electron beam welding is done in a vacuum chamber in which the pressure is held at a maximum of 10^{-4} torr. Maintenance of this high vacuum has important effects on the electron beam and on the properties of the weld and the heat-affected zone.

Effect of Pressure on Beam. In a high vacuum, the electron beam undergoes very little scattering from collisions with gas molecules. The frequency of such collisions is roughly proportional to the concentration of gas molecules in the vacuum chamber. For work-chamber pressures encountered in electron beam welding, the number of gas molecules present in a cube 0.001 in. on a side (a volume of 10^{-9} cu in.) and the corresponding relative frequency of collisions with the electrons are as follows:

Pressure, torr	Number of molecules	Relative frequency of collisions
10^{-5}	5,800	1
10^{-3}	580,000	100
10^{-1}	58,000,000	10,000
760	4.4×10^{11}	100,000,000

At pressures of 10^{-4} torr or less, the beam can be held in sharp focus over a distance of several feet, depending mainly on the characteristics of the electron gun and the electromagnetic focusing system, for maximum effectiveness in producing deep, narrow welds. Beam scattering by collision with gas molecules begins to be significant at a pressure of about 10^{-3} torr, resulting in lower penetration and greater weld width at a given working distance and in shorter maximum working distances (see the section on Welding in Medium Vacuum). At atmospheric pressure (760 torr), the beam is so scattered in traveling about 6 in. as to become completely ineffective for welding. Hence, penetration and working distances for welding at atmospheric pressure are much lower than for welding in high or medium vacuum.

Effect of Pressure on Weld and Heat-Affected Zone. The maintenance of a high vacuum in the work chamber protects the weld metal and the heat-affected zone from oxidation and contamination by harmful gases, serving the same function as inert shielding gases do in arc welding, while also degassing the weld. The contamination level as a function of pressure is discussed in the section "Welding in Medium Vacuum", on the next page.

The nearly complete absence of gaseous impurities eliminates the serious contamination difficulties that are usually encountered when attempting to arc weld reactive metals such as titanium and zirconium.

Width of Weld and Heat-Affected Zone. Electron beam welds made in a high vacuum are narrower and have narrower heat-affected zones than comparable welds made in medium vacuum or at atmospheric pressure, and they are much narrower than the narrowest welds made in production welding by the gas tungsten-arc process. The narrow width of the tempered zone in hardenable steels and other hardenable alloys permits welding of these metals after heat treatment, in many instances without loss of strength (see Fig. 38 and 39).

Limitations. A major limitation in the use of high vacuum in the work chamber is the effect on unit production time, because of the need to pump the chamber down before each load is welded. Pumpdown time is typically about 3 min for a 30-cu-ft chamber and 10 min for a 300-cu-ft chamber. The above pumpdown times are realistic only for a very clean and well-maintained system. In production, pumpdown will often be nearly double the above times.

The effect of this limitation on unit production time is reduced by welding a number of assemblies in each load and by keeping chamber size as small as possible. Small chambers specially designed for use with small workpieces have typical pumpdown times of 1 min (225-cu-in. chamber) and 15 sec or less (60-cu-in. chamber).

A second major limitation in the use of high vacuum is that work size is limited by chamber dimensions. This limitation is sometimes circumvented by the use of a chamber having special openings and seals that permit oversize work to extend outside the chamber, or by the use of a portable clamp-on chamber.

Welding Conditions. Welding in high vacuum is done with low-voltage, as well as high-voltage, equipment. Except for the sections specifically covering medium-vacuum and nonvacuum welding, this article deals primarily with high-vacuum welding. Of the 42 production examples of electron beam welding, 37 describe welding in high vacuum, and the actual welding conditions used on specific parts are given and the critical variables are discussed for each example.

Beam voltage in these 37 examples is 15 to 150 kv; beam current, 2 to 170 ma; and welding speed, 14 to 119 in. per minute (except for Example 485, in which manual guidance along the seam required welding at a speed of 2 to 3 in. per minute).

The energy input to the work needed to produce a weld of the required depth of penetration and width is the basis for selecting the welding conditions.

Depth of penetration is increased by increasing the voltage or current for greater beam power, or by decreasing the welding speed. Table 1 lists approximate energy inputs per inch of weld length for making narrow single-pass electron beam welds 0.25 to 3 in. deep in the weldable alloys of copper, iron, nickel, aluminum and magnesium. These values are intended to serve as starting points for establishing conditions for welding work for which no previous experience is available. Energy-input requirements for specific applications depend on the alloy composition and special operating conditions such as the use of beam oscillation or a defocused beam.

Table 1. Energy Input at the Weld for Single-Pass Electron Beam Welding in High Vacuum for Various Depths of Penetration (a)

Depth of penetration, in.	Kilojoules per inch of weld length for welding alloys of: Cu	Fe	Ni	Al	Mg
0.25	7	5	4	2	1
0.50	15	10	8	5	3
0.75	25	18	15	8	5
1.00	37	27	22	13	8
1.50	62	46	39	23	15
2.00	87	68	60	35	22
2.50	112	90	80	47	29
3.00	137	112	100	59	36

(a) Values are approximate and apply to the commonly welded alloys of the metals. They are intended to serve as starting points for establishing conditions for making narrow welds. Energy input may vary substantially from these values in specific applications, depending on the composition of the alloy and special operating conditions (see text). Energy input at weld (kilojoules per inch of weld length) = beam voltage (kv) × beam current (ma) × 0.06 ÷ welding speed (inches per minute).

Welding in Medium Vacuum

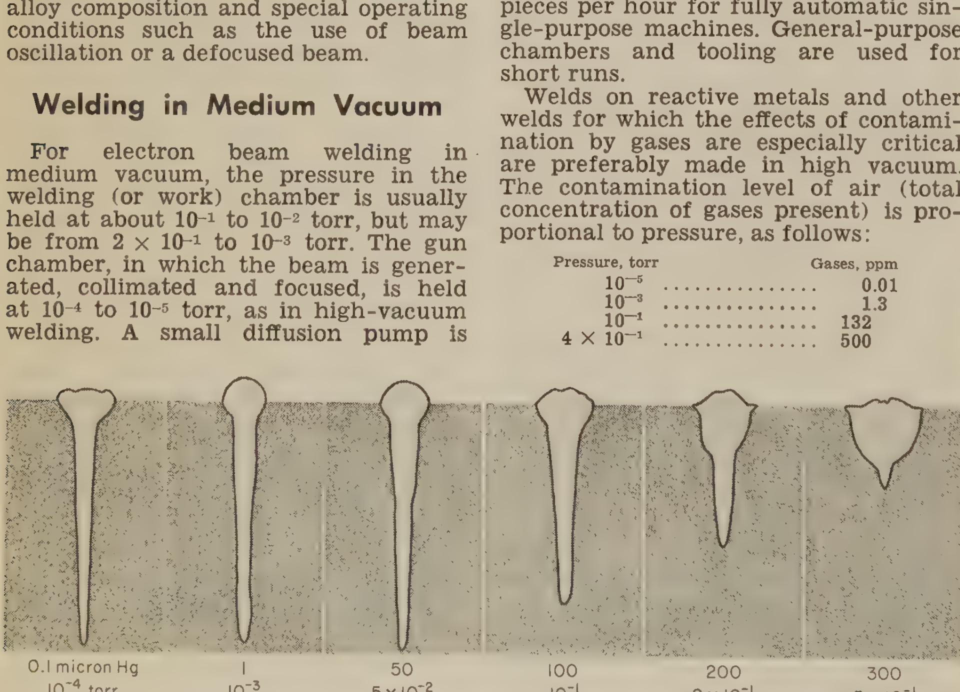
For electron beam welding in medium vacuum, the pressure in the welding (or work) chamber is usually held at about 10^{-1} to 10^{-2} torr, but may be from 2×10^{-1} to 10^{-3} torr. The gun chamber, in which the beam is generated, collimated and focused, is held at 10^{-4} to 10^{-5} torr, as in high-vacuum welding. A small diffusion pump is needed to provide the vacuum in the gun chamber, but a diffusion pump is not needed for pumping down the welding chamber, which can be evacuated with a mechanical pump.

Comparison With High-Vacuum Welding. The chief advantage of welding in medium vacuum, compared with welding in high vacuum, is the short pumpdown time for the welding chamber, which ordinarily does not exceed 40 sec for a general-purpose chamber (of about 4 cu ft), and which is less than 5 sec for the specially designed chambers used in welding small parts. Accordingly, medium-vacuum welding permits mass production of parts, using a chamber of minimum volume.

Production rates for welding in medium vacuum depend on part design and other factors; maximum production rate is typically about 50 pieces per hour for manual equipment, 500 pieces per hour for specially tooled semiautomatic machines, and 1500 pieces per hour for fully automatic single-purpose machines. General-purpose chambers and tooling are used for short runs.

Welds on reactive metals and other welds for which the effects of contamination by gases are especially critical are preferably made in high vacuum. The contamination level of air (total concentration of gases present) is proportional to pressure, as follows:

Pressure, torr	Gases, ppm
10^{-5}	0.01
10^{-3}	1.3
10^{-1}	132
4×10^{-1}	500



For electron beam welds made on type 304 stainless steel, using a beam length of 16 in. without changing focus. Maximum penetration shown is approximately ½ in. Welding conditions were: 150 kv, 30 ma, and 60 in. per minute. (J. W. Meier, *Metal Progress*, July 1966, p 63-64)

Fig. 10. Effect of welding-chamber pressure on penetration and weld shape

Lower contamination levels are obtainable than those actually observed for arc welding with inert-gas shielding.

Penetration and Weld Shape. Penetration at a given power level is ordinarily 5 to 10% less than for high-vacuum welding, and welds are wider and slightly more tapered. These changes are caused by the scattering of the electrons in the beam by collision with gas molecules, which makes the beam broader.

The effect of welding-chamber pressure on penetration and weld shape is shown in Fig. 10 for welds made on type 304 stainless steel, using a beam length of 16 in. Penetration drops off rapidly at pressures of 10^{-1} torr or more at this beam length, and at somewhat lower pressures when the beam path is longer.

Comparison With Nonvacuum Welding. Disadvantages of medium-vacuum welding, compared with welding at atmospheric pressure, are the limitations on work size imposed by the need to enclose the work in a vacuum chamber and the time needed for chamber pumpdown.

Beam deflection and oscillation, which cannot be used in welding at atmospheric pressure, can be used in medium-vacuum welding.

Applications of Medium-Vacuum Welding. Most parts that can be welded in high vacuum can also be welded in medium vacuum. Depth of penetration is less than in high-vacuum welding, and depth-to-width ratio is less than about 10 to 1. Reactive metals are less readily welded in medium vacuum than in high vacuum.

Medium-vacuum welding has been used for welding mass-produced automobile parts, such as gears and shafts, that are welded to close tolerances and are not subsequently finished. The examples of medium-vacuum welding in this article involve steel or stainless steel parts made in small and intermediate quantities.

For instance, in Example 472, transmission gears made of 8620 steel were assembled by ¼-in.-deep medium-vacuum electron beam welds that had a maximum width of 1/16 in. Arc welding processes could not provide an acceptable weld depth-to-width ratio and caused distortion and melting through.

In Example 487, an assembly of a flange to a housing, both made of 52100 steel, was welded at a production rate of 10 pieces per hour. The production rate could readily have been increased to about 40 assemblies per hour if the production quantity had been large enough to justify more efficient work-handling equipment.

In the example that follows, medium-vacuum electron beam welding at a pressure of 5×10^{-2} torr replaced gas metal-arc welding that had excessive labor-time requirements and high filler-metal consumption in joining thick type 410 stainless steel turbine blades.

Example 466. Change From Gas Metal-Arc Welding to Medium-Vacuum Electron Beam Welding To Reduce Labor Time and Cost (Fig. 11)

Steam-turbine diaphragms (stators), ranging from 3 to 12 ft in diameter and from 1 to 2½ in. in thickness, were produced by welding together the more than

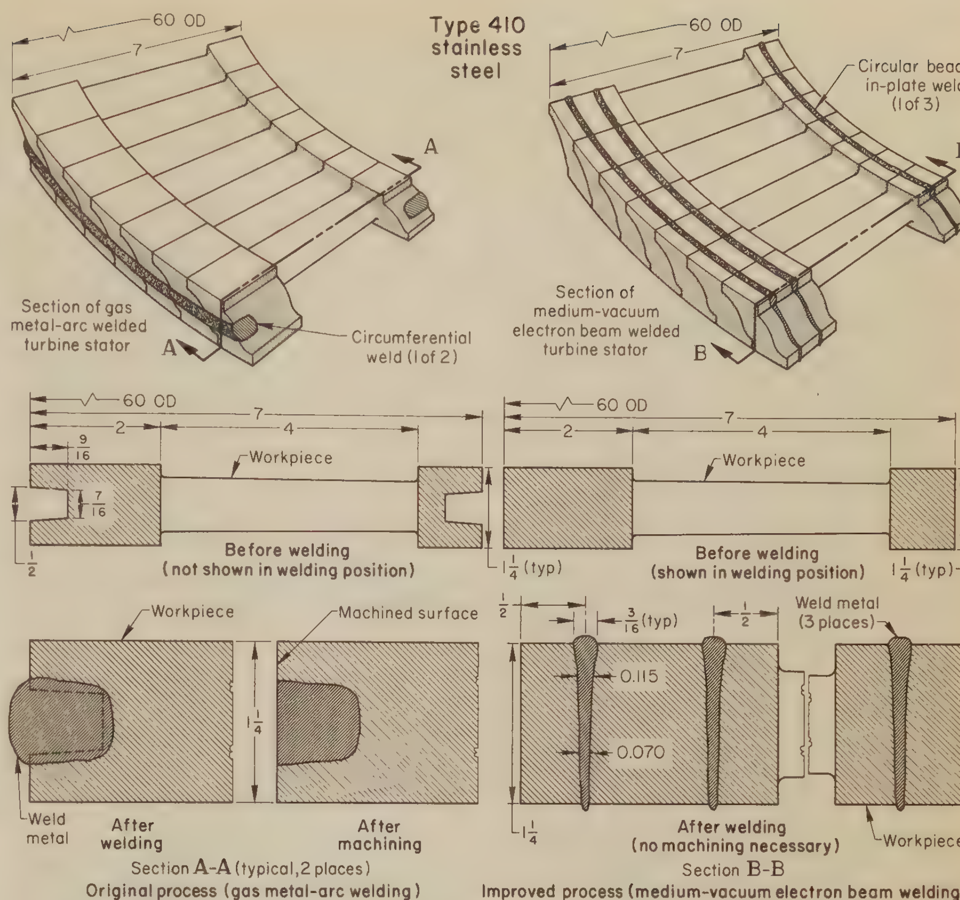
100 separate blades that formed the disk. Automatic gas metal-arc welding had been used satisfactorily, but when electron beam welding was investigated, it was found that labor time and cost could be reduced.

Medium-vacuum electron beam welding was selected to replace the arc welding procedure. Out-of-chamber (nonvacuum) welding would have been ideal because of the large diameter of the diaphragms, but the process was limited to metal thicknesses less than ⅝ in. High-vacuum electron beam welding could easily have met the welding requirements, but the cost probably would have been higher and the large chamber needed would have necessitated long pumpdown times. The medium-vacuum method provided adequate weld quality, full penetration, and short pumpdown time. Welds had a depth-to-width ratio of 6.7 to 1.

A sector of a typical diaphragm, made of 410 stainless steel, is shown schematically in Fig. 11, broken at a joint between blades to show the type of weld made by each process. The function of the welds was to join the blades into an integral disk that would minimize vibration and reduce steam leakage.

The differences between the two welding procedures were substantial (see the list of operations with Fig. 11). For gas metal-arc welding, diaphragms were fixtured and set up in a boring mill and machined to form the inside and outside weld grooves. After setting up for automatic welding, still in the same fixture, the part was torch preheated to 500 F to minimize distortion and prevent cracking in the heat-affected zone. The grooves were filled by multiple-pass welding, using a $\frac{3}{32}$-in.-diam ER410 electrode. After welding, diaphragms were returned to the boring mill, where the welds were faced flush.

In contrast, electron beam welding required no preheat, no machining, and no filler metal, and welding time was reduced about 90%. Preweld cleaning consisted of degreasing. A summary of the average time for welding and related operations for a diaphragm of the size shown in Fig. 11 is given in the table with the illustration. Details of the electron beam welding procedure that replaced the gas metal-arc welding process are also given.



Operation	Gas metal-arc welding	Electron beam welding
Assembling blades in fixture	2 hr	2 hr
Machining weld grooves	4	0
Preweld cleaning	0	1
Setting up for welding(a)	1	1
Preheating	2	0
Welding, inspecting, and repairing	6	0.75
Machining weld faces	2	0
Total time for welding and related operations	17 hr	4.75 hr

Conditions for Medium-Vacuum Electron Beam Welding

Joint type	Special (see sketch)
Weld type	Bead in plate (no groove)
Machine capacity	150 kv at 176 ma
Gun type	Fixed
Vacuum-chamber size	150 by 54 by 180 in.
Maximum vacuum	10^{-2} torr
Fixtures	Holding jig; turntable
Welding power	130 kv at 90 ma
Welding vacuum	5×10^{-2} torr
Working distance	30 in.
Beam focal point	¼ in. below work surface
Beam spot size	⅛-in. diameter
Beam oscillation	None
Welding speed	12 ipm (approx)
Pumpdown time	7 min

(a) Includes pumpdown time for electron beam welding

Fig. 11. Sections of a turbine diaphragm (stator) for which electron beam welding replaced gas metal-arc welding for joining the blades. Process change eliminated preheating and two machining operations, and reduced welding time. (Example 466)

Nonvacuum (Out-of-Chamber) Welding

In nonvacuum, or out-of-chamber, electron beam welding, the work to be welded is not enclosed in a vacuum chamber; it is welded at atmospheric pressure. The electron beam is generated at high vacuum, as for high-vacuum and medium-vacuum welding, and is passed through a beam transfer column, exiting through a small orifice to the atmosphere. The beam transfer column consists of several distinct pumping chambers that are separated by small orifices and maintained at progressively higher pressure levels from the electron emitter to the exit. The equipment is described in more detail on page 530.

The chief reason for using nonvacuum electron beam welding instead of high or medium-vacuum electron beam welding is that production rates are much higher and costs are lower, because no vacuum chamber is needed for the work and time is not consumed in pumping down for each load. In addition, work size is not limited by chamber dimensions. These advantages are gained at the expense of reduced penetration depth and working distance, thus imposing limits on the thickness and shape of work on which the nonvacuum method can be used. Also, out-of-chamber welds cannot be made as narrow and nontapering as welds made in a vacuum.

Nearly all metals that are arc welded, or electron beam welded in a vacuum, can be nonvacuum electron beam welded. Inert-gas shielding of the weld zone is provided when the molten weld metal or the heat-affected zone cannot be exposed to air. On readily welded metals, weld properties approach those of welds made in a vacuum; on difficult-to-weld metals, weld properties are usually lower than those of welds made in a vacuum.

Operating Conditions. The operating conditions for nonvacuum welding differ substantially from those for welding in high or medium vacuum. Beam dispersion increases approximately in proportion to the pressure, and the beam in nonvacuum welding would typically become so dispersed in traveling a distance of about 6 in. in air at atmospheric pressure as to be completely ineffective for welding.

To provide an electron beam of sufficient velocity to offset the scattering effect of collisions with gas molecules in the beam transfer column and the space between the end of the electron gun and the work, voltage is held constant at a high value — in the range of 100 to 175 kv — and the working distance (gun-to-work distance, as measured from the exit orifice) is kept as low as possible. This distance is often ¼ in. or less, and it is usually not greater than about ¾ in.

With voltage held constant, beam current, working distance, and welding speed are selected to provide the

Table 2. Speeds for Nonvacuum Full-Penetration Welding of Carbon and Low-Alloy Steel Pipe at a Beam Power of 12 Kw

Wall thickness, in.	Welding speeds, ipm In air	Welding speeds, ipm In helium	Relative welding speed in helium(a)
0.050	417	900	2.16
0.080	241	528	2.20
0.100	187	412	2.21
0.150	118	264	2.24

(a) Based on welding speed in air as 1.00

required penetration and weld shape for a sound weld. Because it is usually desirable to keep working distance as short as possible and welding speed high, beam current is the primary control variable in nonvacuum welding.

The small size of the exit orifice on the electron gun makes it necessary to focus the beam at or very close to the exit orifice. Accordingly, it is not possible to vary weld characteristics to a significant degree by changing focus. Similarly, beam deflection and oscillation are not possible. The absence of these adjustment capabilities in nonvacuum welding is not a handicap, because beam width is ordinarily great enough so that it does not promote undercut or porosity at the root of the electron beam weld.

A cosmetic pass is seldom needed on electron beam welds made at atmospheric pressure, because a smooth crown is produced on welds in most metals. The smoothness of the crown also improves the ease of nondestructive inspection of the as-welded surface; wire brushing is often adequate preparation for radiographic or dye-penetrant inspection.

The limitation on workpiece shape imposed by the need for a short working distance can be overcome to some degree by the use of electron gun nozzles specially designed to extend into restricted spaces. For instance, a special nozzle was used in making precision circumferential welds at the bottom of 0.070-in.-wide slots ¼ in. deep on a 1¼-in.-diam round shaft in one production nonvacuum application.

Filler metal is not ordinarily used except where necessary for weld reinforcement, to produce the desired weld properties, or to avoid cracking, as in Example 468.

A stream of dry filtered air, or an inert shielding gas such as argon or helium, is passed across the weld region in the space between the work and the electron gun, or may be supplied through a special insert-type nozzle assembly that is part of the exit orifice and is designed to minimize entrance of welding vapors and other contaminants into the gun. Auxiliary inert-gas shielding is supplied where needed for complete protection of the molten weld metal and the heat-affected zone from gaseous contaminants. Welds are sometimes made on carbon and alloy steel, and other readily weldable metals, without using shielding gas, as in Example 467.

However, shielding gas is often used; helium is the preferred gas. Weld shape can be changed by varying the flow of helium.

Penetration. Nonvacuum electron beam welds in production applications are seldom deeper than about ½ in.

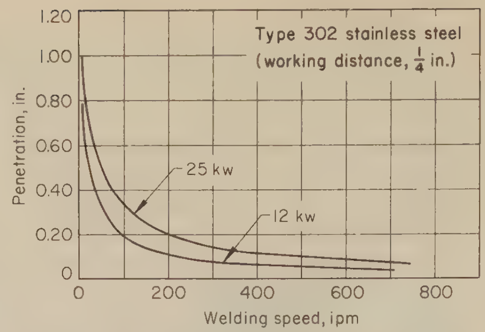


Fig. 12. Effect of welding speed on penetration for welding steel in air at atmospheric pressure, at a beam power of 12 and 25 kw and a working distance of ¼ in.

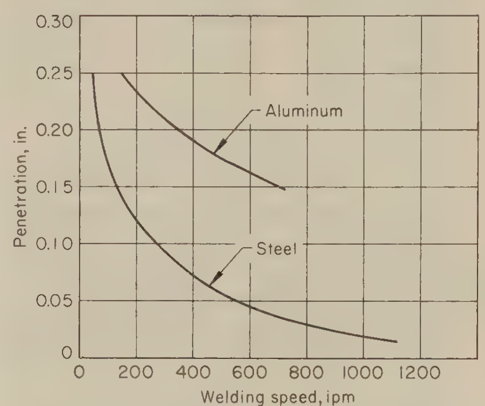

Fig. 13. Effect of welding speed on penetration for welding steel and aluminum in helium shielding gas at atmospheric pressure, using a beam power of 9 kw

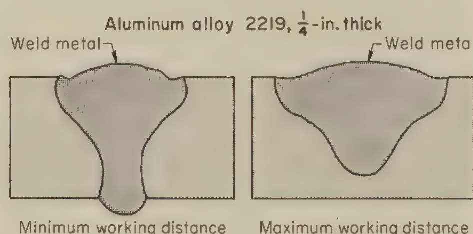

Fig. 14. Effect of varying working distance, within practical operating limits, in nonvacuum electron beam welding of ¼-in.-thick aluminum alloy 2219

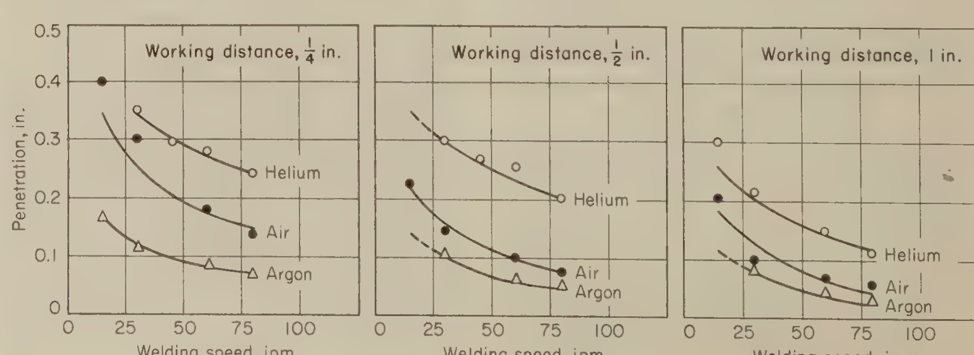
Welds having penetration greater than 1 in. have been obtained, but this ordinarily entails a substantial reduction in welding speed, accompanied by a corresponding increase in welding cost.

Figure 12 shows effect of welding speed on penetration of nonvacuum welds made on steel in air, using 12 and 25-kw beam power at ¼-in. distance. Figure 13 shows effect of welding speed on penetration of nonvacuum welds made on steel and aluminum in helium shielding.

The effect on penetration of varying working distance, within practical operating limits, is shown schematically in Fig. 14 for ¼-in.-thick aluminum alloy 2219. When the maximum working distance was used, penetration was only about 80%, and maximum weld width was about one-third greater than when the minimum working distance was used.

When a shielding gas is substituted for air in nonvacuum welding, assuming the same operating conditions, penetration will be greater when a gas is used that has a lower molecular weight (or nominal density) than that of air, and will be less when a gas is used that has a higher molecular weight than that of air. In tests on welding 4340 steel, using a fixed beam power of 6.4 kw, working distances of ¼, ½ and 1 in., and welding speeds of about 15 to 80 in. per minute, penetration was increased when helium was substituted for air and was decreased when argon was substituted for air, as shown in Fig. 15. The relative capacities of helium, air and argon to scatter the electrons of the beam by collisions of electrons with gas molecules are indicated by their molecular weights and relative densities, which are given below Fig. 15. On the average, when helium was used as a shielding gas, penetration depth was about twice that obtained when welding was done in air, and, when argon was used, about half that when welding was done in air. Thus, with helium shielding, penetration averaged about four times that with argon, especially at higher welding speeds. The speed at which a given thickness of 4340 steel could be welded with full penetration, using helium, was two to four times that with air, and using argon, 25 to 50% that with air.

Studies made of nonvacuum welding of steel pipe showed that, at speeds of 100 to 1000 in. per minute, full-penetration welds could be made in metal twice as thick if helium shielding gas was used instead of air. Table 2 gives the results of this comparison in terms of welding speed for joining steel pipe



Molecular weights: Helium, 4; air, 29; argon, 40
Relative densities: Helium, 0.14; air, 1.00; argon, 1.38

Fig. 15. Effect of shielding gas, working distance and welding speed on penetration for nonvacuum electron beam welding of 4340 steel, using a beam power of 6.4 kw

0.050 to 0.150 in. thick in air or in helium. Welding speeds were 2.16 to 2.24 times as great in helium as in air. Beam power used was 12 kw.

Weld Shape and Heat Input. Nonvacuum electron beam welds are generally wider and more tapered than high-vacuum welds (medium-vacuum welds differ only slightly in shape from high-vacuum welds — see Fig. 10).

Typical shapes of full-penetration welds made in 0.224-in.-thick aluminum alloy 2219 by nonvacuum and high-vacuum electron beam welding, and by gas tungsten-arc welding, are shown in Fig. 16, and conditions are given in the accompanying table.

Comparing the nonvacuum and high-vacuum electron beam welds in Fig. 16(a), heat input for the nonvacuum weld was about 40% greater, producing a midpoint weld width about 33% greater and a maximum crown width 160% greater than those of the high-vacuum weld. Comparing the nonvacuum electron beam weld to the gas tungsten-arc weld in Fig. 16(b), heat input for the typical nonvacuum weld was 32% of that for the arc weld, producing a midpoint weld width about 25%, and a maximum weld width about 56%, of the corresponding widths for the arc weld. Compared to the arc weld, the widest weld produced by nonvacuum electron beam welding under workable operating conditions was about 42% as wide at midpoint and about 70% as wide at the crown.

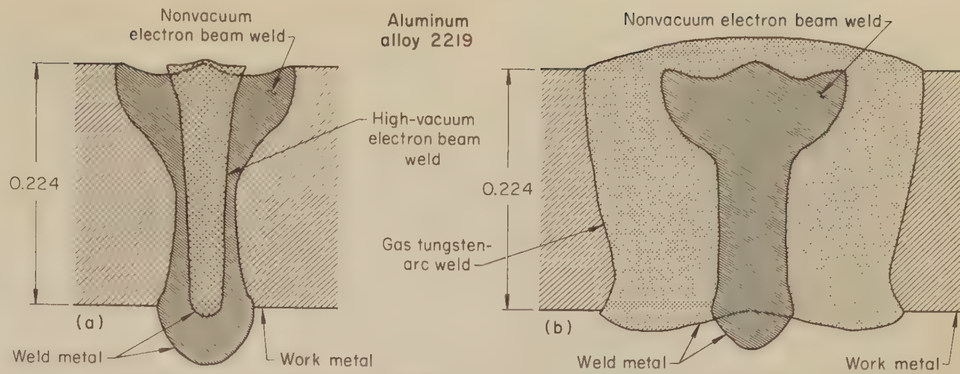
Weld shrinkage across nonvacuum electron beam welds is generally less than half that of gas tungsten-arc welds on the same work metal and thickness, and is typically about twice that for high-vacuum electron beam welds.

Studies on welding ¼-in.-thick aluminum alloy 2219 showed average shrinkage of 0.003 to 0.005 in. for high-vacuum welds, and 0.014 in. for high-heat-input nonvacuum welds, compared with a normal shrinkage of 0.030 in. for gas tungsten-arc welds.

Tooling. The basic welding unit consists of a power supply, an electron gun (emitter and beam transfer column), and controls like those used in a variety of welding applications. Tooling is generally designed specifically for welding a particular assembly in mass production. Providing fixtures and equipment that will permit welding at high speeds and will permit efficient work handling is the key to obtaining high production rates and low cost.

The work-handling equipment is at atmospheric pressure, instead of in a vacuum; hence general-purpose welding positioners and related fixtures are usually satisfactory. Hold-down clamping devices can be simpler than those often needed for arc welding similar parts, because angular distortion, or dihedral warpage, is generally low. Locating and alignment mechanisms are simpler than for welding in a vacuum, because of their accessibility and because beams are wider and such high accuracy is not required in tracking the joint. Maintenance of work-handling equipment is greatly simplified by its out-of-chamber location.

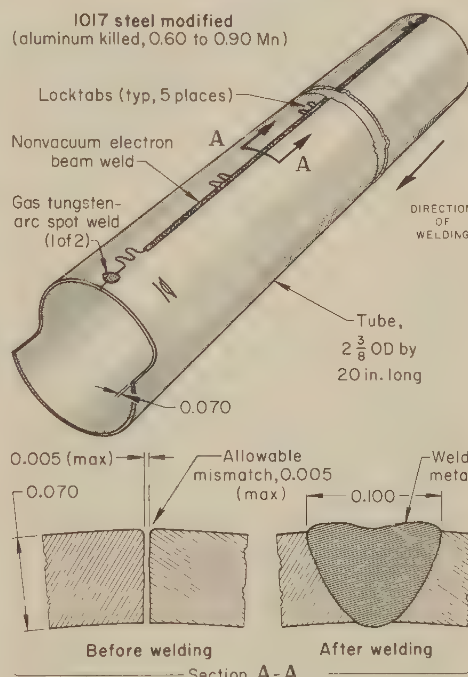
Production Applications. Nonvacuum electron beam welding has been used



Welding conditions	Fig. 16(a) High-vacuum EBW	Fig. 16(a) Nonvacuum EBW	Fig. 16(b) GTAW	Fig. 16(b) Nonvacuum EBW
Voltage, kv	150	140	13 (v)	140
Current, ma	20	30	270 (amp)	20
Welding speed, ipm	100	100	20	50
Welding energy, kj per inch	1.8	2.5	10.5	3.36

EBW = electron beam welding; GTAW = gas tungsten-arc welding.

Fig. 16. Comparison of full-penetration welds in 0.224-in.-thick aluminum alloy 2219, made by (a) *nonvacuum electron beam welding vs high-vacuum electron beam welding, and* (b) *gas tungsten-arc welding vs nonvacuum electron beam welding*



Conditions for Nonvacuum Electron Beam Welding

Joint type	Butt
Weld type	Square groove
Machine capacity	175 kv at 70 ma
Gun type	Self-focusing triode; fixed; with tungsten filament
Exit orifice	0.060 in. in diameter
Automation	Complete, except for manual loading and unloading
Working distance	0.20 in.
Welding power	175 kv at 45 ma
Operating vacuum:	
Upper chamber	10^{-4} torr
Lower chamber	3×10^{-1} torr (300 microns)
Workpiece environment	Ambient air (no shielding gas), at atmospheric pressure
Welding speed	250 ipm (typ)
Number of passes	One
Preheat and postheat	None
Production rate	20,000 pieces per day(a)
Annual production	5,000,000 pieces

(a) Production rate is based on using three welding machines for two shifts per day.

Fig. 17. Collapsible steering-column jacket that was joined by automatic nonvacuum electron beam welding in high-speed mass production, without the use of shielding gas (Example 467)

in commercial production of gears, wheels, ball joints, other automotive parts, refrigeration and appliance components, and tubing and pipe in continuous lengths. The two examples that follow describe the nonvacuum welding of carbon steel assemblies.

Example 467. Development of a Procedure for Nonvacuum Welding of Low-Carbon Steel in Automated Mass Production (Fig. 17)

The original design for the outer jacket of an automobile collapsible steering column called for 15 separate punching operations to be performed on 2⅜-in.-OD by 0.070-in.-wall steel tubing. This procedure, which involved no welding, was slow and costly, and could not meet the anticipated demand for an annual production of 5 million assemblies.

To increase the production rate and minimize costs, the part was redesigned for progressive piercing, blanking and forming from sheet, in a single press, and for welding of the longitudinal seam. At first, welding appeared to be the major obstacle in achieving cost and production objectives. Several joining methods were tried and compared before a satisfactory procedure was developed, based on nonvacuum electron beam welding.

Figure 17 shows part of a 20-in.-long section of the outer jacket partially welded to illustrate joint fit-up details. Blanks were sheared without waste from a 20-in.-wide coil, so that five pairs of locktabs mated exactly when the cylinder was formed. A tight longitudinal butt joint was made by interlocking and pinching the locktabs. A single gas tungsten-arc spot weld at each end of the workpiece was used to help maintain joint alignment during handling and storage. A maximum tolerance of 0.005 in. was allowed in the joint opening.

Weld Requirements. The weld had to be able to withstand the following service. Thirty-two hardened steel balls were uniformly distributed between the outer jacket and an inner steel tube by means of a plastic sleeve that served as a spacer. The tubes were then sized so that the balls slightly indented the tube walls. Thus, when the tubes were forced to telescope from the impact of a collision, the balls, which were fitted tightly between the two tubes, would retard the telescoping action.

Because tube concentricity was essential to the stability of the retarding force, warpage had to be avoided in welding the outer jacket. In addition, it was desirable to minimize weld reinforcement because of the sizing operation. Other weld character-

istics were subordinate to acceptance criteria based on these three requirements. The sizing operation provided an incidental check on joint strength.

Process Selection. When mechanical clamping and gas tungsten-arc spot welding proved inadequate, continuous gas tungsten-arc welding was tried. Samples developed adequate strength, but the warpage of approximately 0.050 in. per foot was too great. Plasma-arc welding produced similar results. Electron beam welding in a vacuum chamber satisfied all mechanical requirements, warpage being held to approximately 0.005 in. per foot. However, the relatively high vacuum required long pumpdown times, slowing production.

Nonvacuum electron beam welding satisfied all requirements. Weld strength was adequate to meet the collapsing forces; warpage was held to a tolerable level of about 0.008 in. per foot; excessive weld reinforcement was avoided; welding speeds of 200 to 300 in. per minute were attained without the need for welding in a vacuum.

Equipment Features. The generating and focusing equipment of the nonvacuum electron beam welding machine consisted of an upper and lower chamber. A high vacuum was maintained in the upper chamber, where the generating gun was located. Magnetic focusing coils were located in the lower chamber, where a medium vacuum was maintained.

The electron beam passed from the gun, through a small aperture in the upper chamber, through the focusing coils, and exited from the lower chamber through a 0.060-in.-diam orifice in a water-cooled copper orifice plate. The workpiece, positioned in ambient air, was held approximately 0.20 in. from the exit orifice, to minimize energy loss by scattering. No shielding gas was used.

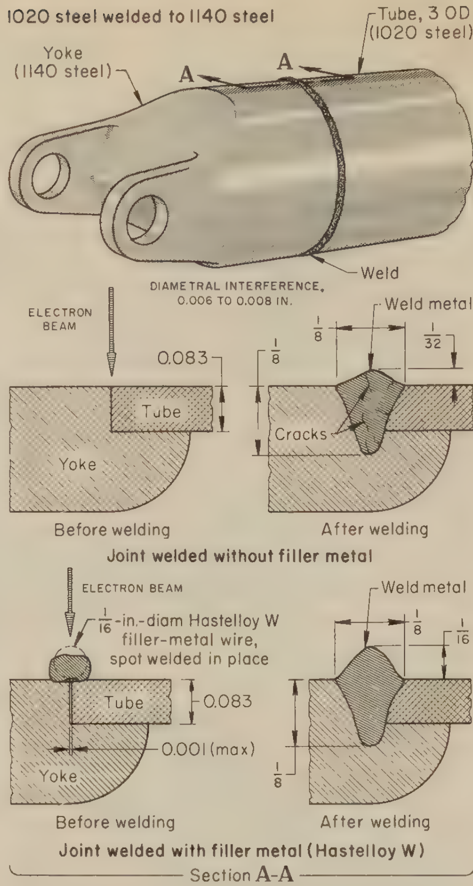
The small diameters of the exit orifice and of the aperture between chambers served to hold the quantity of air entering the lower and upper chambers to a level within the capacity of the vacuum pumps. Filament life varied from 15 to 20 hr.

Material Selection. To suit the various requirements of piercing, shearing, forming, welding and indenting, a low-carbon steel was selected. The material, which was purchased as coiled sheet, was an aluminum-killed 1017 steel with modified manganese content (0.60 to 0.90%). This steel was similar to aluminum-killed 1018, but it was less expensive because of a break in the steel price structure.

Despite the fact that the steel was aluminum killed, considerable outgassing occurred during welding, indicating that a rimmed steel might have caused problems in welding. Variations between different heats of the same steel were noted in welding; some heats produced acceptable welds with joint openings as wide as 0.010 in.; others required a smaller joint opening. For this reason, 0.005 in. was established as the fit-up tolerance.

Preweld Cleaning. Alkaline cleaning removed the oil film used for protection in shipping from the steel mill and for wrap forming. It was found that the oil had little or no effect in welding and on weld strength in collapsing tests. However, the oil caused smoke and soot that contaminated fixtures and equipment.

Welding Conditions. Because the operation was automated for high-speed production, accurate control of positioning, travel and weld timing was necessary. The welding conditions used in the procedure are summarized in the table with Fig. 17. Because neither beam oscillation, nor upslope-downslope current modes, nor starting nor runoff tabs were used, beam initiation and termination were critical. The beam had to be initiated at the exact desired starting point of the weld joint. If the beam was initiated before the moving workpiece reached the beam position, a hole would result. Similarly, the beam had to be terminated approximately ⅜ in. from the intended end of the weld seam, to avoid a hole at the end of the workpiece.



Joint type	Circumferential butt; rabbeted, self-backing
Weld type	Square groove
Machine capacity	175 kv at 40 ma
Workpiece environment	Helium shielding gas, at atmospheric pressure
Filler metal	1/16-in.-diam Hastelloy W(a)
Working distance	1¼ in.
Welding power	175 kv at 35 ma
Beam focal point	At work surface
Beam spot size	0.010-in. diameter
Beam deflection	None
Welding speed	94 ipm
Number of passes	One
Welding time	6 sec
Preheat and postheat	None
Fixtures	Turning rolls

(a) Preplaced by resistance spot welding

Fig. 18. Joint between tube and coupling yoke of a drive shaft that was welded using nonvacuum electron beam welding and helium shielding gas. The yoke was made of resulfurized steel, which caused weld cracking until a suitable filler metal was added. (Example 468)

A jet of compressed air was directed across the exit orifice of the lower chamber to blow the metal vapors and other toxic fumes into an exhaust duct. Ozone, which was formed when the electron beam struck the atmosphere, also had to be removed by forced ventilation. The action of the air jet also served to: (*a*) keep the exit orifice and the orifice plate from being fouled, (*b*) prevent fumes from entering the lower chamber, and (*c*) create a venturi action across the exit orifice to help maintain the vacuum. The compressed air had to be dry because moisture carried in the air would reduce welding efficiency if it entered the lower chamber.

Automation. Three automated welding setups were built, each consisting basically of a circular table that rotated past a fixed electron beam machine. One welding operator loaded and unloaded each table, and a fourth operator monitored and serviced the three welding machines.

Each table contained eleven fixture stations. Parts were manually loaded into a fixture that positioned the joint for welding. As each fixture reached the welding station, a limit switch was tripped, initiating the automatic welding cycle. At this point, the fixture was cam guided to travel in a straight line for the precise length of the weld. Upon returning to the operator station, the part was manually unloaded. Table rotational speed was approximately 1 rpm, or about 650 parts per hour. With crews operating three machines on two shifts, production averaged 20,000 parts per day, and yearly production was approximately 5 million parts.

X-Ray Shielding. Lead shielding was required for protection of personnel. This was done by placing a ¼-in.-thick lead shield tunnel over two-thirds of the circular table and the machine, leaving the operator one-third of the table for loading and unloading. Because considerable electron scattering occurred, lead baffles were used to block off stray radiation.

Quality Control. So long as the entire system — from material procurement to welding — was kept within specifications, adequate welds were produced. As observed earlier, the sizing operation served as a check on weld strength; it also served as a check on warpage and excessive flash, since the operation could not proceed if these factors were out of tolerance. All parts were visually inspected for weld cracks and correct location of the weld on the joint. Twice each shift, parts were checked for dimensional variations.

Ordinarily filler metal is not used in nonvacuum electron beam welding. The addition of a suitable filler metal may be helpful, however, in joining metallurgically incompatible metals or in avoiding weld cracking caused by hot shortness. Selection of the filler-metal composition in such applications is critical, as in the following example, in which a filler metal was used to avoid cracking in welding a medium-carbon resulfurized steel to a low-carbon steel. This welding operation also was unusual in being done at a working distance of 1¼ in., instead of the customary working distance of less than ¾ in.

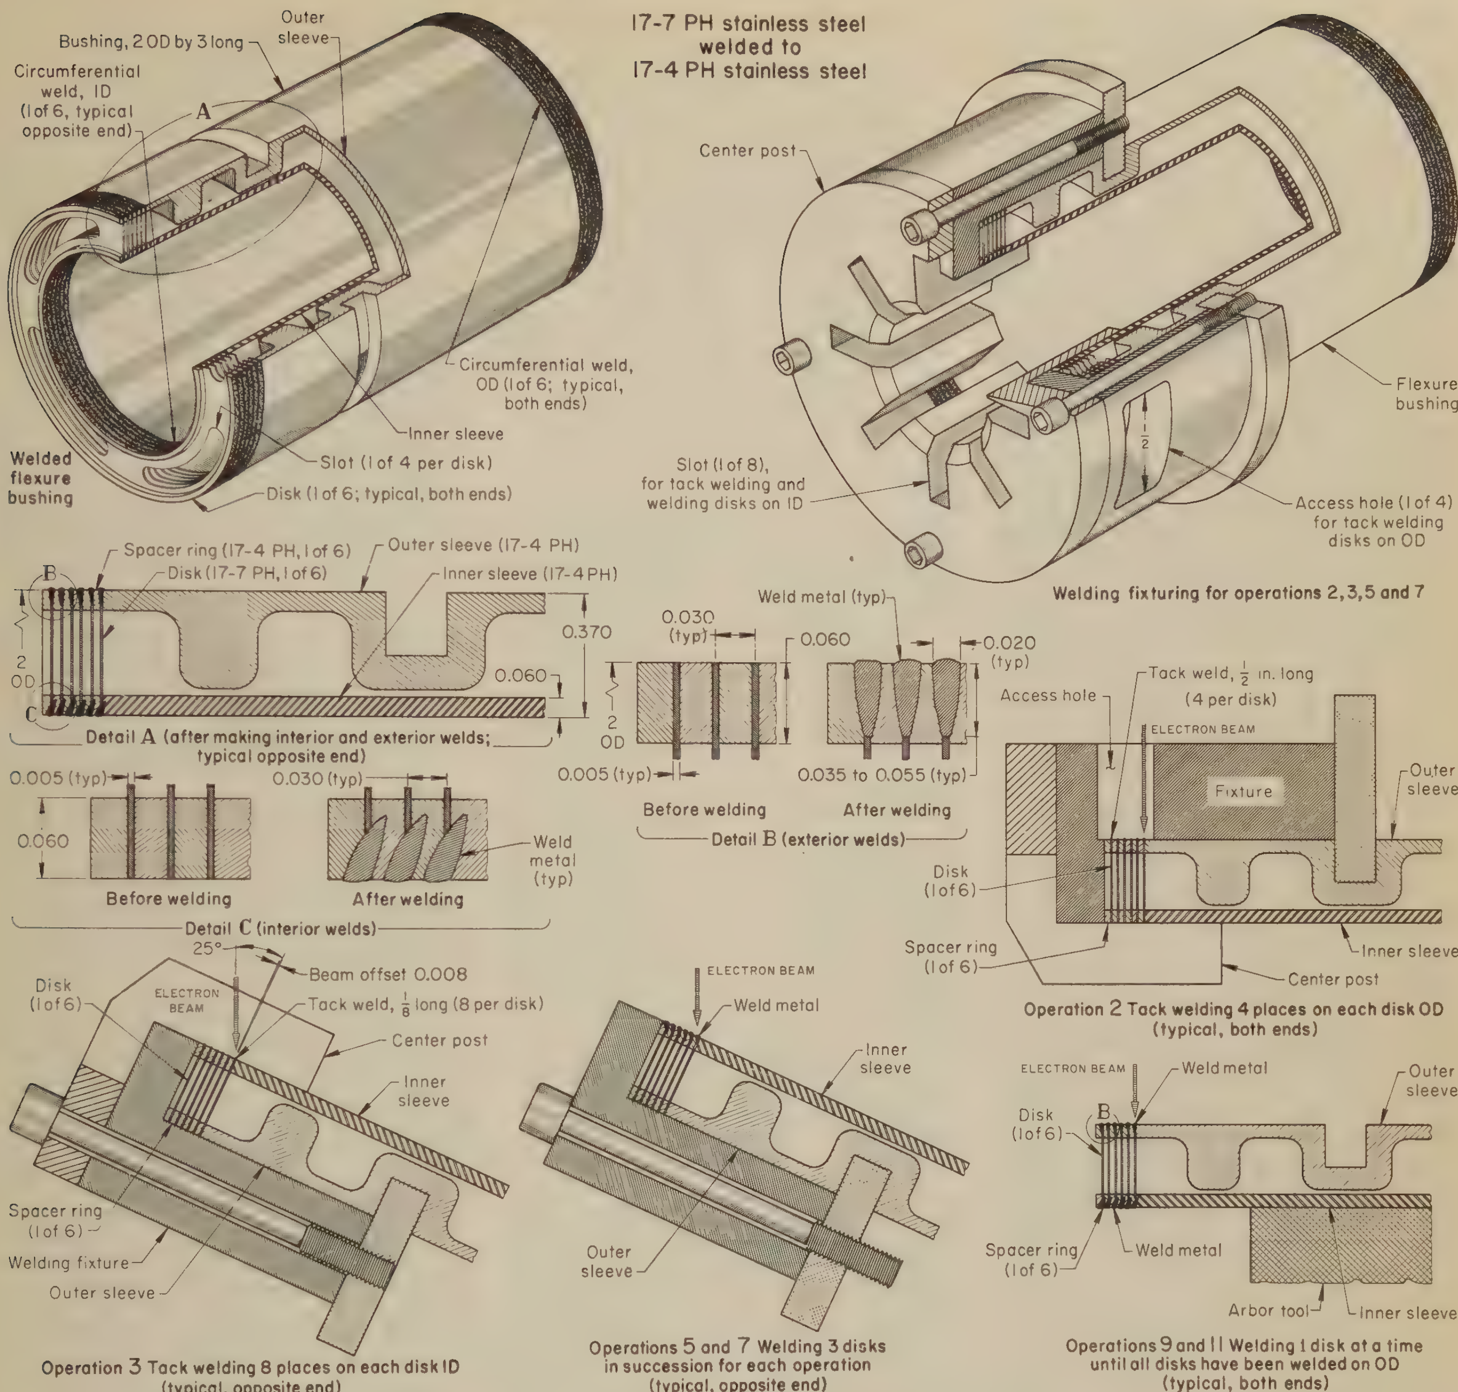
Example 468. Use of Filler Metal To Avoid Cracking in Nonvacuum Welding of 1140 Steel to 1020 Steel (Fig. 18)

Drive shafts were made in small quantities by electron beam welding 1020 steel tubing to 1140 coupling yokes. The nonvacuum method and helium shielding gas were used. The joint of a typical 3-in.-diam drive shaft is shown in Fig. 18. Joints of this type were required to match the ultimate shear strength of the 1020 tube, and to provide a fatigue life of 100,000 cycles or better at 50% of the elastic limit.

Initially, the weld between the low-carbon steel tube and the resulfurized carbon steel yoke was attempted by fusing the joint in a single pass. This was done by rotating the shaft under the beam exit orifice of the machine, using a helium atmosphere. Although high welding speeds were used, many large and small cracks (Fig. 18) developed in the weld, induced by the 0.08 to 0.13% sulfur content of the 1140 steel.

To prevent cracking, various filler metals were tried. Preheating and postheating were not considered because the benefits were doubtful and the cost of additional labor was unwanted. The filler metal that was found to be most successful was a 1/16-in.-diam wire of Hastelloy W. (This alloy, having a nominal composition of 62 Ni, 24.5 Mo, 5 Cr and 5.5 Fe, is useful in welding dissimilar metals.) Before welding, the filler metal was resistance spot welded in place over the joint, as shown in Fig. 18.

Welding was done using the conditions given in the table with Fig. 18. The weld was completed in one revolution of the work, for a welding time of 6 sec. Working distance was 1¼ in.



Item	Tack weld OD	Tack weld ID	Full weld ID	Full weld OD
Weld length	½ in. long (four)	⅛ in. long (eight)	Continuous	Continuous
Welding power	120 kv at 2 ma	120 kv at 2 ma	120 kv at 6 ma	120 kv at 3.2 ma
Working distance	6 in.	6 in.	6 in.	6 in.
Beam focal point	Sharp on surface	Sharp on surface	Sharp on surface	Sharp on surface
Welding speed	About 60 ipm (8 rpm)	About 60 ipm (10 rpm)	About 60 ipm (10 rpm)	About 60 ipm (8 rpm)
Beam direction	Normal to surface	25° off normal to surface	25° off normal to surface	Normal to surface
Number of passes	One	One	One, plus 30° downslope	One, plus 30° downslope

Machine characteristics were as follows: power rating, 150 kv at 25 ma; gun type, fixed, hairpin tungsten filament; vacuum-chamber size, 23 by 36 by 36 in.; maximum vacuum, 10^{-6} torr; fixtures, assembly and tack welding tool, rotatable and inclinable chuck. Cosmetic passes, when used, were made with a welding power of 110 kv at 2 ma, with a defocused beam at 60 ipm, and with circular oscillation at 60 hertz. Pumpdown time for each operation was 5 min. Beam oscillation was 0.015-in. diameter, circular, 500 hertz.

Fig. 19. Flexure bushing (upper left) that involved precision welding of six thin, annular disks at each end to maintain concentricity between inner and outer sleeves while permitting relative displacement in the axial direction. Fixture tool maintained alignment of six disks and twelve ring segments for automatic tack welding. (Example 469)

Welding of Complex Assemblies

The high degree of dimensional control obtainable in the electron beam welding process sometimes makes it possible to weld complex assemblies that would be unweldable by other processes. To make effective use of the precision capabilities of the beam, however, the workpiece dimensions, and the tooling and guidance devices used, must equal one another in precision.

The lengthy and complicated procedure used in fabricating a complex precision assembly for a lunar-module engine required elaborate fixturing for making many closely spaced, partial-penetration welds, using low heat

input, as described in the following example. Examples 489 and 496 also describe electron beam welding of complex portions of the same engine.

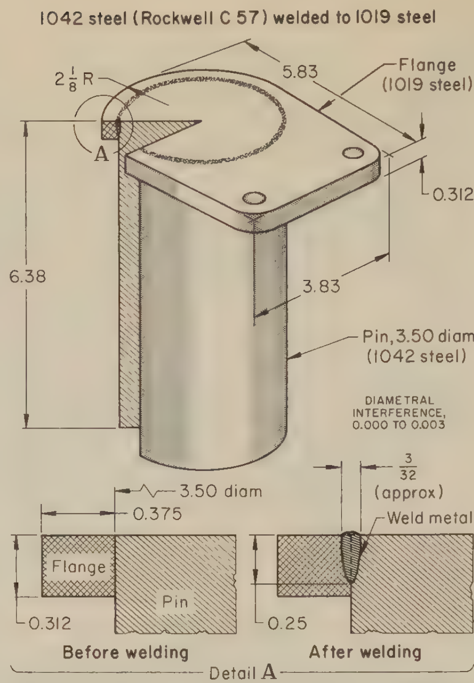
Example 469. Making 144 Tack Welds and 24 Partial-Penetration Welds at Thin, Closely Spaced Joints of a Complex Precision Assembly (Fig. 19)

The capability of electron beam welding to discriminate between closely spaced joints requiring partial penetration in thin material was fully exploited in fabricating the precipitation-hardening stainless steel flexure bushing shown in Fig. 19. The bushing was used in a lunar-module landing engine, to maintain concentric flow of fuel and oxidizer at the point of combustion. The bushing, which consisted of two concentric sleeves of 17-4 PH stainless steel, was designed to permit relative displacement in the axial direction without changing concentricity. This was accomplished by fitting and welding twelve annular spacer rings and six annular flexure disks to each end of the bushing, as shown in detail A of Fig. 19. The spacer rings were made of 17-4 PH and the flexure disks of 17-7 PH stainless steel.

To promote disk flexibility, the 0.005-in.-thick flexure disks were slotted by chemical machining, as shown in the over-all view at the top left in Fig. 19. To maintain optimum flexibility after welding, only partial penetration of the 0.060-in.-thick spacer rings could be permitted; full penetration would have damaged the disks or impaired the flexing action. The most effective means of controlling penetration was by use of the beam-oscillation technique at low amperage and fast travel speed.

Enlarged views of the sleeves, spacer rings, and disks are shown in detail A of Fig. 19; the exterior welds, in detail B; and the interior welds, in detail C. Enlarged views of operations 2, 3, 5, 7, 9 and 11 (see Sequence of Operations list in column 3) are shown in Fig. 19.

A precision fixturing tool was made to ensure correct alignment of the rings and disks on assembly and to provide for automatic tack welding. The tool consisted of an outer casing with a removable center post to contain and line up the components, a collar, and an end washer to hold the assembly together. Figure 19 (top right) shows a cutaway perspective view of this fixture, with the parts assembled for tack welding. Four openings in the outer casing and eight slots in the center post were cut to admit the electron beam for tack welding as the assembly rotated. Between tack welds, beam energy was absorbed by the tool body, the beam being out of focus at these points.



Joint type	Circular corner
Weld type	Square groove
Machine capacity	150 kv at 40 ma
Gun type	Steigerwald; fixed
Vacuum-chamber size	36 by 36 by 36 in.
Maximum vacuum	About 10^{-6} torr
Fixtures	Eight-workpiece rotating tool; table with x-y motion control
Welding power	130 kv at 25 ma
Welding vacuum	10^{-3} to 10^{-4} torr
Pumpdown time	5 min
Working distance	5.4 in.
Beam focal point	0.50 in. below work surface
Beam oscillation	None
Preheat and postheat	None
Number of passes	One, plus ½-in. downslope
Welding speed	39 ipm
Production rate	25 pieces per hour

Fig. 20. Flanged pin made by electron beam welding a flange and a hardened pin, for lower material consumption and simpler processing than in previous method of production, machining a one-piece forging and hardening it (Example 470)

The circumferential weld on the outside was made with the electron beam vertical and normal to the surface (12 o'clock), the bushing being rotated about its horizontal axis. The welds on the inside were made with the axis of the bushing tilted up 25° from the horizontal, so that the vertical beam could just reach the innermost disk without interference. Details A and C in Fig. 19 show the oblique penetration of the inside welds, although the actual welding was done at 6 o'clock with the beam pointed vertically down and offset, as shown in Fig. 19 (operations 3, 5 and 7). (For simplicity, the parts in details A, B and C are shown positioned for the outside welds.) Offsetting the beam approximately 0.008 in. from the joint for the oblique inside welds produced the best weld profile.

The electron beam welding procedure, as outlined below, was lengthy, including at least 20 vacuum pumpdowns and requiring great care in making the 144 tack welds and 24 circumferential welds.

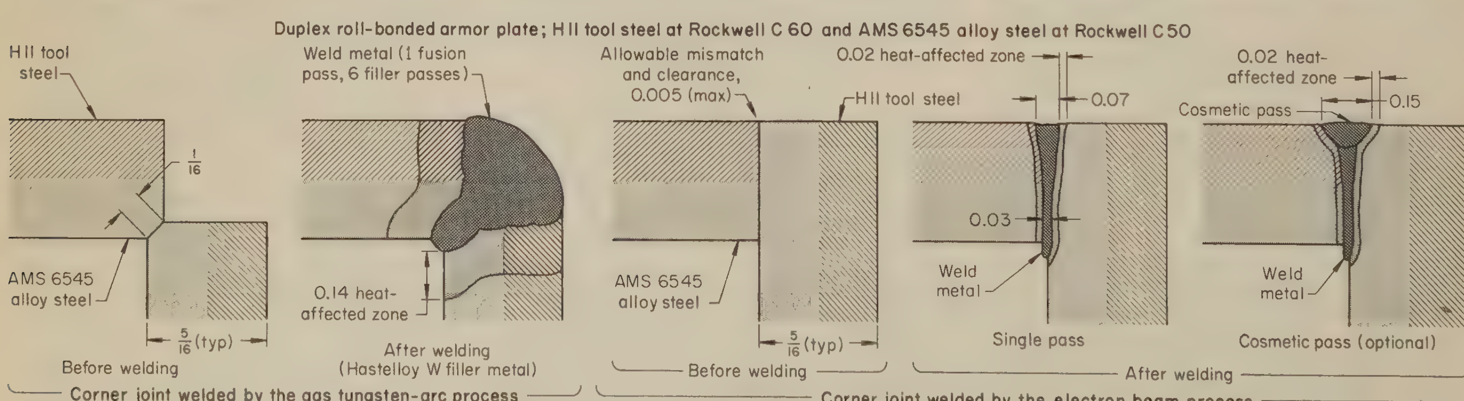
Sequence of Operations (See Fig. 19)

1 Assemble rings and disks to one end of bushing by means of fixture.
2 Tack weld each disk on outside diameter (four places).
3 Tack weld each disk on inside diameter (eight places).
4 Vent machine; remove clamp washer and slotted center post; cool part with liquid propellant; install new clamp washer.
5 Weld three rings in succession on inside diameter.
6 Vent machine; cool part with liquid propellant; tighten clamp washer.
7 Weld remaining three rings on inside diameter.
8 Repeat operations 1 through 7 for opposite end.
9 Remove fixture; mount assembly on arbor tool; weld outside of one ring at each end.
10 Vent chamber; cool part; tighten tool.
11 Continue welding, as in operations 9 and 10, until all six rings on each end are welded.
12 Use cosmetic passes after operations 7 and 11, if necessary, to obtain a smooth weld without undercut.

Several design features of the complex fixture were especially suited to vacuum service. There were no ball bearings or sliding contact surfaces that needed lubrication. The unit was unaffected by moderate contamination from hot gases or metal vapors and could operate in a vacuum as well as in an air atmosphere.

All fixturing was applied, and adjustments to fixtures were made, in a laboratory equipped for the purpose. Operating data and machine characteristics are given in detail in the table that accompanies Fig. 19. After the welding described above was completed, a thick, annular disk (not shown) was temporarily welded to each end of the bushing, to prevent flexing and damage during postweld finish machining. After machining, these disks were removed.

Although fabrication by electron beam welding was exacting and lengthy, the procedure solved a complex and potentially more difficult manufacturing problem.



Joint type	Corner
Weld type	Square groove
Machine capacity	30 kv at 500 ma
Vacuum-chamber size	112 by 50 by 62 in.
Maximum vacuum	10^{-7} torr
Fixtures	Assembly jig; travel carriage
Welding power:	
Penetration pass	30 kv at 170 ma
Cosmetic pass	19 kv at 95 ma
Welding vacuum	10^{-5} torr
Pumpdown time	10 min
Beam focal point, penetration pass:	At surface
Beam oscillation	None
Welding position	Flat
Welding speed:	
Penetration pass	60 ipm
Cosmetic pass	32 ipm
Preheat and postheat	None

Fig. 21. Cross sections through corner joints and welds made in duplex roll-bonded armor plate, showing approximate differences in sizes of the welds and the heat-affected zones resulting from electron beam welding and gas tungsten-arc welding (Example 471)

Welding of Hardened and Work-Strengthened Metals

The full properties of hardened and work-strengthened base metals can be retained on functional surfaces very close to the narrow electron beam weld zone. This aspect of electron beam welding can often simplify difficult and costly manufacturing procedures, as in the example that follows.

Example 470. Welding a Hardened 1042 Steel Pin to a Flange (Fig. 20)

A flanged pin (see Fig. 20) originally was machined from a single forging of 1042 steel and then was heat treated. Machining time was considered to be excessive, and the amount of metal removed was substantial. To meet the final hardness requirement of Rockwell C 57, which was required only for the cylindrical surface of the pin, the entire part was hardened in a difficult heat treatment operation. To simplify the manufacturing procedure, the part was redesigned as a two-piece weldment.

The weldment consisted of a pin cut from 1042 round stock and a flange machined from 1019 plate, thus reducing material costs. Electron beam welding was selected to join the two parts because, with this process, the pin could be welded in the hardened condition, without softening on the critical area. The dimensional tolerances on the flange could be maintained easily, and postweld heat treatment of the pin only was a simple, trouble-free operation. The weld was a single-pass, partial-penetration, square-groove weld between the flange and the pin (Fig. 20).

To reduce the unit cost occasioned by the pumpdown time required by the high-vacuum electron beam welding machine that was available, and to increase the production rate, eight workpieces were loaded in the chamber at the same time and were welded in sequence. A commercially available fixture, modified to suit the application, was used. The fixture consisted of an aluminum box that could be bolted to the table of the vacuum-chamber positioner, which was equipped with an operator-controlled x-y drive. The top of the fixture was fitted with eight tubular receptacles into which the pin assemblies were inserted. The ends of the pins were engaged by a collet attached to a gear. Each of the pins was simultaneously rotated about its own axis by a chain belt that engaged the eight gears.

Before welding, the components were machined for an interference fit, vapor degreased, press fitted, and assembled into the fixture, and the fixture was bolted in place. During vacuum pumpdown, the beam was optically aligned on the joint of the first workpiece as the pieces were rotated at full welding speed (3.54 rpm). Two tack welds were made at approximately 120° intervals by manually energizing the beam intermittently. At 360°, full welding power was initiated and continued for one revolution, with current tapering to zero over an additional ½-in. overlap. The positioner was then moved to the next piece, and the operation was repeated until all eight assemblies were welded.

Welding conditions are summarized in the table with Fig. 20.

In the example that follows, electron beam welding was chosen over gas tungsten-arc welding because of the narrow fusion and heat-affected zones obtained by the electron beam process.

Example 471. Selection of Electron Beam Welding To Minimize Tempering in the Heat-Affected Zone in Joining Hardened Duplex Armor Plate (Fig. 21)

Fabrication of armor for military aircraft involved the welding of corner joints in 5/16-in.-thick armor plate. The armor plate was made by roll-bonding H11 tool steel to an alloy steel (AMS 6545) containing 9% nickel, 4% cobalt and 0.30% carbon. Welding was done with the plate in the hardened condition, the H11 steel being at Rockwell C 60 and the alloy steel at Rockwell C 50. The plate was not difficult to weld. Either gas tungsten-arc or electron beam welding could be used to obtain sound welds using the joint designs shown in Fig. 21.

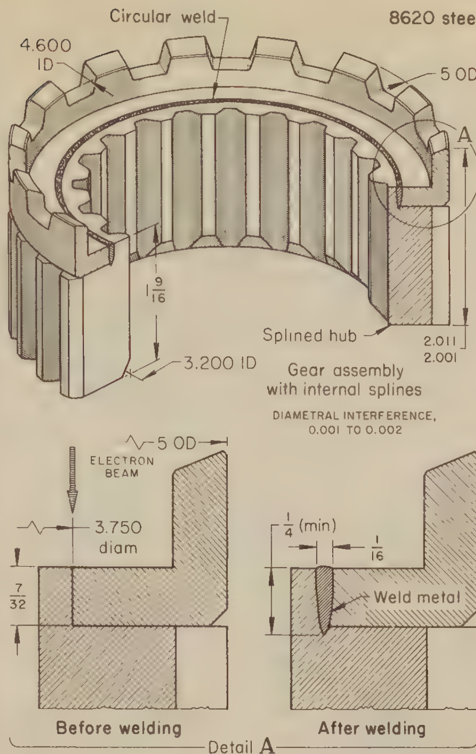
The weld and heat-affected zone of the electron beam process are compared with those of the gas tungsten-arc process in Fig. 21. Joint designs differed; if the joint for gas tungsten-arc welding had been made the same as the joint for electron beam welding, a V-groove would have been required, and about the same amount of weld metal would have been needed. Gas tungsten-arc welding was done in one fusion pass and six filler-metal passes, using 0.062-in.-diam Hastelloy W wire.

Electron beam welding was done in a single pass, using the equipment and the welding conditions given in the table with Fig. 21. Because of occasional undercutting, a second (cosmetic) pass was sometimes used. Even when the second pass was used, the weld and the heat-affected zone were much narrower than were those from arc welding, and they were unaffected below the crown of the weld. Because the general effect of the welding heat was to decrease the hardness and strength of the base metal, electron beam welding, which produced less heat, was selected.

There were no unusual problems associated with the electron beam welding procedure. Plates were machined square and then were degreased. Just before welding, surface films were removed from all surfaces to be welded, by brushing with a stainless steel wire brush followed by wiping with alcohol. The plates were then fixtured into an assembly roughly resembling a bathtub having sides about 10 in. high and a floor area of about 20 by 40 in. A maximum tolerance of 0.005 in. was allowed on fit-up for joint mismatch and clearance. Starting and runoff tabs, made of the same duplex plate, were attached to joint ends to contain variations in beam initiation and termination. The fixture was a simple arrangement of toggle clamps and stainless steel blocks that could be set up for flat-position welding on a track-guided carriage in the vacuum chamber.

After beam alignment and vacuum pumpdown, each joint was welded in a single pass without tack welding and without beam oscillation. Because undercutting occurred where fit-up approached the maximum tolerance, a second (cosmetic) pass occasionally was used. The effect of the cosmetic pass on the weld cross section is shown in Fig. 21; the machine settings for the defocused beam used to make the cosmetic pass are in the table with Fig. 21.

The capability of electron beam welding to produce deep, narrow welds makes it possible to design steel assemblies that include splines and bearing or wear surfaces very close to the welded joint, as in the next example.



Joint type	Circular butt; self-backing
Weld type	Square groove
Machine capacity	30 kv at 50 ma
Gun type	Fixed
Vacuum-chamber size	50 by 30 by 42 in.
Maximum vacuum	10^{-4} torr
Filler metal	None
Fixtures	Chuck; turntable
Welding power	30 kv at 22 ma
Welding vacuum	0.1 torr
Pumpdown time	0.25 min
Working distance	8 in.
Beam focal point	1 in. above work surface
Welding speed	30 ipm
Number of passes	One, plus 20° overlap

Fig. 22. Transmission-gear assembly designed for compact, two-piece fabrication by electron beam welding. Other welding processes could not provide satisfactory depth-to-width ratios, nor freedom from distortion or melt-through of nearby splined surfaces. (Example 472)

Example 472. Medium-Vacuum Welding of a Transmission-Gear Assembly, With Splines Close to the Joint (Fig. 22)

Double gears of the type shown in Fig. 22 were designed as two-piece weldments to reduce weight and save space in a transmission system. The gear assembly consisted of two components machined from normalized 8620 steel and assembled with an interference fit of 0.001 to 0.002 in. on the 3.750-in.-diam, 7/32-in.-deep joint, as shown in detail A in Fig. 22. This joint required a ¼-in.-deep weld, to ensure complete joint penetration.

Several welding processes were considered for making small quantities of a number of different gears of this type. There were a number of restrictive requirements for the weld; the most important involved the depth-to-width ratio. The proximity of the internal spline surfaces to the weld joint (slightly over ⅛ in.) made it necessary that the depth-to-width ratio be greater than 2 to 1, to avoid overheating the spline.

On the basis of this restriction, the weight-saving, compact design shown in Fig. 22 could be used only if welding were done by the electron beam process. There was no problem in obtaining a 4-to-1 depth-to-width ratio with electron beam welding. Carburizing followed welding.

The gear assemblies were welded in a single pass, using medium-vacuum equipment, with the conditions given in the table with Fig. 22. No distortion occurred. Although, because of the small quantity of parts involved, electron beam welding was the most costly process, it was the only one that could do the job.

In addition to confining the decrease in base-metal properties to a very narrow zone, as illustrated in the preceding three examples, electron beam welding of hardened or work-strengthened metals also generally produces joints superior in quality to those produced by arc welding.

Fourteen examples in this article deal with electron beam welding of hardened ferrous and nonferrous met-

als. The work metals involved and the example numbers are as follows:

Carbon steels 470
Alloy steels 465, 471, 472, 486, 504, 505
Tool steel 488
Stainless steel 489
Aluminum alloys 475, 493, 494
Copper alloy 502
Titanium alloy 496

Exceptions. Some high-strength steels cannot be electron beam welded in the hardened condition without cracking or an unacceptable decrease in strength and hardness. These steels are normalized or annealed before welding and heat treated for controlled strength and hardness after welding. This order of operations was followed in welding 4340 steel in Examples 464 and 503, and 52100 steel in Example 487.

Controlling Heat Effects

The extent of heat-affected base metal in electron beam welding is controlled mainly by regulating the width and shape of the weld. In general, the width of the heat-affected zone is proportional to the average width of the weld, which also strongly influences shrinkage and distortion.

Damage to heat-sensitive attachments, inserts or encapsulated materials close to the weld joint is controlled mainly by regulating the width and shape of the weld bead. Damage to nearby finished functional surfaces on the workpieces or to nearby drilled or tapped holes or other critical features of the workpieces can often be avoided in electron beam welding because of the narrowness of the welds, as in Examples 480, 481 and 496.

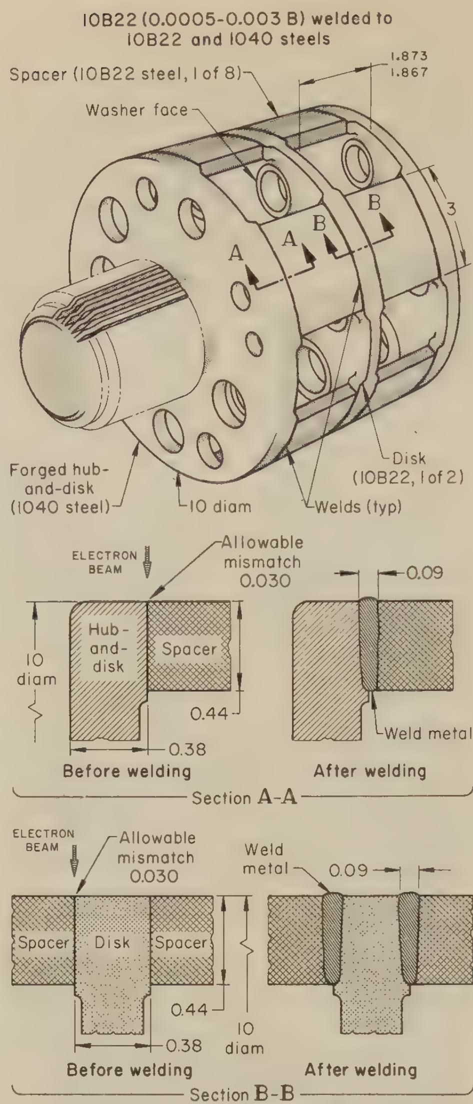
Joint designs that provide constricted sections near the weld to retard heat transfer from the weld, or that provide an integral heat sink, and the use of external heat sinks or chill bars are also helpful in controlling heat effects in electron beam welding (see Joint Design, page 521, and Welding of Thin Metal, page 536).

Holding shrinkage and distortion to low values was important in nearly all of the examples in this article. In the example that follows, narrow full-penetration welds with only a slight taper allowed final sizing of all components before assembly and welding.

Example 473. Electron Beam Welding To Maintain Dimensions of Prefinished Components for Minimum Shrinkage and Distortion (Fig. 23)

Planetary-gear carriers for tractor transmissions originally were machined from one-piece ductile iron castings. When the number of gears was increased from nine to twelve for greater power selectivity, the carriers were redesigned for electron beam welding (Fig. 23). The change from a casting to a weldment was made because: (*a*) the one-piece design precluded access for accurate machining of the larger number of washer faces, and (*b*) to meet higher strength requirements, the hardness of the casting would have had to be increased, which would have increased machining difficulties. Arc welding was ruled out because of excessive shrinkage and distortion.

Each weldment consisted of two disks, an integral hub-and-disk, and eight spacers. All parts were made of 10B22 (boron intensified) steel, except the hub-and-disk, which was forged in one piece from 1040 steel. Composition of the 10B22 steel was 0.19 to 0.25 carbon, 0.60 to 0.90 manganese, 0.04 max phosphorus, 0.05 max sulfur, 0.15 to 0.30 silicon, 0.0005 to 0.003 boron. Sixteen 3-in.-long complete-penetration welds were made to join the disks and spacers.



Joint types	Corner and T; circumferential (see illustration)
Weld type	Square groove
Machine capacity	150 kv at 40 ma (6 kw)
Vacuum-chamber size	36 by 36 by 36 in.
Maximum vacuum	About 10^{-6} torr
Fixtures	Clamping jig; lathe-type positioner
Preheat	None
Welding power	110 kv at 35 ma
Welding vacuum	10^{-4} torr
Working distance	8.75 in.
Beam focal point	At work surface
Beam oscillation	None
Welding speed	40 ipm (1.27 rpm)
Number of passes	One per joint
Production rate	Four assemblies per hour
Postheat	Induction harden splined hub to Rockwell C 50

Fig. 23. Planetary-gear carrier made to strength and accuracy requirements, for which electron beam welding permitted use of prefinished components, for minimum shrinkage and distortion (Example 473)

The new design and the use of electron beam welding made it possible to finish all components by conventional machining methods before welding. Electron beam welding was the only process by which the joints could be fully penetrated in a single pass with low heat input, to produce a narrow, only slightly tapered weld. Shrinkage and distortion were minimal.

Before welding, the two 10B22 disks and the 1040 hub-and-disk forging were in the hardness range of 241 to 285 Bhn, and the 10B22 spacers were in the hardness range of 207 to 241 Bhn. The only heat treatment after welding was selective induction hardening and tempering of the splined hub to Rockwell C 50.

The disks and the joint surfaces of the spacers were machined to a 32-micro-in. finish. They were vapor degreased, and then assembled and aligned in a holding fixture designed for mounting between the headstock and tailstock of a lathe-type positioner located within a vacuum chamber. The assembly rotated about a horizontal axis with the electron beam gun in a fixed vertical position. Beam alignment was done by telescope; welding was observed directly, through chamber windows. A second fixture was loaded while the first one was in the vacuum chamber. The tooling was also equipped with limit switches that turned the beam on and off for the interval required by each spacer. To avoid heat buildup, the two welds at the center disk were made first and last. Welding conditions are given in the table with Fig. 23.

Maximum weld width was about 0.090 in., for a depth-to-width ratio of 5 to 1.

Heat-Sensitive Attachments and Inserts. Narrow, closely controlled electron beam welds, with low heat input, can be made in close proximity to heat-sensitive attachments, inserts or encapsulated materials without damaging them, often when no other welding process can meet this requirement, as in the next two examples.

Example 474. Full-Penetration Welding of an Aluminum Alloy Section ⅛ In. Thick That Encased Nuclear Fuel Only 0.030 In. Away From the Joint (Fig. 24)

A nuclear fuel element consisting of a sheet of uranium-aluminum alloy that was clad with 99.9% aluminum on all sides and formed into a tube ¾ in. in outside diameter and 48 in. long, had a total wall thickness of about ⅛ in. The location of the longitudinal welded joint, relative to the cladding and the fuel, is shown in Fig. 24. Specifications for welding prohibited the fusion zone from extending to the fuel core material, which approached within 0.030 in. of the joint edge. Joint penetration had to be as deep as possible, without drop-through or the formation of an appreciable underbead. The outside weld face had to be smooth and flat.

An electron beam welding procedure, and the welding conditions shown in the table accompanying Fig. 24, were developed to meet the requirements. Details of the procedure were as follows:

A high-vacuum electron beam welding machine was used because it was the only type available. The welding could have been done more quickly in a medium-vacuum machine because pumpdown time would have been less. Gas tungsten-arc welding could have met the penetration requirements, but a wider fusion zone would have resulted, with the danger of melting through into the fuel.

Proper cleaning of the weld-joint surfaces was essential in obtaining porosity-free welds to meet radiographic standards. After edge preparation, the flat plates were vapor degreased, cleaned in a commercial cleaner, and rinsed in water. They were then formed into cylinders and vapor degreased in trichlorethylene.

Joint design was a tightly fitting butt joint with a tolerance of +0.010 in. max, as shown in Fig. 24 (lower left). This was obtained by machining the joint edges and clamping the cylinder in the split stainless steel fixture shown at the upper right of Fig. 24. No filler metal was used.

To protect the tube from weld spatter and to prevent possible impingement of the beam on the side of the tube opposite the weld, a thin aluminum spatter shield, also shown in Fig. 24, was loosely inserted.

The fixtured tube was mounted on a sliding carriage having a variable-speed

drive. Welds were initiated and terminated on starting and runoff tabs (not shown). The welding conditions given in the table with Fig. 24 were determined by welding test pieces.

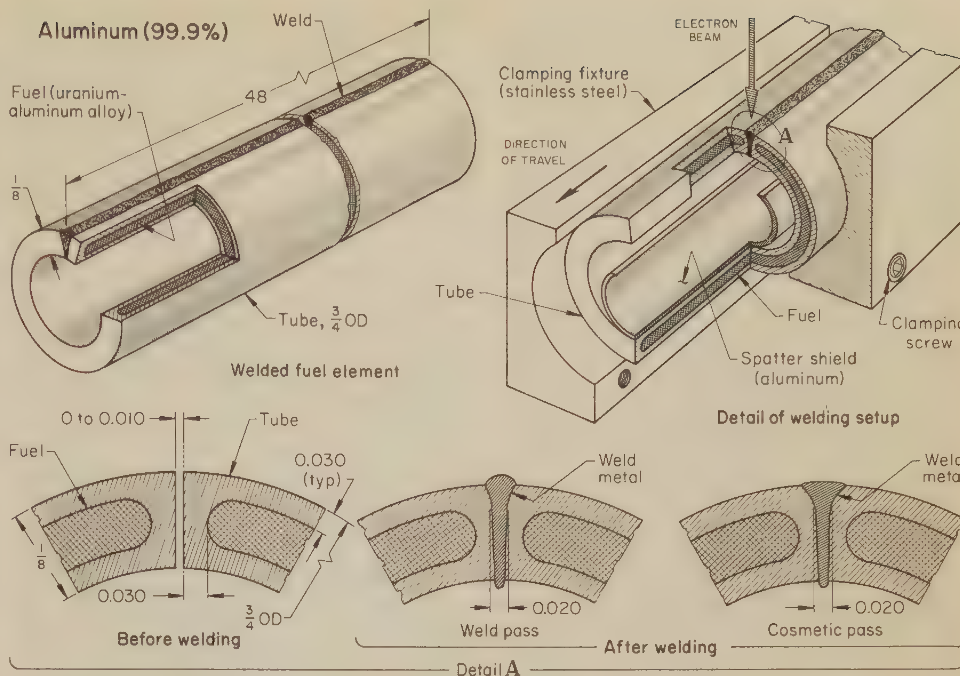
After pumpdown and beam alignment, the weld was made in a single pass, using a beam sharply focused on the workpiece surface. (Detail A in Fig. 24 shows the typical weld shape and dimensions.) Power and focus settings were then changed to form a beam of lower energy and larger spot size for the cosmetic pass, which was made at the same speed. This pass flattened the weld crown formed during the previous pass (see detail A of Fig. 24).

Completed fuel elements were checked by visual and radiographic inspection. A ring gage was used to determine the flatness of the weld crown.

Example 475. Precise, Low-Heat Welds Made in an Aluminum Alloy Within ¼ In. of an Explosive Charge in a Fuze Assembly (Fig. 25)

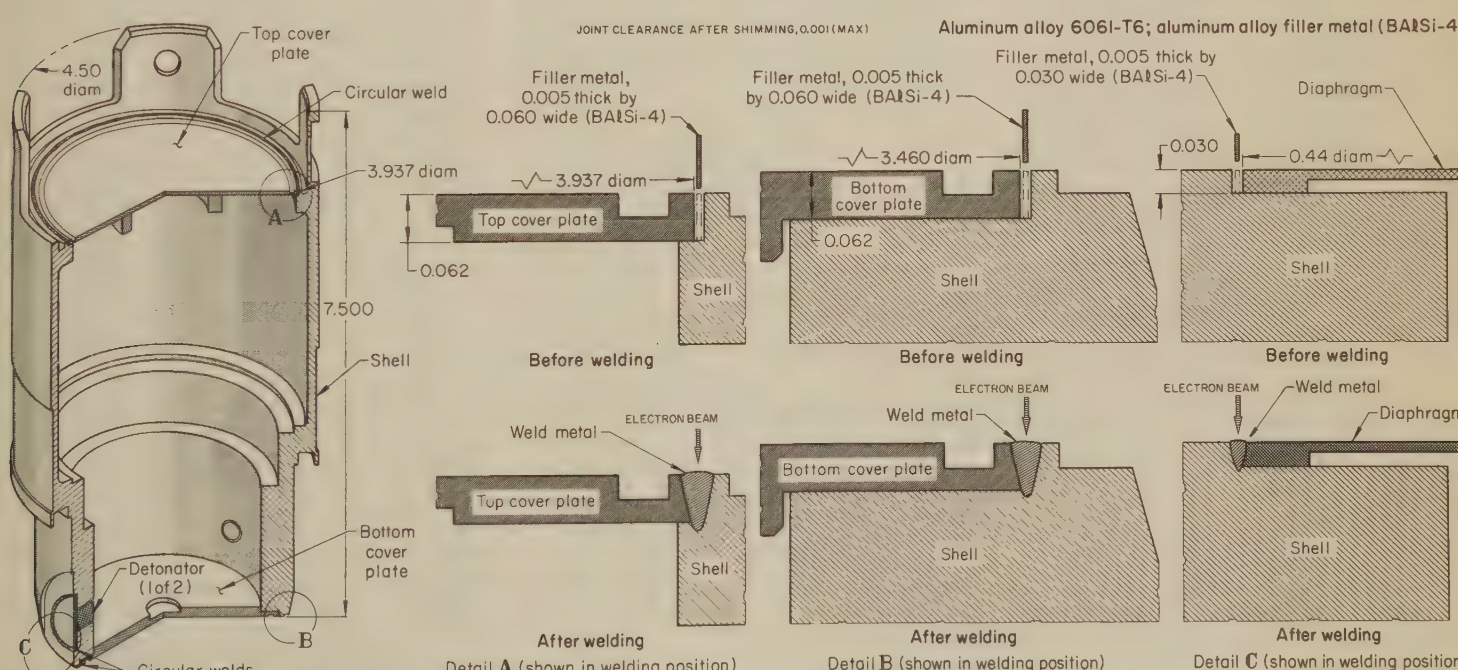
Electron beam welding was selected for the delicate final closure of the loaded fuze assembly shown in Fig. 25. The enclosure, which consisted of a shell, top and bottom cover plates, and two identical, oppositely located diaphragms, contained two stab detonators and two high-explosive (RDX) leads. Because the joints between the shell and the diaphragm were less than ¼ in. from the explosive, the safety of the operator and of the equipment depended on small, accurately placed welds with low total heat input, and careful handling.

Design considerations called for attaching the two cover plates and two diaphragms by controlled-penetration welds, of medium strength (18,000 psi) and capable of leak rates of less than 10^{-7} cu cm of helium per second at a difference in pressure of 1 atm. Preheating and postheating were not permitted. All of the components were made of aluminum alloy 6061-T6. Filler metal



Joint type	Butt	Welding power:	
Weld type	Square groove	Penetration pass	130 kv at 7 ma
Machine capacity	150 kv at 40 ma	Cosmetic pass	130 kv at 4 ma
Gun type	Fixed; with hairpin tungsten filament	Welding vacuum	10^{-4} torr
Vacuum-chamber size	36 in. in diameter by 144 in. long	Beam focal point:	
		Penetration pass	Sharp at work surface
		Cosmetic pass	Defocused
Maximum vacuum	10^{-5} torr	Beam deflection	None
Fixtures	Clamping tool; travel carriage	Working distance	12 in.
Pumpdown time	20 min	Welding speed	30 ipm (each pass)

Fig. 24. Aluminum-encased nuclear fuel element that was electron beam welded within 0.030 in. of the uranium-aluminum alloy fuel (Example 474)



Joint types	Circular corner and butt; rabbeted, self-backing	Filler metal	0.005-in.-thick foil of BAlSi-4	Beam oscillation(a)	0.010-in. diameter, at 1000 hertz(b)
Weld type	Square groove	Welding power(a):		Welding speed(a):	
Machine capacity	150 kv at 40 ma	Top cover (detail A)	130 kv at 6 ma	Top cover (detail A)	62 ipm (5 rpm)
Gun type	Steigerwald; fixed	Bottom cover (detail B)	110 kv at 5 ma	Bottom cover (detail B)	54 ipm (5 rpm)
Vacuum-chamber size	36 by 23 by 30 in.	Diaphragm (detail C)	130 kv at 4 ma	Diaphragm (detail C)	58 ipm (42 rpm)
Maximum vacuum	About 10^{-5} torr	Welding vacuum	10^{-4} torr or less (all welds)	Working distance	7½ in. (all welds)(c)
Fixtures	Universal chuck; turntable	Beam focal point	Sharp at surface (all welds)	Production rate	2.7 parts per hour

(a) Same for tack and final welds; weld time for tack welds was 0.05 sec. (b) Circular deflection. (c) Measured from top of chamber to workpiece.

Fig. 25. Aluminum alloy 6061-T6 fuze assembly and details of final-closure electron beam welds made between shell and cover plates and diaphragms. Low heat input and high precision of welds joining the diaphragms to the shells were highly critical, because the joints were less than ¼ in. from the explosive charge (not shown in illustration) in the shell at the time of welding. (Example 475)

was BAlSi-4 brazing alloy (12% Si), in the form of foil 0.004 to 0.006 in. thick cut to widths of 0.030 and 0.060 in. to fit tightly in the joint openings (see "Heat treatable alloys" and Example 493, on p 555, for discussion on crack sensitivity of alloy 6061-T6 in the absence of filler metal).

Weld width was about 0.020 in. on the diaphragms and 0.032 in. on the cover plates. Penetration was just beyond joint depth, to ensure consistent joint strength. At the joints between the shell and the covers, a circular recess was cut inside the joint (see details A and B of Fig. 25). The recess served to reduce the heat path to the cover, and the small lip allowed movement to help reduce residual stress from weld shrinkage on cooling. The reduced section of the diaphragms (about 0.010 in. thick) facilitated detonation.

After machining, the components were cleaned and degreased. Just before assembly for welding, the oxide was removed from welding surfaces by brushing with a small stainless steel wire or fiber glass brush. Dust was removed by wiping with a solvent, and care was taken to leave no fingerprints on the cleaned surfaces.

Each of the covers and diaphragms was assembled, fixtured, tack welded, and welded as a separate operation, the vacuum chamber being loaded and unloaded four times to complete one unit. Tack welding was used: (*a*) to eliminate the need for an additional costly fixture, (*b*) to prevent displacement of parts from thermal expansion during welding, and (*c*) to anchor the filler-metal strips against curling out of the joint during welding and to prevent distortion (curling) of the thin diaphragms and covers during welding.

Welding conditions for each of the operations are summarized in the table with Fig. 25. The sequence of operations for welding the top cover plate to the shell (detail A in Fig. 25), as described below, was typical for the four joints.

With the top cover plate shimmed tightly in place by filler metal, the subassembly, with its axis vertical, was chucked on a turntable inside the chamber. Using a 20-power telescope, the weld joint was checked for alignment, adjusted, and rechecked. A circular weight was placed on the cover to hold it in place for tack welding. Beam power and beam oscillation settings were made (these were the same as for the final welds), and the automatic weld timer was set for 0.05 sec. After vacuum pumpdown (2½ to 2¾ min), four tack welds were placed at 90° intervals by pressing the "on" switch, and rotating the part.

To make the final circular weld, the machine settings were adjusted as necessary, and the power supply was set for automatic upslope and downslope. Rotation was started and the "beam on" switch was pressed. Upon completing one revolution under welding power, the "beam on" switch was released, thereby actuating the downslope power mode, which carried the beam for a short distance, to taper the weld overlap. The overlap could be distinguished from the remainder of the weld only with difficulty. There was no evidence of the tack welds.

After the top cover was welded, the machine was unloaded. The bottom cover (detail B of Fig. 25) and the two diaphragms (detail C) were then welded similarly.

Testing of the completed units consisted of the leak-rate test described earlier. In addition, destructive tests were made on test pieces that simulated the weld areas of the fuze assembly. Periodically, three such samples were tension tested and examined macroscopically for weld soundness. Similar tests were also made on a regular sampling basis of one part out of twenty.

Welding of Thin Metal

Electron beam welding can be advantageous for joints in which at least one member is made of thin metal (less than 3/32 in. and as thin as 0.001 in.). Applications include instrument parts, instrument enclosures, pressure or hermetic seals, diaphragms, encapsulations, electrical connectors, and electronic devices, of various metals.

Table 3. Relation of Depth to Width (D/W) for Partial-Penetration Electron Beam Welds in Thin Sections(a)

Work metal	Thickness, in.	Weld depth, in.	Weld width, in.(b)	D/W for weld
Aluminum Alloys				
6061-T6	0.005	0.003	0.015	0.2
5052	0.010	0.005	0.012	0.4
	0.020	0.017	0.015	1.1
Stainless Steels				
17-4 PH	0.005	0.004	0.014	0.3
Type 301	0.010	0.006	0.011	0.5

(a) All welds were made in a high vacuum; chill tooling was in intimate contact with the underside of the work at the weld location. (b) Width of the weld at the crown, which was the greatest width for the gently radiused wide-angle V-shape welds.

The joint area must be heated to melting temperatures in joining thin sections, just as in joining thick sections, but the rate of heat transfer away from the joint is much lower, because of the reduced cross section. Hence, local heat buildup is greater, which increases weld width and decreases depth-to-width ratio. In addition, minimum beam spot size has a much greater effect on depth-to-width ratio in joining thin metal than in joining thick metal. The minimum usable beam spot size obtainable generally ranges from about 0.005 to 0.020 in. in diameter. Because of these conditions, depth-to-width ratio for full-penetration welds joining two sections thinner than about 3/32 in. usually does not exceed about 5 to 1, and may be less than 1 to 1.

When voltage, current, welding speed, and other conditions discussed in the section on Welding in High Vacuum have been optimized for a specific joint, use of a heat sink may still be necessary to avoid overheating thin material, depending on base-metal properties (melting point, specific heat, and thermal conductivity) and metal thickness. Best results usually are obtained by the use of copper chill blocks machined to fit the workpiece closely at the joint area. Fixtures made of other metals may be effective as chill blocks if contact area is sufficiently large and close to the heat source.

In the examples in this article, the thinnest section of work metal joined by electron beam welding was 0.010 in. thick (Examples 482 and 490).

Examples of welding metal thinner than 3/32 in. are:

Low-carbon steel	Ex. 467
HS-25	477
René 41	481
Copper alloys	482
D-6ac	486
Cb-752	490
Tantalum alloy	491
Aluminum alloys	493 and 494

Joining Thin Sections to Thick Sections. In joining thin sections to thick sections by electron beam welding, the joint is usually designed so that the thick member serves as a heat sink for the thin member, and the point of beam impingement is slightly removed from the thin metal. When these precautions are taken, welding behavior and heat dissipation are generally the same as in welding thick sections under similar conditions. Depth of penetration in the thicker section is usually made only slightly greater than the thickness of the thin section.

Six examples in this article deal with the welding of thin to thick sections:

1020 to 1140 steel	Ex. 468
Type 304 stainless steel	476
17-4 PH stainless steel	489
Aluminum alloy 2024-T4	495
Aluminum alloy 5052	492
Aluminum alloy 6061-T6	475

Even with the aid of the heat-sink capacity of a thicker member, heat input by arc welding often cannot be localized sufficiently and controlled closely enough to avoid damage to metal of foil thickness. In the example of welding type 304 stainless steel that follows, in which 0.002-in.-thick foil was sandwiched between 0.040-in.-thick sheet and the edge of a 0.100-in.-thick cylinder wall, gas tungsten-arc welding was replaced by electron beam welding to eliminate excessive foil melting.

Example 476. Melt-Through Welding of 0.002-In.-Thick Foil Between 0.040-In.-Thick Sheet and the Edge of a 0.100-In.-Thick Cylinder Wall (Fig. 26)

A rupture-disk assembly (Fig. 26) designed for gas-pressure relief consisted of three components: (*a*) a 2-in.-diam nozzle of 0.100-in.-thick type 304 stainless steel attached to an outer pressure vessel (not shown); (*b*) a 0.002-in.-thick cupped rupture disk of type 304 stainless steel; and (*c*) a 0.040-in.-thick cap, also of stainless steel, containing an off-center flued-in hole with downward-pointing knife edges.

The three components were joined by a single weld that was required to have a leak rate of less than 10^{-8} cu cm per second when tested with a helium mass spectrometer. When pressure in the nozzle exceeded the design limit, the cupped rupture disk reversed its shape from concave to convex, puncturing itself against the knife-edge of the cap. Leaktightness, rather than high tensile strength, was the welding objective. The material was selected for long maintenance-free service, rather than for resistance to a corrosive environment.

Originally, the components were joined in one pass by automatic gas tungsten-arc welding, using the design shown in detail A, original method, Fig. 26. A circular groove was cut in the nozzle wall to help localize the weld bead, which was made without filler metal. Light pressure was applied at both ends of the assembly to hold the parts in alignment for welding.

This procedure resulted in numerous rejects because of leaks. Often, difficulty was encountered in getting the disks to lie absolutely flat on the joint surface. The 0.002-in.-thick rupture disks, having been blanked and formed in the work-hardened condition, were tough, springy and sometimes burred. As a result, they occasionally were burned back, instead of being fused into the weld bead, causing leaks. It was usually impossible to salvage this type of defect by rewelding.

To eliminate these difficulties, the operation was converted to electron beam welding, even though initial equipment and tooling costs were high. The equipment was also profitably used for other applications (see Example 499).

The electron beam welding machine used for this application had a relatively large vacuum chamber with full-width doors, to facilitate loading and unloading of large, multiple-part fixtures. The holding fixture used had 56 receptacles to position and in-

dividually rotate 56 assemblies under a stationary gun. The fixture was mounted on a horizontal table equipped with x-y motion control to permit optical alignment of the beam for welding each part in turn.

Each assembly was fitted into a cylindrical receptacle, or pot, that was equipped with a hold-down ring that forced the periphery of the disks and caps into close alignment, as shown in detail A, improved method, Fig. 26. A melt-through, or spike, weld was made, rather than an edge-flange weld at the periphery.

With this setup, the blanking and forming operations on the disks could be allowed the more realistic tolerance of ±0.002 in. on flatness. The electron beam was angled slightly, as shown, and was positioned close to the hold-down ring so that, in the event of a leak, the joint could be rewelded by running a second weld just inside the first weld.

The weld-localizing groove needed for the original gas tungsten-arc method was eliminated, and the electron beam melt-through weld was made at a heat input of 0.25 kj per inch of weld length, which was much lower than for arc welding. The hold-down ring provided only a slight chill effect, but enabled the nozzle body to function effectively as a heat sink.

Welding conditions for the electron beam process are given in the table accompanying Fig. 26.

Welding results from the electron beam procedure were good. Joint defects of all types dropped to 3%, and most of the rejects could be salvaged by rewelding. A production rate of 44½ assemblies per hour was a significant improvement over the original arc method.

Partial-Penetration Welds. The precise control of heat input obtainable in electron beam welding permits partial-penetration welds having uniform depth to be made in metals as thin as 0.010 in., and sometimes less.

Work-metal thickness must be uniform, and workpiece, fixture arrangement, and dimensions must be selected to provide a constant rate of heat loss adjacent to the path of the weld along its entire length, with special provisions made for weld starting and stopping. Beam power, focus, and workpiece travel speed must be closely regulated to minimize variation in penetration.

For the closest control of penetration, both beam power and focus can be regulated by sensitive, fast-response closed-loop servomechanisms or feedback controllers, and workpiece travel speed can be held within extremely narrow limits by precision, mechanical worktable traverse or by rotary-motion systems. To compensate automatically for the effect of any variation in voltage on focus, the servomechanism regulating the beam focus can be coupled to the voltage supply by solid-state devices that have a response time of less than 17 microseconds.

Partial-penetration welds in thin metal are not subject to root voids, root porosity, or cold shuts, which are defects frequently encountered in partial-penetration welds in thick metal, because such welds in thin metal have relatively low depth-to-width ratios and a wide-angle V-shape with a gently radiused bottom.

Data on the relation of depth to width for high-vacuum partial-penetration welds in thin sections is given in Table 3. The ratio of depth to width is lower for the welds in the thinner sections. Penetration was from 50 to 85% of the work-metal thickness, and all welds were made with chill bars in intimate contact with the underside of the work at the weld location.

Depth of penetration generally varies 10 to 15% from a mean value for a work thickness of about 0.020 in., and the percentage variation is greater for welds in thinner metal. Accordingly, partial-penetration welds are not ordinarily made in metal thinner than about 0.010 in. Beam oscillation is sometimes used to smooth out variation in penetration, but such oscillation must be controlled closely in order to be effective.

In the example that follows, low beam power and circular oscillation were used in producing sound partial-penetration welds 0.030 to 0.045 in. deep and 0.026 in. wide at the crown (average depth-to-width ratio of 1.4, and 50 to 75% penetration) in 0.060-in.-thick HS-25 heat-resisting alloy.

Example 477. Partial-Penetration Welding of Thin-Wall Joints in HS-25 Rocket-Engine Nozzles (Fig. 27)

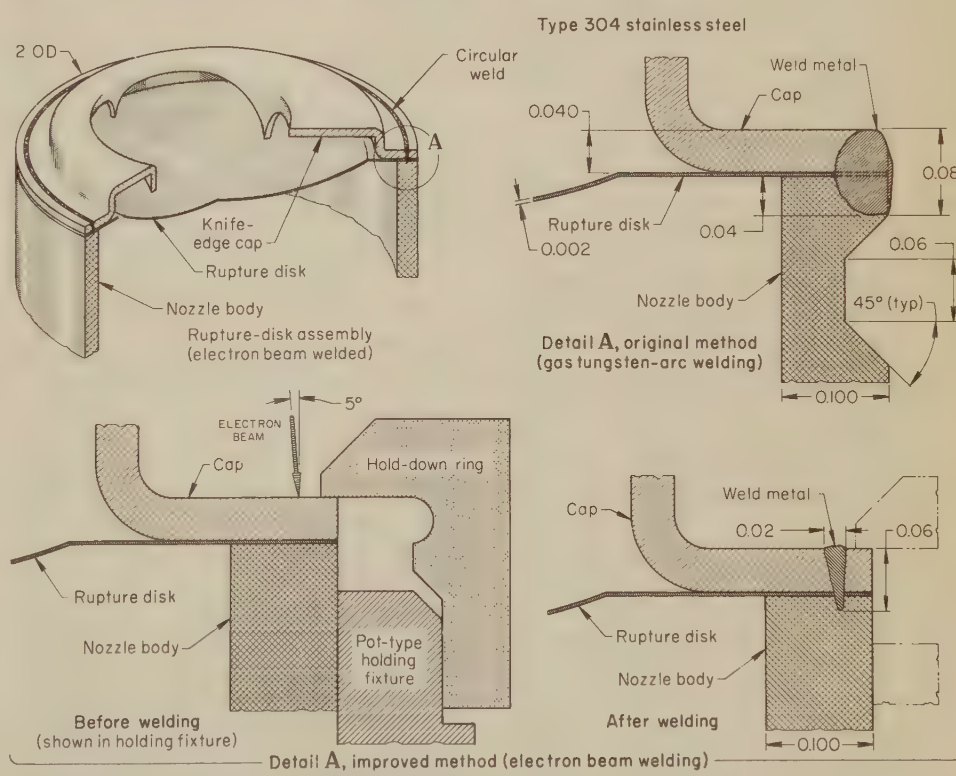
Proper functioning of the rocket-engine nozzle assembly shown in Fig. 27 required a welding procedure that would: (*a*) avoid distorting the critically aligned parts; (*b*) avoid internal spatter or melt-through to disturb flow characteristics; and (*c*) minimize heat effects in the base metal. Gas tungsten-arc welding was considered, but could not provide the low, accurately controlled, localized heat input needed for freedom from cracking and distortion. Partial-penetration electron beam welds finally met the requirements, with special attention given to joint preparation.

A rabbeted, self-backing, square-groove butt joint, as shown in Fig. 27, detail A, was selected to ensure a tight fit for accurate alignment of the two joints and to facilitate partial penetration into the thicker member.

When trial welds were made to determine machine settings, it was found that the alloy used, cobalt-base alloy HS-25, although heat resistant, was highly susceptible to microcracking during cooling from welding temperature. The cracking was promoted by loose fit-up, which was traced to the procedures used in machining, annealing, and mechanical cleaning.

For the trial welds, the joint edges had been machined with the metal in the annealed condition, using single-point tools. Because HS-25 alloy strain ages at 700 to 1100 F, as well as from cold work, the manufacturing sequence was changed so that annealing was done after rough machining with form tools, and only a light finish cut was taken after annealing and before welding. The slight bevel shown at the inside corner of the joint in Fig. 27, detail A, aided in assembly for welding and was also a check on penetration, during radiographic examination.

All mechanical cleaning methods, such as filing, scraping and wire brushing, were avoided. Joints were cleaned chemically and rinsed in acetone. Extra care was taken in handling the parts to avoid nicking or breaking the edges.



Conditions for Electron Beam Welding

Joint type	Circular, three-piece corner	Welding vacuum	5×10^{-5} torr
Weld type	Melt-through (spike)	Pumpdown time	10 min
Machine capacity	50 kv at 250 ma	Working distance	1.5 in.
Gun type	Diode; fixed during welding	Beam focal point	Sharp at work surface
Vacuum chamber	Steel; 54 by 48 by 48 in., with full-width end doors	Beam spot size	About 0.020-in. diameter
Fixtures	56-piece holding tool with individual rotation; table with x-y motion	Welding speed	100 ipm
Welding power	26 kv at 16 ma	Number of passes	One, plus 30° downslope
		Setup time	48 min
		Production rate	44½ pieces per hour

Fig. 26. Stainless steel rupture-disk assembly, originally joined by gas tungsten-arc welding, for which change to electron beam welding increased production rate and eliminated fit-up problem that caused burning of 0.002-in.-thick foil. Joint details of both gas tungsten-arc and electron beam welding are shown. (Example 476)

To reduce shrinkage stresses, joint fit-up tolerances were tightened. Allowable joint mismatch was held to ±0.002 and root-opening tolerances were set at zero to 0.004 in. Although the slip joint appeared tight, some loosening occurred during welding, and so the joint was tack welded.

The beam was circularly oscillated over an 0.015-in. diameter at 500 hertz, to avoid joint underfill at the weld surface. This technique was preferred to the use of a cosmetic pass with a defocused beam, which had caused distortion and cracking in welds on other alloys of this type.

The weld was made in one pass, with a short overlap to permit smooth downslope of the beam power. Downsloping the beam power helped to avoid crater cracks at the beginning of the overlap. No preheat was used in this application, nor was chill tooling used. Although postweld annealing would have been desirable, it was not done because it would damage the catalysis chamber. The completed weld is shown at the lower right of Fig. 27.

When all of the foregoing precautions and techniques were adopted, good welds resulted. Welding conditions are given in the table with Fig. 27.

Special Welds. Thin sections are frequently electron beam welded in special shapes, as dictated by the design of the weldment and the need for control of heat input in welding. In some cases, joint-design criteria, as ordinarily applied, must be compromised to a small extent in order to accomplish such welds. In Example 469, 0.005-in.-thick foil was placed between 0.060-in. stock; Examples 481 and 482 describe multiple-tier welding; and in Example 485 a filler-metal wire was placed in a bevel groove atop a 0.010-in.-clearance joint to make a seal weld.

Welding of Thick Metal

For joining thick sections, electron beam welding in a vacuum has three principal advantages over other welding processes:

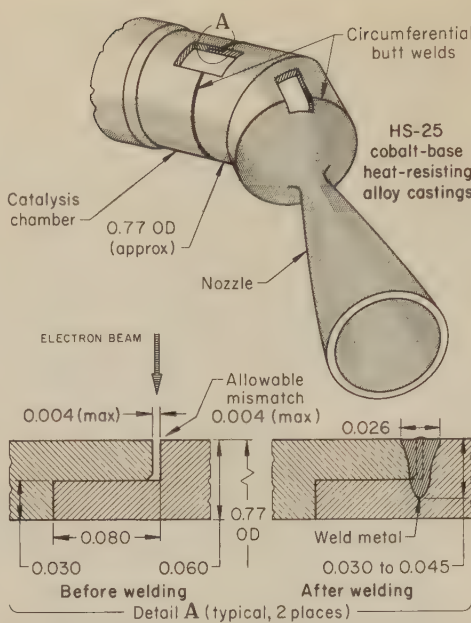
1 Much deeper penetration can be obtained in a single pass. Extremely narrow, only slightly tapered welds and small heat-affected zones can be produced.
2 For joints on most weldable metals, no filler metal is needed. Where a filler metal is required, the quantity is usually very small.
3 Joints have closely fitted parallel groove faces requiring no edge preparation, instead of V-grooves or U-grooves.

The disadvantages of electron beam welding for joining thick metal are those usually associated with this process: high equipment cost, size limitations imposed by the dimensions of the vacuum chamber in which the work must be placed, and the time needed for evacuating the chamber.

Nonvacuum electron beam welding is not ordinarily used for welding thick metal and is seldom practical for making welds deeper than about ½ in.

Deep welds made in a vacuum are usually narrow; weld width for penetration deeper than about ¼ in. is typically about ⅕ to ⅒ of the section thickness, except for a somewhat greater width at the crown of the weld. Welds may be either full-penetration or partial-penetration.

Effects of Pressure. Penetration capability is greatest for electron beam welding in high vacuum. The effect of the pressure at which the welding is



Joint type	Circumferential butt; rabbeted, self-backing
Weld type	Square groove
Machine capacity	150 kv at 40 ma
Gun type	Steigerwald; with tungsten filament
Vacuum chamber	Lead-lined steel; 36 by 23 by 23 in.
Maximum vacuum	10^{-5} torr
Fixtures	Three-jaw chuck; rotating spindle
Welding position	Horizontal rolled
Welding power	100 kv at 2.2 ma
Welding vacuum	5×10^{-5} torr
Pumpdown time	5 min
Beam oscillation	0.015-in. diameter, at 500 hertz
Working distance	6 in.
Power density of beam	1.25 megawatts per square inch
Welding speed	39.7 ipm (16.4 rpm)
Number of passes	One, plus overlap

Fig. 27. Small HS-25 heat-resisting alloy rocket-engine assembly consisting of catalysis chamber, 45° elbow, and thrust nozzle, which were joined by partial-penetration electron beam welding to prevent distortion, maintain smooth interior, and avoid cracking (Example 477)

done on the maximum penetration obtainable in steel at 9-kw beam power is shown by the following data, which are typical for commercial equipment:

Type of system	Pressure at workpiece, torr	Penetration (max), in.	Welding speed, ipm
High vacuum	10^{-4} to 10^{-5}	3½	4
Medium vacuum	10^{-1}	2½	6
Nonvacuum	760	½	20

Full-Penetration Welds. In welding carbon steel, single-pass, full-penetration, vacuum electron beam welds are made commercially in thicknesses ranging up to approximately 2 in. Production electron beam welding has been done on aluminum alloy plate 6 in. thick, and 9-in.-thick aluminum alloy sections have been welded experimentally under near practical conditions.

Examples in this article that deal with full-penetration welds in thick sections are as follows:

Type 410 stainless steel	Ex. 466
Duplex metal	471
10B22 to 1040 steel	473
Invar to Mn-18Cu-10Ni	478
4340 steel	503
AMS 6265 steel	504

Two-Pass Full-Penetration Welding. Penetration can be nearly doubled by making two passes, one on each side of the work, but cold shuts, voids and porosity are encountered at the root of the second weld unless conditions are adjusted for the pass made on the second, or back, side. A broader second-side weld with a larger radius at the root helps to reduce the incidence and severity of these defects, but they often remain a problem.

The example that follows describes the full-penetration welding of ⅝-in.-thick metal in two passes, one on each side, in welding together large billets of unlike metals for subsequent rolling into thin bimetal strip.

Example 478. Full-Penetration Welding of a ⅝-In.-Deep Joint Between Unlike Metals in Two Passes, One on Each Side (Fig. 28)

Electron beam welding was used to join massive bars of Invar and a manganese-copper-nickel alloy into bimetal billets that were rolled into thin strip for use in thermostats (Fig. 28). Nominal composition and room-temperature coefficients of thermal expansion for the two alloys, which show a wide difference, were as follows:

Alloy	Nominal composition	Expansion, micro-in./in./°C
Invar	36 Ni, 64 Fe	0.877
Mn-Cu-Ni	18 Cu, 10 Ni, 72 Mn	28.5

Normally, bimetal billets were joined by furnace brazing, but an alternative method was sought for joining this combination because of difficulties in brazing and an undesirably low production rate.

A uniform metallurgical bond over the entire interface was required, since after bonding, the billets were hot rolled and then cold rolled to final thicknesses of 0.005 to 0.060 in., depending on the application.

Bars of the two metals were machined to the dimensions shown in Fig. 28 and the surfaces to be welded were ground to a finish of 32 micro-in. max, in preparation for joining. Initial thicknesses of the bars to be joined were 1½ in. for the manganese alloy and 1 in. for the Invar, to allow for lower hot strength and greater reduction of the manganese alloy during hot rolling. Final thickness ratio was 9 to 11 (manganese alloy to Invar).

The first method tried as an alternative to furnace brazing was diffusion welding, because large, vacuum hot-pressing furnaces were available in which many pieces could be bonded in a single load. However, good pressure bonds were difficult to obtain, even in small laboratory furnaces at vacuums less than 5×10^{-2} torr, because of the ease with which the manganese alloy oxidized.

Several attempts were made to produce the diffusion bond in a production furnace having a normal operating vacuum of about 3×10^{-1} torr. No filler metal was used. Results obtained after hot and cold rolling the bonded billets were not satisfactory. Temperature seemed extremely critical (1900 F +10, −20 F), and control within this narrow range was not feasible on a production basis.

When electron beam welding was tried, excellent bonding results were obtained. The two bars were clamped in heavy-duty vises and C-clamps on a traversing table in the vacuum chamber, with the joints in the vertical position as shown in section A-A in Fig. 28. Using the conditions given in the table with Fig. 28, a 3-in. depth of penetration was achieved in each pass, which provided full penetration with an overlap of ⅝ in.

One of the problems encountered was that, when the billet was removed from the clamping fixture to turn over for making the second weld, the heated piece bowed. Rather than attempt to reclamp the billet in this condition, it was allowed to return to room temperature and thereby to resume its original shape.

There was some concern over maintaining uniform weld width through the depth of the joint, because nonuniform weld width might ultimately result in irregular bimetal deflection. However, except for a depth of about ½ in. at each surface where the electron beam impinged, the weld width was held to ⅛ in. +0, −1⁄32 in. After reducing the 2½-in.-thick billets to an average strip thickness of 0.020 in., the weld fusion zone could not be identified.

After four bimetal billets were welded by this procedure, the electron beam welding procedure was accepted as an alternative method to furnace brazing.

Partial-Penetration Welding. Welds that do not penetrate completely through the work metal are satisfactory in many applications in welding thick metal; joint design and product requirements often rule out full penetration.

Examples in this article that deal with partial-penetration welds (0.30 to 1.5 in.) in thick sections and the work metals involved are as follows:

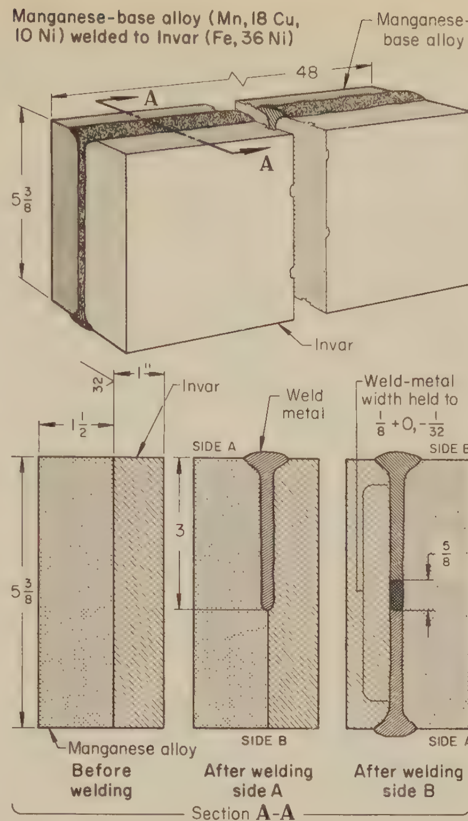
4340 steel	Ex. 464
AMS 6260 steel (9310)	505
H11 tool steel	488
Aluminum alloy 356	480
Copper alloy 175	502
Magnesium alloy AZ91C	479
Titanium alloy (6Al-4V)	496

Additional partial-penetration welds that had a depth of at least ⅛ in. are described in Examples 465, 468, 470, 472, 483, 487, 496 and 499.

Problems and Defects. In making vacuum electron beam welds ⅛ to ½ in. deep in weldable metals, weld quality is ordinarily equal to or better than that of arc welds in the same metal. Special precautions are needed to avoid certain types of defects in welds about ½ in. deep or deeper. Fusion-zone porosity, gas pockets, and cold shuts are more serious problems than in arc welding, particularly in deep welds.

Reducing the welding speed usually helps to reduce porosity and gas entrapment. Extreme care in cleaning the work metal may be necessary where the problem is severe. When defects are found near the root of the weld, they can be avoided or minimized by any adjustment of welding conditions that broadens the weld and increases the radius of the weld at the root. Sometimes, the joint can be designed so that any root defects are in a noncritical region, or in integral or separate backup metal that will be machined away after welding.

As in arc welding, cold shuts (incomplete fusion) are sometimes encountered at the root of a deep partial-penetration weld or of a full-penetration weld that has a poorly fitted backing strip. These defects are troublesome because they are difficult to detect. Normally they cannot be detected by radiographic methods. Ultrasonic testing can detect the larger cold shuts. Many cannot be observed on roughly polished macrosections of electron beam welds, but require a metallographic polish and examination at a magnification of at least 100 diameters for detection. Cold shuts can usually be avoided or minimized by reducing the welding speed or by otherwise changing conditions so as to broaden the weld and increase the radius of the weld at the root.



Joint type	Edge
Weld type	Double square groove
Machine capacity	150 kv at 200 ma
Gun type	Fixed
Vacuum-chamber size	56 by 56 by 114 in.
Fixtures	Vises; C-clamps
Welding power	150 kv at 170 ma
Welding vacuum	5 × 10^{-4} torr
Beam focal point	¼ in. below work surface
Welding speed	18 ipm

The welded bimetal billets were later reduced by hot and cold rolling to make 0.005 to 0.060-in.-thick bimetal strip for use in thermostats.

Fig. 28. Three stages in two-pass (one per side) electron beam welding of Invar and manganese-copper-nickel alloy for a narrow, full-penetration edge weld over a bond area of 5⅜ by 48 in. (Example 478)

Poor fit-up or excessive joint gap can cause excessive shrinkage, underfill, undercut, voids, and cold shuts. Joint gap should not exceed 0.010 in. for narrow welds deeper than about ½ in. in most metals, although sound welds have been obtained using joint gaps of 0.030 in., by use of a procedure that increased weld width to 0.275 in. MIL-W-46132 requires a maximum separation of 0.004 in. for welds deeper than ⅛ in.

Welding with the beam at a slight angle to the joint is helpful in avoiding defects related to poor fit-up, but may increase weld width excessively and require an unduly low welding speed for deep welds.

Excessive mismatch can cause defects of the same general types as poor fit-up; mismatch limits depend on joint design and dimensions, and operating conditions. Weld quality in joining thick sections is ordinarily unaffected by changes in surface roughness of the joint faces between about 63 and 1000 micro-in.

A problem that is to some extent unpredictable and inconsistent in making electron beam welds deeper than about ½ in. is arc-outs, or sudden failures of electron emission during welding. However, problems of arc-out have decreased with the newer machines and experience accumulated in operation.

Work-metal composition and quality also influence arc-outs, which are more frequent when welding materials with low vaporization points, or when welding materials susceptible to outgassing in a vacuum or those that contain nonmetallic inclusions.

Use of Filler Metal

Fusion of closely fitted groove faces generally provides sufficient weld metal, or extra metal is provided where necessary by including extra stock thickness or integral shoulders or lips in the joint preparation (see the discussion of welds using integral filler metal, page 524).

Where product requirements or other circumstances prevent the use of a joint preparation and welding conditions that will provide sufficient weld metal, filler metal is added. This was done in welding the type 304 stainless steel assembly of Example 485.

Prevention of Cracking. Filler metal (shim stock) additions can prevent cracking in electron beam welds in a crack-susceptible metal or combination of dissimilar metals. It may be needed even when joint design, fit-up and operating conditions are selected to achieve minimum joint restraint and residual stress. In other applications, the use of preplaced filler metal can provide weld metal that is less brittle than would be obtained by welding a base metal (or metals) alone.

Among the base metals for which added filler metal is often required are heat treatable aluminum alloys 6061, 6063 and 6066, free-machining steels, and other free-machining alloys. Example 468 describes the use of Hastelloy W filler metal in welding 1140 free-machining steel to 1020 steel. In Examples 475, 493 and 494, in which 6061-T6 aluminum alloy was electron beam welded, brazing filler metal BAlSi-4 was used to prevent cracking.

Many combinations of dissimilar metals that are susceptible to cracking when welded directly, usually because of the formation of brittle intermetallic phases, can be electron beam welded with the aid of filler metal that has a composition compatible with both metals of the combination (see the section on Joining of Dissimilar Metals, page 559).

Preventing Porosity. The electron beam welding of rimmed steel without filler metal ordinarily results in severe porosity in the weld, even when welding speed is slow and other conditions are selected to increase the time during which gas can escape from the molten weld metal. Inserting a filler metal that contains a deoxidizer such as aluminum, manganese or silicon helps to minimize porosity.

Copper alloy 110 (ETP copper) and other types of copper that do not contain residual deoxidizers also produce porous welds when joined without filler metal, but sound welds can be made with the aid of nickel filler metal or a deoxidizing filler metal.

In welding terminals in Example 482, the copper core of each terminal was clad on both sides with BCuP-5 filler metal to provide deoxidation.

Preplacement of Filler Metal. The technique most frequently used for the addition of filler metal in electron beam welding, especially for deep welds, is preplacement. A shim of filler metal, usually of foil thickness, can be inserted between the groove faces when the joint is assembled for welding, as in Examples 475, 493 and 494, or a wire or other suitable shape can be preplaced over the joint, being held in position by tack welding, if necessary, as in Examples 468 and 485.

Filler-Wire Feeding. Electrically operated filler-wire feeding systems that are modifications of wire-feed equipment used in gas tungsten-arc welding, or specially designed electron beam wire feeders, are sometimes used in the vacuum chamber.

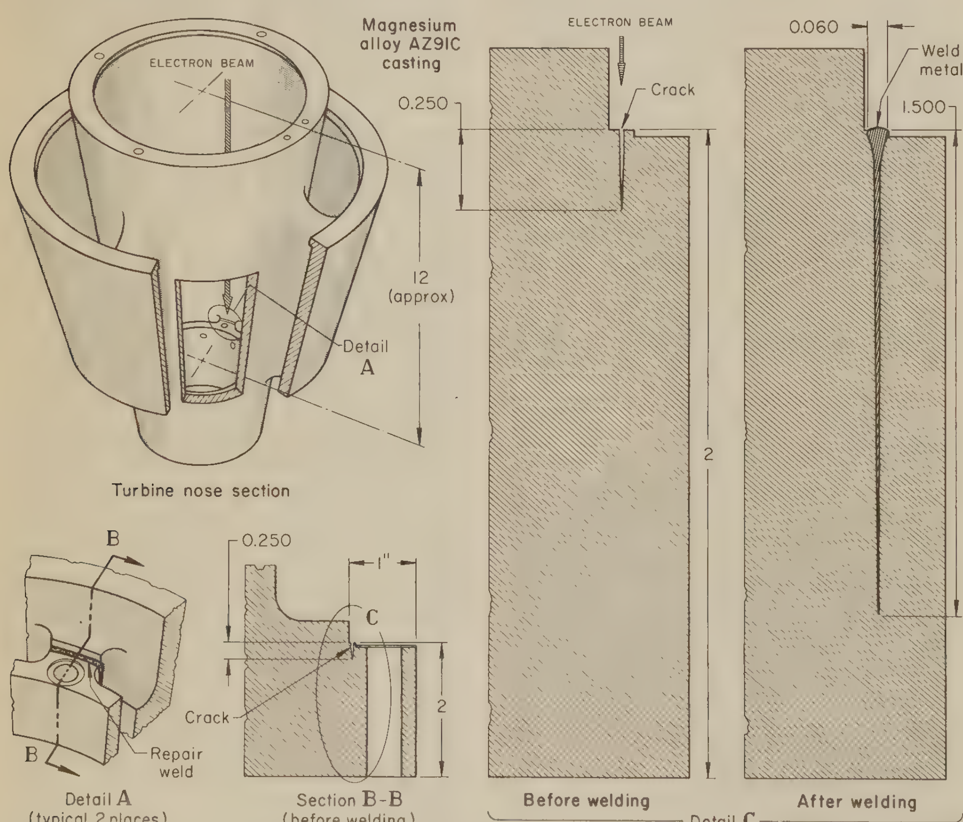
Usually, filler-wire feeding will not help in joining incompatible metals unless they are very thin.

The design of the wire-feeding nozzle and the technique with which it is used are important in guiding the wire so that it intercepts the electron beam. Failure to intercept the 0.010-to-0.030-in.-diam beam results in irregular application of filler metal. Any filler metal inserted into the beam path absorbs energy and affects penetration.

The wire-feeding nozzle is normally held as close to the weld puddle as is possible without damage to the nozzle, and the wire is directed into the forward edge of the puddle. The tip of the nozzle should be made of a heat-resistant material and should be coated so as to prevent molten weld metal from adhering to it if inadvertent contact is made. The nozzle is usually pointed in the direction of workpiece travel.

Wire-Feeding Equipment. Several design features are desirable in a wire feeder for electron beam welding. These include means of making positioning adjustments from outside the vacuum chamber during welding, such as: changing the proximity of the nozzle to the weld puddle, changing the angle of incidence between the workpiece and nozzle, and controlling the movement of the wire relative to the beam to ensure accurate interception.

A simple, variable-resistance, controlled motor drive is ordinarily satisfactory, as a 10% variation in wire speed causes no adverse effect other than a slight variation in weld width. It is desirable to be able to control the timing so that wire feed can be started and stopped independently of the beam and table. Being able to adjust the timing of the wire feeder eliminates sticking of the wire to the workpiece at the end of the weld.



Weld type ....Crack repair	Welding power ....140 kv at 40 ma
Machine capacity ....150 kv at 40 ma	Welding vacuum ....2×10^{-4} torr

Vacuum-chamber size ....25 by 22 by 28 in.	Beam spot size ....About 0.030 in.
Fixtures ....Track-guided carriage; holding clamps	Welding speed ....30 ipm
	Preheat and postheat ....None

Fig. 29. Nose section of a turbine engine showing method of repairing two fatigue cracks by electron beam welding. Limited access and likelihood of distortion precluded the use of other welding processes. (Example 479)

Vibrating the nozzle at subsonic rates promotes flow of molten metal into the weld joint and results in less wire sticking at the end of the weld.

Welding Technique When Feeding Filler Wire. The wire-feed rate is usually set at approximately the same rate as the welding speed. Beam power must be sufficient to melt the wire as fast as it is fed. The wire diameter is selected so as to provide 1.25 times the volume of filler metal needed to fill the joint cavity. Where needed, backing strips or rings are used to prevent loss of molten weld metal.

The filler metal can be deposited during the weld pass, using a low welding speed to allow time for the molten metal to fill the joint gap, but for deep welds it is preferably deposited in a separate pass.

If cracking is a problem, another method used on thin metal is to deposit filler metal on the joint, and then make the welding pass to distribute the filler metal more effectively.

Tack Welding

In fixturing work for electron beam welding, clamping is often supplemented or replaced by tack welding, which is usually done with the electron beam. Fixturing time and cost are often substantially reduced by the effective use of tack welds.

In some applications, selection of the tack welding procedure is critical, to avoid unacceptable variation in the shape and dimensions of the final weld bead, and to avoid root porosity or cold shuts. Reduced power and other special operating conditions are often used.

Techniques. Perhaps the most common technique is to make one or more suitably spaced tack welds at full or reduced beam power before making the welding pass. For circular or circumferential welds, one or more tack welds are usually made, as was done in Examples 465, 469, 470, 477, 489, 492, 496, and 501. Melt-through (spike) tack welds were used on the straight-line lap joints described in Example 502.

A shallow seal pass at reduced beam power can also be made along the full length of the joint to keep the workpieces aligned, to be followed by the full-power penetration pass, as in Example 484. For some applications, it is convenient to leave occasional unwelded gaps as an aid for tracking the joint during the penetration pass.

Electron beam tacking can hold preplaced filler metal in position in or over a joint, as in Examples 475 and 494; resistance spot welds were used to hold filler-metal wire in position over the joint in Examples 468 and 485. Arc spot welds can be used for tacking some types of work (see Example 467).

Welding of Poorly Accessible Joints

One of the advantages of electron beam welding is the capability of reaching into areas lying deep within narrow openings. This is accomplished by virtue of the electron beam having a small diameter, long working distance and, frequently, the capability of

being projected at an angle. Many joints that are inaccessible for welding by other processes can be electron beam welded. This capability is used both in fabrication and in repair work. It is especially useful in salvaging intricate castings.

Workpiece Requirements. For limited-access welding, the workpiece must satisfy three general requirements: (*a*) the weld area must be on a line-of-sight path from the beam source; (*b*) there must be sufficient sidewall clearance to avoid beam-fringe interference; and (*c*) the beam path must be free of magnetic fields.

Beam characteristics that determine applicability of electron beam welding to poorly accessible joints are beam diameter and the working distance, or effective beam length available between the exit end of the beam transfer column and the work. These characteristics in turn depend on the beam power used, which is selected to produce the desired penetration, and on beam focal length, which is influenced by the design of the gun, the chamber and the focusing coil.

Sidewall Clearance. Parts intended for fabrication by electron beam welding can often be designed with sufficient sidewall clearance for the beam power required. Where insufficient sidewall clearance exists in repair welding, lowering the beam power or slightly changing the angle of incidence of the beam will often avoid interference. In repair welding, tests should be made on simulated joints, using the same type of work metal and the required beam power, rather than to risk damaging difficult-to-replace parts.

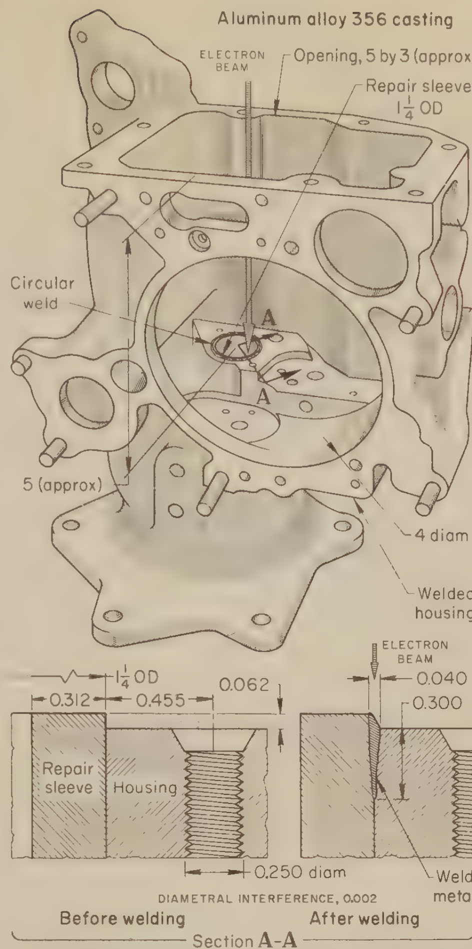
Where close sidewall clearances are involved, it is especially important to avoid magnetic fields, which can cause damage to the part by deflecting the beam. A test run on low power is commonly used to detect beam deflection; however, allowance must be made for the increase in deflection at full welding power. Magnetically soft materials with induced magnetism can usually be demagnetized with magnetic-particle inspection equipment or with coils.

Minimum beam clearance for making welds close to magnetic metal that projects above the work surface at the joint is given on page 523 (top of column 3) and in Fig. 7.

Examples of Practice. The use of electron beam welding to make repair welds at sites deep within finish-machined castings, where access was too limited for repair by any other method, is described in the next two examples:

Example 479. Repair of Cracks in a Magnesium Alloy AZ91C Casting (Fig. 29)

The long-focal-length capability of the electron beam simplified repairing of fatigue cracks in the nose section of a magnesium alloy turbine casting. The casting, as shown in Fig. 29, had straight, partially penetrating cracks running across the ligaments connecting the body to a bearing support. The cracks were located approximately 12 in. down in the nose, in a narrow area where access by any other welding process was virtually impossible. In addition, because the nose section was finish machined and matched to its counterpart, neither distortion nor further machining to overcome distortion could be tolerated.



Joint type	Circular butt
Weld type	Square groove, integral filler-metal shoulder
Machine capacity	150 kv at 40 ma
Gun type	Triode; fixed; with long focal length
Vacuum-chamber size	25 by 22 by 28 in.
Maximum vacuum	5×10^{-5} torr
Fixtures	Holding clamps; turntable
Welding power	150 kv at 10 ma
Welding vacuum	2×10^{-4} torr
Working distance	10 in.
Beam focal point	¼ in. above work surface
Beam spot size	About 0.020 in.
Beam oscillation	None
Travel speed	30 ipm (6 rpm)
Number of passes	One, plus 60° overlap
Total machine time	20 min(a)

(a) Includes part setup, beam alignment, pumpdown, weld traverse, and unloading

Fig. 30. Completely machined aluminum alloy housing that was initially rejected because of an oversize bore, but later salvaged by inserting a repair sleeve and welding it in place by electron beam welding. Access to the joint was too limited for other welding processes. (Example 480)

Preparation for welding consisted of flushing the cracked areas with methyl ethyl ketone. The cracks were not chipped out, and no filler metal was required. The casting was positioned on a traveling table with the work surface located 15 in. below the electron gun. Beam alignment was checked optically for each weld traverse before welding power was turned on, to ensure adequate clearance of projections.

Beam power was selected to penetrate well beyond the apparent crack depth, but not through the section. Beam focal point was adjusted at ¼ in. above the work surface, the slight defocus serving to minimize weld porosity. The cracks were sufficiently straight to be traversed automatically in a single pass, requiring only a few seconds. Using the welding conditions shown in the table with Fig. 29, narrow welds were obtained with heat input low enough to preserve machining tolerances. Completed welds were examined by radiography to ensure freedom from gross porosity. The casting was returned to service at a small fraction of the cost of replacement.

Example 480. Repair of an Oversize Bore in an Aluminum Alloy Casting (Fig. 30)

A finish-machined 356 aluminum alloy housing, which represented an investment of more than $500, was rejected because of an oversize bore at a site deep inside. The casting was salvaged by fitting and welding a repair sleeve in the bore.

Electron beam welding was suited to the requirements of the salvage operation, producing a weld 0.040 in. wide (max) at the repair site, which was about 5 in. below the face of the top flange. The electron beam, projected from outside the housing, could just clear the internal obstructions; access was too limited for welding by other processes. There were no magnetic fields in the workpiece to cause unwanted beam deflection, and the low heat input produced no noticeable distortion.

Figure 30 shows an enlarged view of the welded repair sleeve; the edges of two tapped holes were only 0.33 in. from the centerline of the weld. A partial-penetration weld only 0.300 in. deep was made at the joint. The underside of the joint was inaccessible for welding. The single weld was strong enough that the sleeve could be finished and the cast housing could fulfill its operating function.

The repair sleeve was machined from aluminum alloy 356 with a diametral interference of 0.002 in. max for a press fit. After degreasing, the sleeve was fitted to the bore with a 1/16-in. projection to provide metal for the joint and fillet reinforcement.

After setup, beam alignment and pumpdown, the actual weld was made in about 10 sec, using the settings shown in the table with Fig. 30. This procedure not only saved the cost of a new housing, but also avoided delay in delivery of a replacement.

Multiple-Tier Welding

The deep-penetration properties of the electron beam make it possible to weld two or more tiers of joints simultaneously. The joints can be separated by an air space as great as several inches, provided that the space can be evacuated and the joints aligned in the path of the beam. This type of weld cannot be made by any other welding process.

In multiple-tier welding, the electron beam must pierce at least the upper tiers in such a way that the molten metal flows in behind the advancing beam as in keyholing. The molten weld metal is held in place by the combined forces of capillarity, surface tension, and viscosity. Welding conditions must be carefully selected and controlled.

Difficulties. In-line welds are progressively different in shape and size, because of the scattering and reduction in beam density and other effects on the beam that take place when it penetrates each layer of metal in turn.

Internal weld spatter may cause difficulty if it interferes with service performance and there is no access for cleaning. Other difficulties such as undercut, underfill and excessive root bead may be correctable. Hidden welds, which are difficult or impossible to inspect, require some acceptable indirect method of controlling joint reliability.

Applications. Multiple-tier welding has been applied to a variety of joints. Two-tier joints separated by as much as 3 in. have been welded in a single

pass in joining honeycomb panels to end frames or structural shapes where only one side was accessible.

The example that follows describes the problems encountered, and the methods used to solve them, in the two-tier welding of a gas-turbine component, in which two layers of 0.075-in.-thick René 41, about ½ in. apart, were welded simultaneously.

Example 481. Two-Tier Welding of René 41 Gas-Turbine Component (Fig. 31)

A unique solution to the problem of designing and fabricating a component of an aircraft gas-turbine engine was achieved by electron beam tier welding. As indicated in Fig. 31, the component consisted of a cylinder with an external flange on one end, an internal flange on the other, and a tubular annulus between. The components were assembled by welding the trough-shape ends of two subcomponent cylinders by a single two-tier circumferential weld.

The components were made of René 41, for service at elevated temperature. The chief welding objectives were to obtain sound welds and to avoid distortion of the part, and especially the alignment of the 288 holes located in the annulus less than ½ in. from the joints. (The holes had to be drilled before welding because they could not be deburred if drilled after welding.)

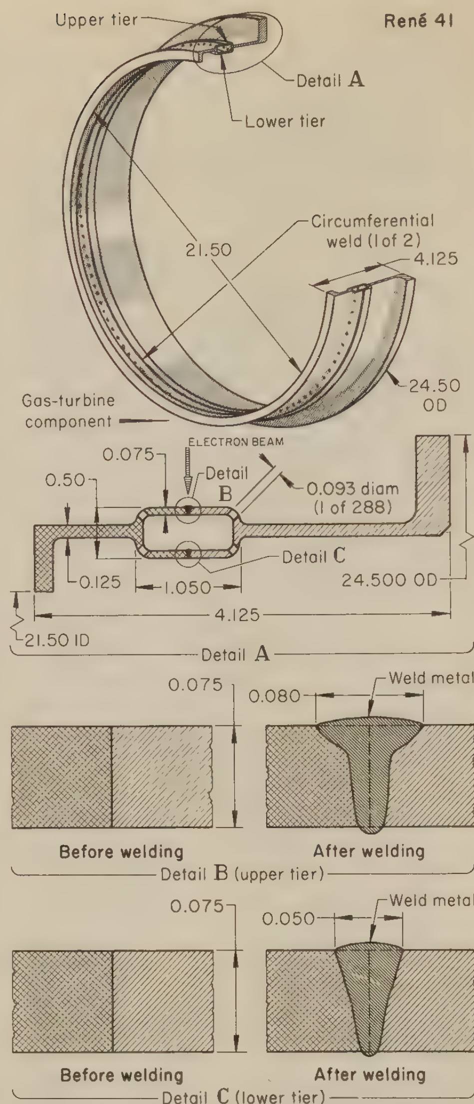
Arc welding was rejected as a possible joining method because it would have been necessary to use internal chills with gas backing in the annulus to minimize distortion and avoid atmospheric contamination. Electron beam welding not only met the basic requirements but also made both welds simultaneously, even though the two joints were separated by approximately ½ in., as shown in detail A of Fig. 31.

Fixturing was relatively simple. The joints were accurately machined square and the components were assembled between two aluminum plates fitted over the flanges. The plates were connected and forced together by bolts located inside the inner flange. This fixture was then mounted on the faceplate of a welding positioner in the vacuum chamber so that the part would rotate with its axis horizontal. The electron beam gun was in a fixed, overhead position.

Success of the two-tier welding operation depended on careful control of part alignment, beam alignment, beam focal point, power adjustment, and travel speed. The joints for the upper-tier and lower-tier welds had to rotate in the same vertical plane, although, by direct viewing, they could not be observed simultaneously. In addition, beam impingement on the joint of the lower-tier weld could be verified only by emergence of the weld bead from the underside, or by sectioning of test pieces.

Alignment of the part for true horizontal-axis rotation was done with the aid of a precision level (sensitivity of 0.0005 in. per foot) and precision spacer blocks placed on the face of the 24.50-in.-OD flange. Beam alignment was done by centering the beam spot on the reticle of the scope and moving the joint to this position. Beam focal point, beam power, and travel speed were adjusted by trial and error on test components until a satisfactory welding procedure was established. The final settings are shown in the table with Fig. 31. By adjusting the beam focus for an indicated setting midway between the two tiers, the weld shapes of Fig. 31, details B and C, were obtained.

The mushroom-head shape of the upper-tier weld was caused by the defocused condition of the beam at that point, while the somewhat oversize root reinforcement resulted from the excess of power needed to penetrate to and through the lower tier. The relatively narrower weld face of the lower-tier weld, as well as the narrowing of the weld in its progress through the joints, was explained as an effect of a charged



Joint type	Circumferential, two-tier butt
Weld type	Square groove
Machine capacity	150 kv at 40 ma
Gun type	Fixed
Maximum vacuum	10^{-5} torr
Fixtures	Bolted end plates; rotating positioner
Preheat	None
Welding power	125 kv at 9.3 ma
Welding vacuum	10^{-4} torr (min)
Working distance	12 in.
Beam focal point	Midway between tiers(a)
Welding speed (at 0.42 rpm):	
Upper tier	30 ipm
Lower tier	28.7 ipm
Beam oscillation	None
Number of passes	One, plus 30° downslope
Postweld heat treatment	Age 16 hr at 1400 F

(a) Indicated machine setting. See text of example for explanation of beam focal point.

Fig. 31. Section through a cylindrical component of an aircraft gas turbine, showing tiered welds made simultaneously by electron beam welding (Example 481)

plasma that surrounded and refocused the beam on its passage through the material. The plasma, having a net negative charge, repelled the beam electrons, causing the beam to constrict and to change its focal point. The net result on the lower tier was to produce a weld closely approaching the contour of a normal single-thickness weld made with a tight, surface-focused beam. Thus, the indicated focal-point setting was more virtual than real.

Both welds were satisfactory as to soundness and shape. Because of lack of access to the interior of the joint, weld spatter and undercutting were of concern, and spatter associated with penetration of the upper tier was a problem. Most of the particles were loosened with pipe cleaners and were flushed out with solvent at high pressure. The few small particles that remained were judged to be acceptable after radiographic examination. Undercutting was not a problem. The René 41 material was capable of withstanding considerable excess beam power, which was especially important in making the upper-tier weld.

The two-tier welding procedure was used to produce three components, which met all test requirements and were accepted.

An ingenious and practical arrangement for multiple-tier welding was used to electron beam weld more than 12,000 terminal interconnections per pumpdown, in the automated mass-production application described in the next example. The usual problems associated with the multiple-tier technique were minimized, and the joints were easily inspected.

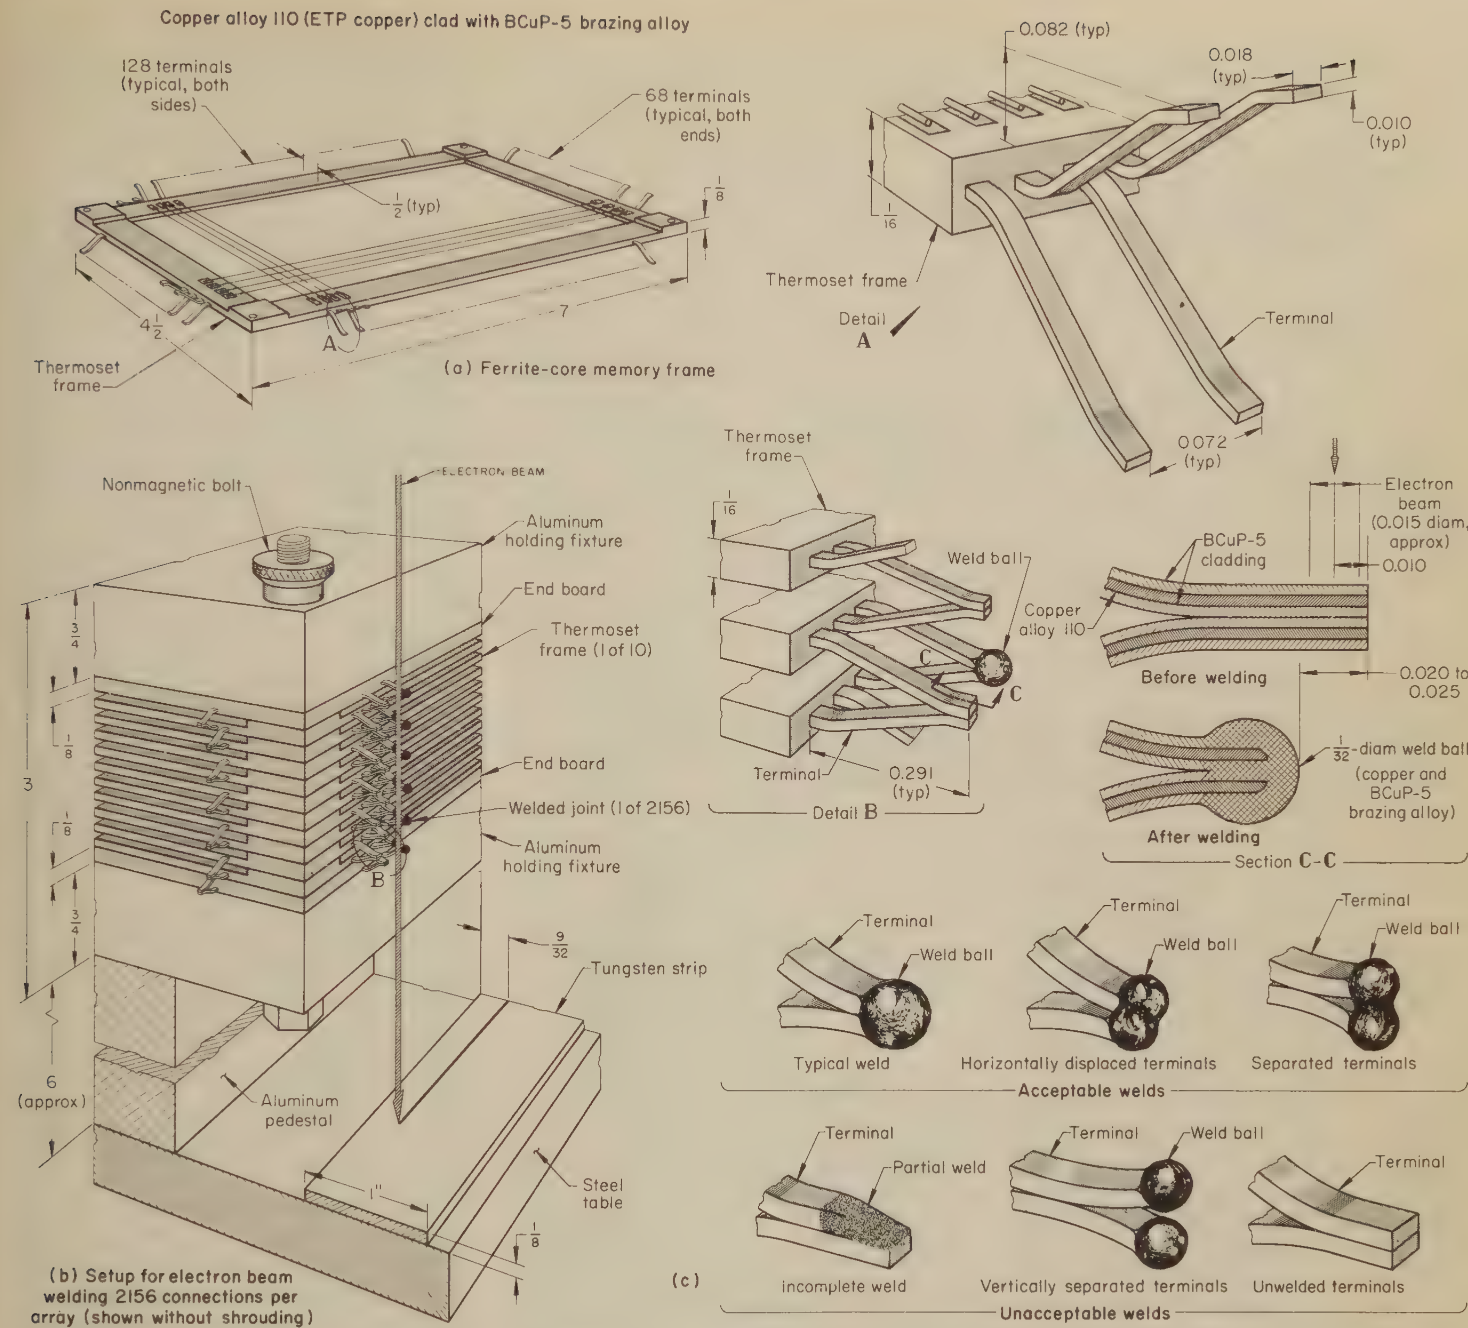
Example 482. Multiple-Tier Welding of Terminal Joints in Stacked Arrays of Ferrite-Core Memory Frames (Fig. 32)

Ferrite-core memory arrays for electronic computers were fabricated by stacking individual core frames, of the type shown in Fig. 32(a), and joining their corresponding terminals to form a network. A typical stack of frames, assembled in an electron beam welding fixture, is shown in Fig. 32(b) as consisting of ten frames (called planes) and two end boards that completed the array. This arrangement resulted in aligning the terminal leads on all four sides of the array in a series of vertical columns that alternately contained five and six terminal joints per column. Each terminal lead consisted of a 0.010-by-0.018-in. rectangular wire with a copper core and a copper-base brazing alloy cladding. Terminals were spaced on 0.036-in. centers.

Originally, terminal interconnections were made, one at a time, by resistance spot brazing, using specially designed electrodes mounted in an automatically indexed head. However, this method was not fast enough to meet the demand, and efficient mechanization was made difficult by electrode pickup and other uncontrollable process variables. Also, to ensure joint reliability, it was necessary to apply a time-consuming pull test to all joints.

When the joining operation was changed to electron beam welding, production rate was increased substantially, joint appearance and reliability were improved, and a simple visual test was found to be adequate for inspecting the welds. The electron beam procedure consisted of passing the terminal tips of a stacked array through a fixed electron beam (Fig. 32b), welding the terminal ends, column by column, on each of the four sides of the array. Six stacked arrays were welded consecutively in one chamber load. Success of the operation depended primarily on obtaining and maintaining accurate alignment of the joints with respect to each other and of the beam with respect to the terminal tips.

Three important features of the electron beam welding machine used in this operation were a long-focal-length beam, a table capable of x-y motion, and a stereoptic viewing system. Long focal length permitted the stacked arrays to be raised about 6 in. above the table to avoid the heat and spatter generated when the beam, after passing through and between the terminal columns, impinged on tungsten strips placed to absorb the energy. In addition, beam diameter remained essentially constant over the vertical depth of the array. The table accommodated six fixtured arrays and provided travel speeds of 3 to 120 in. per minute, as set by the operator. The optical system, which was collinear with the electron beam, permitted the operator to align the work accurately with the beam by means of a crosshair reticle.



Joint type	Edge flange	Machine capacity	150 kv at 40 ma	Beam oscillation	None
Weld type	Multiple tier, square groove (see figure)	Gun type	Fixed; long focal length	Welding speed	36 ipm
Fixtures	Alignment tool; holding jig; support pedestal; tungsten target plates; table with traversing carriage; optical system	Welding power	100 kv at 10 ma	Number of passes	Two
		Welding vacuum	10^{-4} torr	Welding time per pass(a)	About 0.048 sec
		Beam spot size	0.015-in. diameter	Production rate	323 connections per min(b)
		Beam focal point	Midpoint of stacked array		

(a) Time for a vertical column of terminal joints to traverse beam. (b) Six arrays (12,936 connections) welded in total time of 40 min, one pumpdown.

Fig. 32. Electron beam welding of terminals of ferrite-core memory frames used in electronic computers (Example 482)

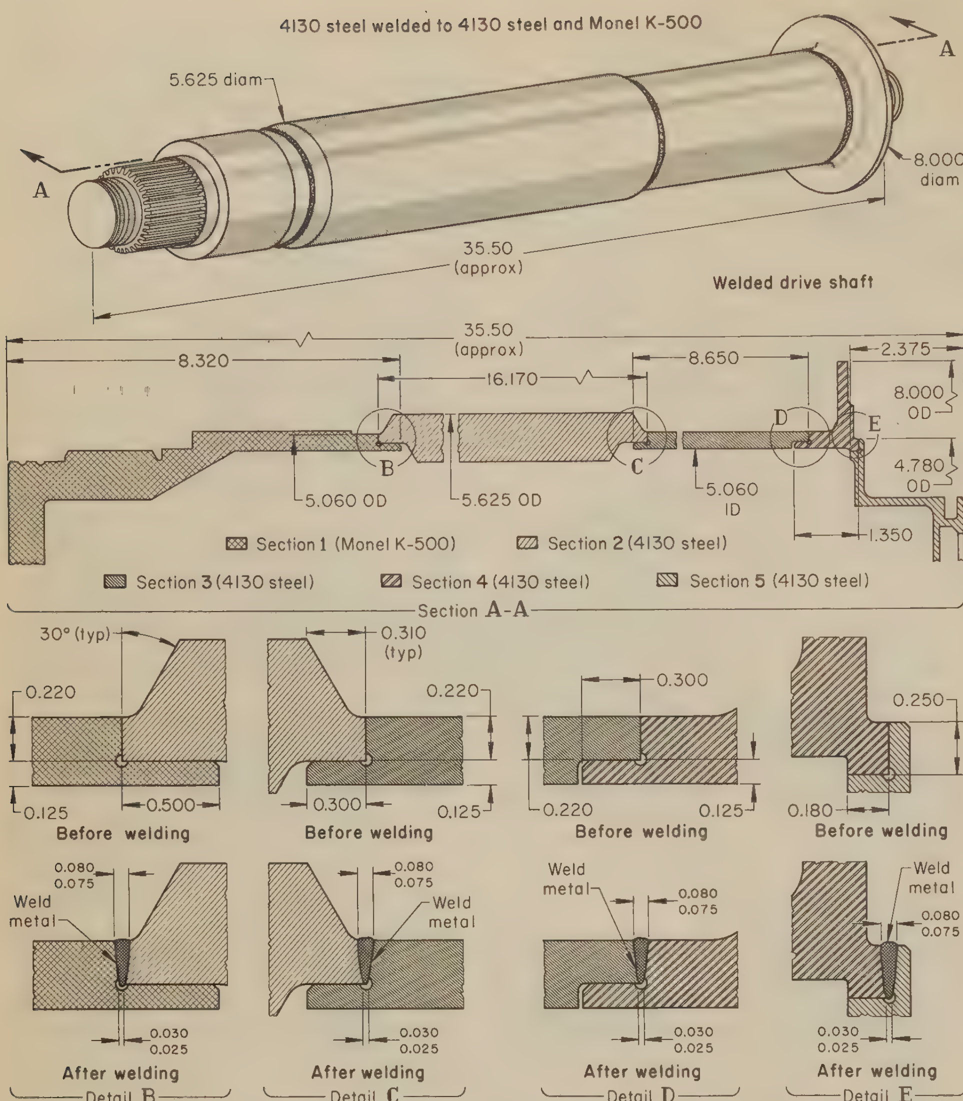
Before stacking the core frames, the upper and lower terminals on each frame were spread apart to ensure positive contact with the mating terminals of adjacent frames, as shown in details A and B in Fig. 32. The frames were then stacked in an aluminum holding fixture, to which was attached a comblike aligning tool. When the assembly was completed, the holding fixture cover was bolted in place and the aligning tool was removed. By this means, the 25,872 accurately formed and trimmed terminals in a batch of six arrays were aligned vertically within a tolerance of 0.002 in. to make 12,936 welded joints.

Fixtured arrays were next shrouded in an envelope of 0.002-to-0.003-in.-thick aluminum foil. A soft rubber roller was used to press the foil in and around the terminal joints, puncturing the foil so that the terminals were exposed for welding. This technique protected the remainder of the assembly from spatter and also grounded the electrically floating terminals, which otherwise would become statically charged by the beam to cause beam deflection.

Six 6-in.-high pedestals were secured to the table in the vacuum chamber, and the fixtured arrays were positioned accurately on the pedestals by means of locator pins. The arrays were arranged three across (x-direction) and two deep (y-direction), and were spaced about ½ in. apart at the terminal ends. All fixturing was made of aluminum or other nonmagnetic materials, to avoid magnetic beam deflection. Strips of tungsten were placed on the table around each assembly to absorb beam energy.

After pumpdown, the electron beam was focused on a tungsten target plate set at the vertical midpoint of the arrays. The beam spot, approximately 0.015 in. in diameter, was aligned on the crosshairs of the optical system, and the beam was then turned off. The terminal joints of the first array to be welded were then moved into view, with the crosshairs positioned 0.010 in. from the end of the first terminal and slightly before the starting edge.

Beam power was turned on and the table was traversed forward and back at 36 in. per minute, each column of joints passing under the beam twice. Two welding passes were made to ensure complete welding of



Joint type	Circumferential butt(a)	Welding power:	
Weld type	Square groove	0.220-in.-thick joints	115 kv at 9.6 ma
Machine capacity	6 kw at 150 kv	0.250-in.-thick joint	120 kv at 11.7 ma
Gun type	Fixed	Operating vacuum:	
Vacuum-chamber size	108 by 56 by 56 in.	Setup	2×10^{-4} torr (max)
Maximum vacuum	10^{-6} torr	Welding	5×10^{-5} torr
Fixtures	Horizontal positioner with mounting and driving plate; loading track	Welding speed	About 30 ipm
		Beam spot size	0.015 in.; flush focus
Preheat	600 F (in a furnace)	Postheat	600 F; air cool

(a) All four of the circumferential butt joints were self-backing.

Fig. 33. Five components of a hydrofoil drive shaft that were shrink fitted and electron beam welded to a tolerance of ±0.002 in. for concentricity and straightness (Example 483)

joints in the lower tiers that may have been deprived of some of the beam energy during the first pass. Ten double passes were required to make the welds on a batch of arrays. The first four double passes were in the *x*-direction, each double pass sweeping one side of three arrays per traverse. Six double passes were made in the *y*-direction, each double pass sweeping one side of two arrays per traverse. The beam was realigned for each double pass.

As each vertical column of five or six joints moved into the path of the electron beam, the ends of each terminal pair in the column were melted back 0.020 to 0.025 in., as shown in section C-C in Fig. 32, forming a shiny weld ball about 1/32 in. in diameter at each joint. The action was extremely rapid; the heating time per joint at a traverse speed of 36 in. per minute was only about 0.048 sec.

Power settings and other welding conditions were established by trial. Optimum settings for welding a ten-frame array with two end boards are given in the table accompanying Fig. 32.

One of the results of electron beam welding was to simplify quality control and inspection. Because of the approximately spherical shape of a properly made weld, it was possible to correlate joint strength with weld shape by destructive testing. As a consequence, a set of workmanship standards was set up for acceptance or rejection of the welded joints, based on visual inspection. Figure 32(c) shows the shape of acceptable and unacceptable welded joints. Visual scanning of completed arrays proved successful — none of the acceptable joints welded by the electron beam procedure described here has ever failed in a product.

A six-array batch was completed in 40 min, including 15 min for mounting the arrays and pumpdown, 15 min for electron beam setup, and 10 min for double-pass welding of the 12,936 connections. Over-all production rate was thus 323 connections per minute. Over-all rate for the original process (resistance spot brazing) had been about 51 connections per minute, including setup, alignment and handling.

Defective electron beam welds were repaired by manual resistance spot brazing, using hand-held tongs. However, the incidence of unacceptable electron beam welds was extremely low.

Welding With Extreme Accuracy

The development of feedback servomechanisms for controlling variations in beam power and beam spot size, as well as in work travel and speed, permits electron beam welding within tolerances of a few thousandths of an inch in high-vacuum machines.

With the use of closed-loop feedback control systems, variations in beam voltage and current can be held to approximately 1% for a 10% variation in the supply line, which is well within the tolerances that can be maintained by the remainder of the system.

Although the diameter of the beam spot cannot be measured directly with great accuracy, it can be estimated by measuring the width of the weld or by calibrating the controls for the focusing and beam-power settings. Depending on machine characteristics, beam spots effective for most welding purposes can be set up in the range of 0.010 to 0.030 in. in diameter without difficulty. Assuming a very small beam variation, an application requiring a beam spot of only 0.010-in. diameter would require a means of holding the joint-to-beam coincidence with a runout of less than ±0.005 in.

For welding with a 0.010-in.-diam beam, a pileup of manufacturing tolerances could easily cause the beam to miss the joint. Therefore, for most production purposes, small beam spots are not economically feasible.

Various types of travel mechanisms of rigid construction are available with runout tolerances of approximately 0.001 in. per foot or with total deviations of 0.003 to 0.005 in. for a complex traverse pattern. However, joint runout depends also on the manufacturing tolerances of the part, and accuracy of fit-up and fixturing. In some applications, 20 to 25 possible sources of error, such as magnetic deflection of the beam, and human and systematic errors in beam alignment, can be found.

Sometimes, extreme accuracy can be justified on the basis of necessity. In Example 469, 0.020-in.-wide welds were placed on 0.030-in. centers with controlled penetration. In Example 481, beam alignment was more critical than weld size in making the two-tier weld. All other factors, from part manufacture through fixturing and rotation, had to be held to close tolerances.
